THE ENGINEERING RECORD,

BUILDING RECORD AND THE SANITARY ENGINEER.

VOL. 56. NEW YORK, JULY 6, 1907. No. 1.

THE ENGINEERING RECORD

PUBLISHED WEEKLY BY THE

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

114 LIBERTY STREET, NEW YORK.

BRANCH OFFICES:

PHILADELPHIA: Real Estate Trust Bldg.
CHICAGO: 590 Old Colony Bldg.
CLEVELAND: Schofield Bldg.
SAN FRANCISCO: 701 Atlas Bldg.

LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico	$3.00 a year
Canada	$4.50 a year
Foreign subscription	$6.00 a year

25 shillings 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGES OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1905, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 16,000 copies are printed. Total circulation for 1907 to date 392,000 copies, an average of 14,519 copies per week.

TABLE OF LEADING ARTICLES.

New Views of the Cause of the Corrosion of Iron.

At the recent meeting of the American Society for Testing Materials, Dr. Allerton S. Cushman, of the United States Department of Agriculture, made the first public announcement of the very interesting investigations he has been carrying on for several years on the causes which underlie the corrosion of iron. A number of new points were brought out, among which the most startling are that oxygen plays only a secondary role in the rusting of iron and that the best preventatives of rust are to be found among the most effective oxidizing agents known, such as chromic acid and its salts. This view is so contrary to all previous conceptions that it is naturally received with some incredulity when first heard, yet those who are familiar with the investigations and conceptions upon which the new theory of corrosion is based are of the opinion that the evidence which has been brought forward is not only convincing but conclusive. Dr. Charles B. Dudley, whose conservatism in expressing opinions on theoretical subjects is well known, stated at the close of the presentation of Dr. Cushman's paper that he considered this work to be the most important contribution to a metallurgical problem that has been made in the last quarter century. The same opinion was expressed privately by others who are familiar with the work.

The fact that chromic acid and its salts act as inhibitors of rusting has been known for some time, but no explanation of the curious phenomenon has ever been offered heretofore nor has its application to practice ever been suggested. Dr. Cushman has made a special study of this problem, and although it remains to be seen what practical benefits may develop out of these new ideas, it is most gratifying to be able to state that if any patents are granted covering rust inhibitors they will be taken out in accordance with the practice of the Department of Agriculture, so that they will be free for all American citizens. The investigation was begun by Dr. Cushman as a part of his study of the corrosion of fence wire, in the interest of the farmer. A farmers' bulletin on this subject was published by the Department of Agriculture about two years ago. It is safe to say that the public benefit which is likely to follow these investigations is on a par with the important economical benefits which will probably be derived from the same author's researches on the decomposition of feldspathic rocks and their use as fertilizers. Both of these investigations, made in the interests of the people, demonstrate the great national benefit which is derived from the scientific research of our federal departments, conducted by specialists of the highest rank. It is to be hoped that Congress will not fail to appreciate the advisability if not the necessity for providing the funds to carry on work of this kind, the expenditure for which is so small in relation to the public benefit.

If a text-book is consulted for an explanation of the rusting of iron, it will be found that carbonic acid has heretofore been generally held responsible for the formation of rust. Iron is supposed to be attacked by carbonic acid, with the formation of carbonate, which is then acted on by water and the oxygen of the air to form the red hydroxide known as rust, the carbonic acid being again set free to take up its destructive work. According to this theory, in an atmosphere which did not, like that of this earth, contain about four one-hundredths of one per cent. of carbonic acid, the rusting of iron would be an unknown phenomenon. That this, as well as the peroxide hypothesis which has lately been developed in England, must be relegated to the dump pile of abandoned theories, seems to be conclusively shown by these latest researches.

According to the electro-chemical or electrolytic theory which Dr. Cushman upholds, the first attack on iron is not made by oxygen, even in the presence of water, but by hydrogen in the form of the hydrogen ion. According to the modern theory of solutions, many substances when dissolved in water are dissociated into ions, which may be regarded as atoms carrying static electrical charges. Water itself, even when pure, contains a certain proportion of hydrogen ions, and the presence of many impurities, especially those which are by nature acid, increases the hydrogen ions and thus the tendency to attack iron and carry on corrosion. The action is entirely electrolytic, being continually accompanied by an exchange of the electro-static relations between the iron and the attacking hydrogen. Such oxidizing agents as the chromate and bichromate of potash inhibit rusting by polarizing the iron to the condition of an oxygen electrode, thus preventing the approach or attack of the hydrogen ion. One of the most extraordinary points brought out is that this polarization effect is to some extent lasting. That is, to say, if iron is immersed or "pickled" in a concentrated solution of bichromate acid and is then washed and wiped, it is rendered passive, so that it resists electro-chemical attack whether this take the form of rust formation or the well-known plating out of copper which takes place if the chromated specimen is immersed in a dilute solution of copper sulphate. In short, the action which goes on when iron rusts is in every respect analagous to that which takes place when iron is immersed in a solution of a copper salt. In the later case, copper ions carrying positive electro-static charges are present, iron passes into solution and assumes the electro-static charge, while copper plates out and becomes visible. When iron rusts, iron passes into solution while hydrogen "plates out." Once in solution the oxygen of the air oxidizes the iron to the insoluble form of the red hydroxide known as rust. This electrolytic action can be shown taking place by the use of a special polar indicator which has been called "ferroxyl." It follows from this that anything that will inhibit electrolytic action will act the part of a rust preventative.

To what extent the various salts of chromic acid will come into use for the treatment of boiler feed waters and for "pickling" structural material will depend upon experiments carried out on a large scale. Dr. Cushman himself is emphatic in pointing out the necessity for care and conservativeness in approaching the practical application of these purely scientific investigations. One of the modern problems in boiler practice is the rapid corrosion of boiler tubes used in connection with turbine engines. The copper which is dissolved by the action of the setam jets impinging on the bronze blades of the turbine rapidly corrodes the iron in the boilers by the electrolytic action just described. Since

it has been found that the presence of bichromates in feed water will prevent this action, it seems as though the solution of this important problem has been discovered. The engineering world will eagerly await the detailed publication of Dr. Cushman's researches, as well as the results of the practical tests which are sure to follow.

Structural Lessons of the San Francisco Earthquake and Fire.

Although much has been already written regarding the conclusions to be drawn from the structural results of the San Francisco earthquake and fire, the excellent reports submitted to the United States Geological Survey regarding the subject of Prof Frank Soulé, Captain John Stephen Sewell, Corps of Engineers, U. S. A., and Mr. Richard L. Humphrey, structural expert of the Geological Survey, much of which was printed in The Engineering Record of June 15, are worthy of close consideration. These three engineers have made probably the most complete and thorough studies of the conditions resulting from the San Francisco catastrophe of all that have been reported. Furthermore they were completely unbiassed by any possible motives of self-interest, and their conclusions may therefore be regarded as based essentially upon the conditions as they found and interpreted them.

The first prominent conclusion to arrest the attention of the technical reader is the statement that the fireproofing in the city was, as a whole, defective, and, further, that it is practically impossible to construct any building which shall be entirely and absolutely fireproof in all respects. The latter dictum is not new nor unexpected, while the former statement finds so many exemplifications in every large city of this country that it was to be expected as a matter of course. Owners seem to fail completely to realize the imminent danger courted by cheap so-called fireproof methods. This feature of the old city is far too likely to be reproduced in the new, as it is constantly found in the majority of building operations in every large city. The authors of the reports mentioned recognize, however, that it is entirely feasible so to design buildings by a proper use of suitable materials as to make them so highly fire-resistant that they are to all practical purposes essentially fireproof.

A most important feature emphatically insisted upon by both Prof. Soulé and Captain Sewell is that the joints of columns with floors of all buildings shall be of the stiffest and strongest character. This is equally true of the steel-frame building and of the reinforced concrete structure. The former engineer speaks particularly of the steel-frame type of building whose adaptation to earthquake resistance as well as to fire resistance when properly protected with fireproofing material he comments upon in the most favorable terms. This also is what might be expected. The steel frame building, when properly designed, has in it all the elements of toughness and resistance to vibrations which could be desired, although such conflagrations as those of Baltimore and San Francisco have demonstrated in the most conclusive manner that the necessity of their being fireproofed is imperative. Captain Sewell states that "where reinforced concrete is used throughout, whether the building is very tall or not, great care should be taken with the design and execution of the connections between columns and members of the floor system. There should be heavy knee-braces for the connection of all girders and beams . . ." This, as The Engineering Record has frequently insisted upon editorially, is one of the most important features of concrete-steel design. It is interesting in this connection to observe that the building which will shortly become the future home of The Engineering Record is a reinforced concrete structure embodying among other advanced elements of design these essential features so strongly insisted upon by Captain Sewell. He lays down the fundamental proposition, although not in just these words, that the floors and columns of an earthquake-proof and fireproof reinforced concrete building should be actually continuous so as to secure the most rigid and unyielding structure attainable, and precisely these basic principles have governed the design of the building of the McGraw Realty Co., where the continuity of floors and columns has been secured throughout the entire structure by both the steel connections and the concrete. It is Captain Sewell's opinion that such a monolithic concrete-steel structure is secure against damage even by severe earthquakes, unless it should happen to lie across the actual slip. In fact, it is probable that unless such a slip were of considerable magnitude, the building would be but little damaged even under such circumstances.

It is not entirely clear why he should limit the extreme height of reinforced concrete buildings to 125 ft.; or again why he should state that the "bracing of a reinforced concrete building of any height" is a problem which "has not been solved as yet." It may be admitted at once that the great majority of buildings of this class do not show a satisfactory solution of that problem, but in such a reinforced concrete structure as the McGraw building it is quite reasonable to state that the problem has been completely solved throughout its height of nearly 150 ft. above the street. The type of columns employed in that building, involving every essential element of good design set forth by Captain Sewell, the steel portions of which are essentially continuous with the reinforcing steel of the floor girders and beams, attain most completely the element of rigid bracing which he so properly insists upon. As a matter of fact the general system used in the design of that building is capable of being adapted to any degree of rigid bracing and practically to any height to which it may be desirable to carry the structure.

One of the most essential lessons to be learned from the great conflagrations of the near past, which these experts insist upon with most commendable emphasis, is the imperative need of a greatly improved system of fireproofing, not only in the interior parts of the structure but especially for the exterior openings. It is well known, as they maintain, that many large buildings would have escaped an interior conflagration if the exterior openings had been properly guarded with suitable metal or metal-covered shutters or doors. Moreover, buildings of the steel frame or reinforced concrete type so fitted would frequently prove most effective fire stops, and an effective fire stop is practically the only real bar to the rapid extension of a great conflagration.

These three reports constitute the most valuable of the latest additions to the literature of earthquake-proof and fireproof building construction. They should be carefully studied by the building department of every large city and their recommendations should be heeded. The general principles which they set forth are sound and not the least of their services to modern building construction is the authoritative statement of the excellent part played by the few substantial reinforced concrete buildings exposed to the San Francisco fire.

It should be added, however, that fireproofing is largely a matter settled by the owner. Baltimore and San Francisco have shown the importance of good fireproofing, but owners too rarely are willing to pay for it.

Flood Prevention.

It is interesting to observe that last Spring's freshets and floods in a good many portions of the country have at last aroused communities exposed to injury from these occurrences to the advisability of taken measures to prevent them. It is not often that a single city is able to carry out a complete system of works for this purpose, and until co-operative measures can be arranged between several cities or under the direction of State commissions, it is useless to expect the best results. A good example of this is shown by the works constructed at Ithaca which were recently described in this journal; in order for them to be of maximum efficiency it is essential for various improvements to be undertaken by the State of New York in connection with its barge canal work. It is this interrelation of all parts of a waterway which produces such a complication in flood-prevention measures. Numerous communities have learned by bitter experience that works constructed for a short stretch of river may increase instead of diminish flood troubles, unless great care is taken to provide for carrying off the water below the improvement. Probably the unfortunate experience of many communities in constructing small and inadequate preventative works has been responsible for the general backward state of such undertakings in this country at the present time. Nevertheless the large flood loss which takes place almost every year has at last aroused public appreciation of the importance of the subject and has proved that it is sound business economy to spend a considerable sum of money in order to prevent such damages.

The methods to be followed in flood prevention are extremely varied, and anyone who will take the time to study the numerous works built in different parts of Europe will be impressed by the complexity of the problems and the necessity of regarding each one as an independent subject of investigation in order that not only the cause of the freshet but also its remedy may be ascertained. There is a prevalent opinion that forestry is a universal preventive of floods, but there are portions of Europe where works have been executed with successful results in which no reliance was placed on trees. Where a mountainous country has been stripped of its forests for some time and the rocky surface has been bared by rain, it is idle to expect more trees can be grown successfully. Other preventive measures must be taken in such districts, but national economy as well as the regulation of stream flow demand that forestry should be given a thorough trial where it stands any show of success. It is to be regretted that the bill for the establishment of forest reserves in the Appalachian and White Mountains, passed without dissent in the United States Senate at its last session, failed to pass the House, although it was unanimously recommended by the House Committee on Agriculture. This is one of the most important bills from the standpoint of flood prevention and forestry introduced for some years. The regions which it was proposed to set apart for forest reserves not only furnish the water supply for numerous communities and power plants but must also eventually supply valuable timber, and if they are not protected by federal legislation it is probable that their denudation and its attendant evils will continue. Fortunately the importance of this bill was thoroughly recognized by both branches of Congress and it is but reasonable to expect its passage at the next session, provided all who are interested in the subject, sufferers from floods, believers in the federal control of our important forests and users of water for power purposes and municipal supplies, take steps to urge their Congressmen to push for-

ward this bill as speedily as possible at the next session.

While the prevention of floods by protective measures on the watersheds from which the freshets come is a practicable measure for many districts, it is out of the question for places like Kansas City or New Orleans. The government has investigated the flood conditions at the former city and the probability of a recurrence of great damage there has been pointed out by a board of army engineers. These specialists have shown that just so long as the city encroaches on the natural waterway of the Kaw River, there will be danger of great damage. At New Orleans the situation is different. The city is guarded by a system of levees controlled by municipal officers, independently of the works executed elsewhere under the direction of the State Board of Engineers. These city levees were recently examined by order of the Governor of Louisiana and the engineers reported that out of thirteen miles of embankment on the left side of the river none is up to the State standard of 5 ft. above the flood mark of 1903. Moreover there are many places in this embankment which are declared to be unsafe and others that are unsatisfactory. On the other bank of the river the fourteen miles of municipal levees also present many features which are not what they should be. The results of the investigations seem to have aroused public appreciation of the dangers of the situation in New Orleans, and it is to be hoped that definite action will be taken before long to remedy the defects.

The Importance of Water Powers.

The Taylors Falls plant, which is described in this and the last issue of The Engineering Record, is a type of the hydraulic work of great economic importance now steadily under way. It is not at all sensational in capacity, voltage or distance of transmission, but it is a fine example of a well-planned and executed plant admirably constructed for economical and reliable service. Its most novel and interesting feature is the way in which the dam and power house are worked out together in massive concrete construction, giving a compact and convenient plant with the important feature of very short penstocks giving a most excellent opportunity for close regulation. The lesson it teaches is chiefly the economic one of the facility with which central stations can utilize water power anywhere within a radius of many miles to keep down the cost of electrical energy. At the present time electrical power transmission involves little of difficulty and is settling down to standard forms of practice. The voltage of 50,000 used in this Taylors Falls system would have been looked upon as rather hazardous even a few years ago. To-day it must be regarded as within the bounds of safe and conservative practice. In fact, one might almost say that 60,000 volts is now standard for large projects involving long transmissions, and 50,000 is certainly well within safe bounds.

The question of reliability which used so often to be raised with respect to long transmission has now been pretty thoroughly settled in the affirmative. It is true that lines sometimes break down, but with well-constructed duplicate circuits the chance of actual failure of service is not a frequent one. Against it must be set off the fact that the chance of failure of the motive power is considerably less with water than with steam. Something may now and then go wrong even with a hydraulic plant, but there are fewer chances for little things to cause a shut down than in a steam plant. It is a wise and far-sighted thing for a central station to develop hydraulic power for its own use and it nearly always pays from the start. Coal prices are upon the up grade and no return trains are running, so that what pays reasonably well now will be a splendid investment a few years hence. Plants like this at Taylors Falls are permanent. They are certain to give many years of valuable service, and there is little likelihood that the apparatus will go out of date for the purpose of its use. The distributing appliances may change and the receiving end of the plant go out of date, but there is small probability that the generating station will become materially less economical as time goes on. Dynamos and water wheels are unlikely to be materially improved in efficiency, and modern electrical machinery has a very long, useful life. As a matter of fact the first polyphase generators put into operation in this country some fourteen years ago are still in successful operation, and generators as built to-day are even more durable. It pays to do a thing a well, if at all, and plants built as thoroughly and planned as carefully as this one at Taylors Falls are likely to justify the wisdom of their constructor for many years to come. As time goes on more and more of the larger central stations are likely to do likewise. Few can find power so near at hand as in Minneapolis, but transmissions of a hundred miles or more are now as safe and practicable as those of twenty or thirty miles a few years ago, and are not to be feared.

THE PANAMA CANAL SITUATION seems to be unnecessarily troubling a number of people having access to the columns of daily papers. The latter have been manifestly misled lately concerning the management of affairs under the new commission and the feeling of its leading subordinates. It has even been stated that the chairman of the commission was dissatisfied and wished to be relieved from his duties. While The Engineering Record has no knowledge of the opinions of Lieutenant-General Goethals concerning his work, it is in a position to state positively that there is no such marked dissatisfaction with conditions among the technical employees of the commission as recent published reports would indicate. Wherever many thousand men are engaged on an undertaking which necessarily compels them to go without some of the comforts to which they have been accustomed elsewhere, a certain amount of grumbling and a few cases of positive discontent must be expected. Fortunately most discontented people went home before the present commissioners assumed office, and those who are now there are thoroughly alive to the importance of their work and to the credit that all will receive in due measure from participation in the undertaking. It is true that there was some apprehension in the engineering staff when military engineers were placed in control of the commission, but this disappeared as soon as the men had an opportunity of becoming acquainted with their new leaders. There will always be differences of opinion between those engaged on the work, which may lead in some cases to resignations, but there has never been a time when the force of canal builders felt more satisfied with their conditions than at present. Where work can be pushed it is going ahead energetically; where investigation is necessary in order to avoid mistakes, it is being made; and where the data for plans are complete, the designs are being pushed. There is no ground for any other statements.

THE NEW YORK RAPID TRANSIT RAILROAD COMMISSION has passed out of existence but it has left behind it a record of good work very well done. In the face of all kinds of opposition and in spite of the apathy of the public for some years it blazed the way for improved transportation facilities in Greater New York. It built one great subway line, it partly built others, and it left plans by which the transportation needs of the city can be met for a good many years to come. It went about its work with great shrewdness. The technical features of designing its proposed works were entrusted to an engineer, Mr. William Barclay Parsons, who had been engaged in studies of the city's transportation needs for some years before the organization of the commission. When the blight of politics settled on its work, the latter was quietly stopped until a time arrived when it could be carried on with a decent regard for the interests of the taxpayers. Instead of asking what terms would be acceptable to possible bidders the commission prepared its own requirements and at last succeeded in making a contract with responsible people, which was a good one in view of the novelty of the undertaking. The first subway was a thing untried; it was essential to make no false step at any stage of its history, and so the Commission necessarily moved slowly, and only after a full deliberation of the probable result of each proposed act. And on account of this deliberation and the self-sacrificing public spirit of the members of the Commission, there have been no mistakes to check the progress of rapid transit and the city is to-day in full possession of detailed information concerning every feature of the subject. The Engineering Record considers the abolition of the Board a great mistake, provided its members could be persuaded to continue in office, but it must be admitted that the transit work now pressing for early execution is so extensive and varied that it would probably unduly tax men of such large affairs as the commissioners who have retired.

THE PUBLIC SERVICE COMMISSIONS which will exercise supervision of the railway and lighting companies in the State of New York are made up of men of high standing. Some of them have taken an active interest in party politics, but none are "politicians." Most of them are lawyers, but business, manufacturing and engineering are also represented. Whether these men are capable of team work cannot be foretold; if they are not then the famous plan of controlling public utilities devised by Governor Hughes will come a tremendous cropper, for the commissions replaced by the two new ones did fair work. The new commissions undertake their duties with a great handicap, from the fact that the same kind of control in different parts of the State is vested in two independent bodies, each with powers of making rules and regulations to govern the companies under its jurisdiction. If the New York Central & Hudson River Railroad Co. has to obey one set of regulations until it comes down to the New York City line, and then must obey a different set of regulations, is there any likelihood that this complication cannot be utilized by the company to nullify effectively any regulations it does not like? While the apointment of two commissions with equal powers, one for the city and the other for the State outside the city, may have been a good political move to secure the adoption of the general principle of centralized State control of public utilities, it seems a pretty severe tax on human nature to expect the two commissions to agree, even on the most important features of their work. It is therefore reasonable to expect that before long the two bodies will be consolidated, and the work of the consolidated commission will be arranged so that everywhere in the State the supervision of public utilities contemplated by the spirit of the legislation will be uniform and effective. Such supervision is desirable, both technically and as respects rates, but The Engineering Record has no expectation that it can be exercised successfully by two independent bodies.

THE POWER PLANT OF THE NORFOLK & PORTSMOUTH TRACTION CO.

The new electrical generating station of the Norfolk & Portsmouth Traction Co., at Norfolk, Va., with a capacity of 10,500 kw., made up of a 1,500-kw. and three 3,000-kw., turbo-generator units, is thoroughly modern in all the details of its design. This station will furnish power to operate the street railways in Norfolk and Portsmouth and a number of electric railways running from those cities to resorts along the shore of the Atlantic Ocean and arms of the latter; the traffic between the Jamestown Exposition grounds and Norfolk will also be handled entirely by electric lines supplied with power from this station. The latter will also furnish power for electric lighting in Norfolk and the adjacent cities and for the brilliant electrical display at the Jamestown Exposition. The station occupies a rather prominent site in Norfolk on the bank of the Elizabeth River, a broad tidal stream connecting with Hampton Roads and the ocean. The station building exterior is designed in keeping with the surroundings, and although no attempt at elaborate architectural treatment has been made, the style of the architecture is expressive of the purpose for which the building is intended. The footings and substructure of the building are of concrete built on piles driven into the sandy soil of the site. The walls are of red brick and are surmounted by a concrete roof supported by steel trusses carried by columns in them. The building is 148 ft by 154 ft. 3 in. in plan, a brick wall dividing it into a boiler room 87 ft. 5 in. wide, and a turbine room 66 ft. 10 in. wide, both of which extend the full length of the building.

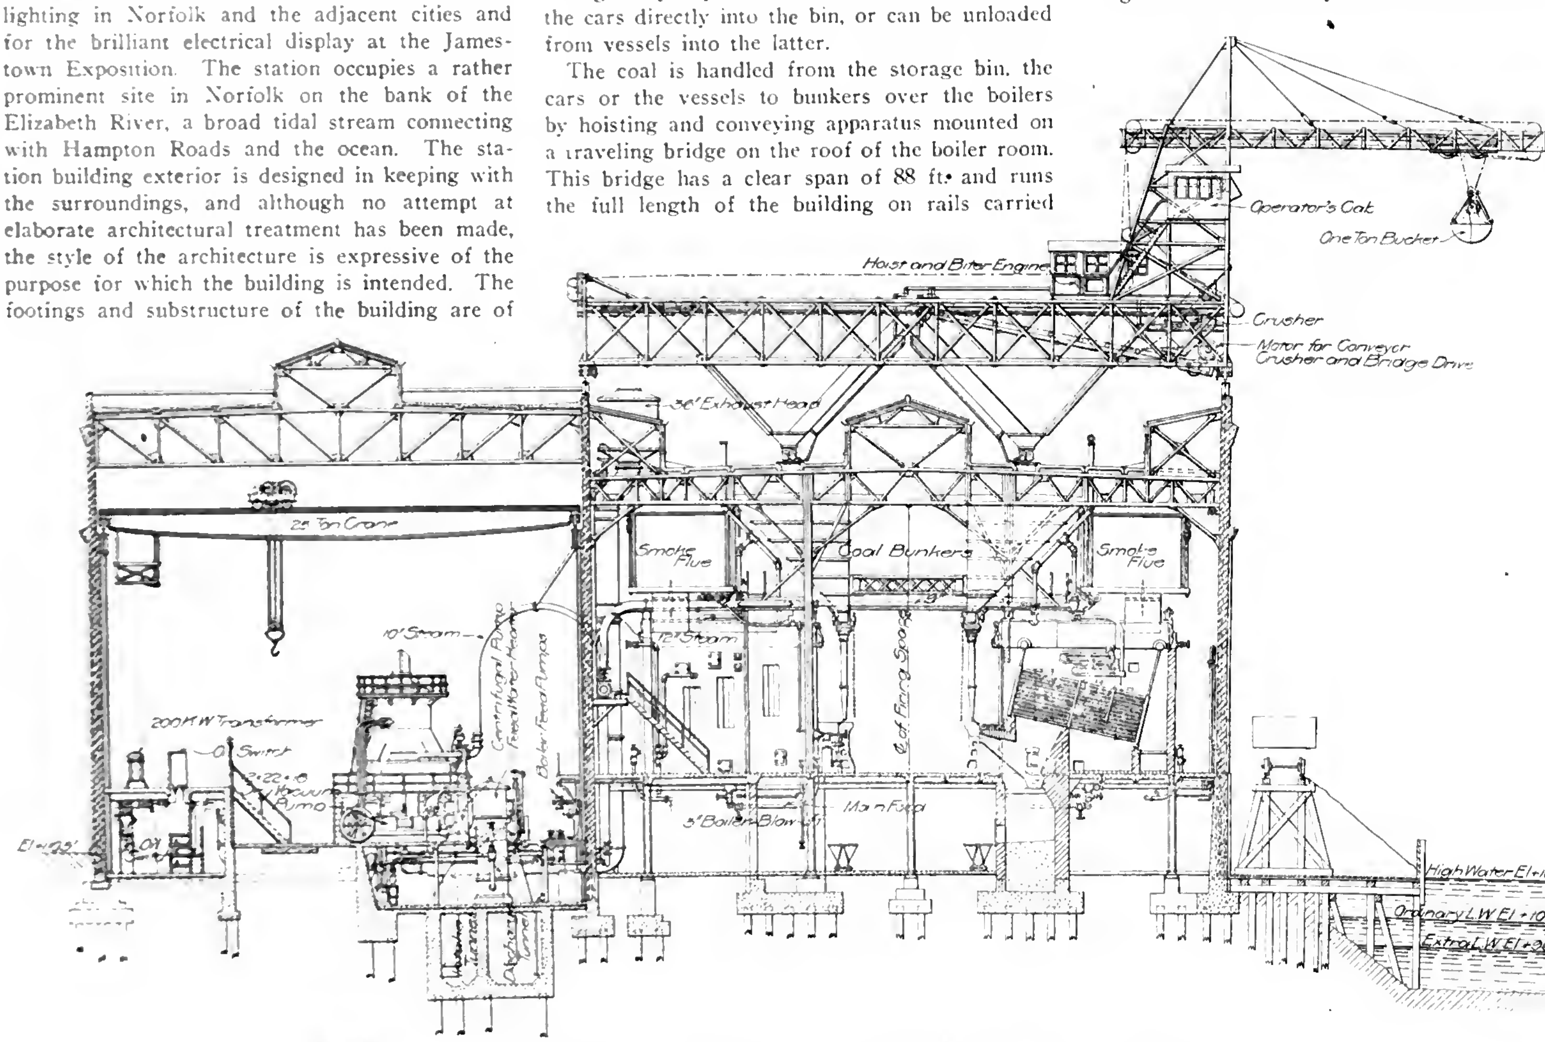
The boiler room is along the river side of the building and contains fourteen 500-h.-p. Babcock & Wilcox double drum water tube boilers. These boilers are set in batteries of two each, the batteries being in two rows, with six boilers in one row and eight in the second. The two rows face on a firing floor having a clear width of 15 ft. at the level of the boiler room floor, the fronts of the boilers in the two rows being 27 ft. apart. The space over the firing room floor is open and is surmounted by a monitor in the roof having side windows and skylights; a monitor with side windows and skylights also extends the length of the building along both sides of the roof over the boiler room. This arrangement of monitors produces good light and secures ventilation for all parts of the boiler room.

The coal supply for the boilers can be delivered in cars on a switch track on a trestle along the river side of the building, or by vessels in the river. An open storage bin, 26 ft. wide and with its outer side 5.5 ft. high, is built on piles directly under the trestle. This bin is against the side of the building, extending the full length of that side and along one end of the latter. The floor of the bin is at the extreme high-water level in the river, while the base of rail on the trestle is 14 ft. above that level so the bin has a large storage capacity. The coal is dumped from the cars directly into the bin, or can be unloaded from vessels into the latter.

The coal is handled from the storage bin, the cars or the vessels to bunkers over the boilers by hoisting and conveying apparatus mounted on a traveling bridge on the roof of the boiler room. This bridge has a clear span of 88 ft. and runs the full length of the building on rails carried by steel girders supported on columns in the building walls. The bridge carries a cantilever crane, an electrically-driven hoisting engine, an operator's cab and an electrically-driven coal crusher in a tower at the end next to the river. A traveling carriage is mounted on the crane, which extends out 42 ft. from the side of the building. The coal can be elevated from the cars on the trestle, from the storage bin, or from vessels moored along the dock on which the bin stands by a 1-ton clam-shell bucket swung by a hoisting cable from the traveling carriage.

The clam-shell bucket dumps into a hopper at the inner end of the crane. A chute leads from this hopper to the coal crusher immediately under it, the crusher discharging on a belt conveyor inclined upward toward the top of the traveling bridge and extending to the middle of the latter; the crusher may be by-passed and coal discharged from the hopper directly to the conveyor. Gates are arranged at the end of the conveyor so the latter will discharge at the middle of the bridge into either or both of two inclined chutes leading down to openings in the roof of the boiler room. These chutes are each fitted at the lower end with an undercut gate controlled from the operator's cab. Coal is supplied by these chutes to two rows of bunkers over the fronts of the boilers, each boiler having a separate bunker with a capacity of 95 tons. An opening in the roof, normally covered with a tight hatch, is provided over each of the bunkers, which are fed through these openings by the chutes on the traveling bridge. The bunkers are carried by steel columns in the fronts of the boiler settings and by the roof trusses. A vertical chute controlled at the top by a gate operated from the firing room floor feeds coal from each bunker to the charging hopper of the stoker immediately under it.

The ashes from each stoker are discharged into a tight chamber directly under the front of the boiler setting. A chute also leads into this chamber from back of the furnace bridge which is provided for conducting into the ash chamber the soot and fine ashes that collect back of the bridge. Two 24-in. gauge tracks are laid the length of the floor of the basement under the firing floor in the boiler room, one track in front of the ash chambers under each row of the boilers. The ashes are drawn out of these chambers through doors directly into 1-yd. dump cars running on these tracks. These cars are pushed out of the building by hand to low ground around the station on which the ashes will be dumped for filling.



Cross-Section of Norfolk Power Plant of the Norfolk & Portsmouth Traction Co.

The setting and arrangement of the boilers do not involve any unusual features. The boilers are designed to operate at 195 lb. pressure and are each equipped with superheaters capable of raising the temperature of the steam to 150° Fahr. above the temperature of saturated steam. Two brick stacks, 12.5 ft. in diameter and 200 ft. high above the boiler room floor, are built on separate

concrete footings at one end of the building, each stack serving one row of boilers. A smoke flue built of riveted steel plates extends through the entire length of the boiler room from each of the stacks and is swung over the rear of the boiler settings from the steel roof trusses. Each boiler is connected to one of the flues by a short vertical breeching.

Two pairs of 18x12x24-in. Atlantic type upright Dean Bros. feed-water pumps and two Alberger feed-water heaters, with 2,500 sq. ft. of heating surface each, are installed in the turbine room, one pair of pumps and one heater forming a set. The four main units in the turbine room are all operated condensing. A separate hot well is provided to receive the discharge from the condenser of each unit, an 8x12x12-in. Alberger vertical pump being installed at each of these wells to deliver the condensed steam to the feed-water heaters; these pumps may also discharge into the tunnel under the turbine room basement. Make-up water is supplied to the heaters from a connection with the city mains, and a second connection with those mains is provided so the heaters may be supplied entirely with cold water, if necessary. The steam-consuming units of the auxiliary equipment in the station discharge their exhaust steam into the feed-water heaters.

The boiler-feed pumps can draw either from the feed-water heaters, from a condenser discharge tunnel under the engine room, or from the city mains. Each pair of pumps supplies a separate system of feed-water piping for the boilers, the two systems being interconnected so any pump can supply either row of boilers. A 4-in. main feed-water header, hung from the ceiling of the basement under the boilerroom is provided for each row of boilers. These headers are supplied through a connection from both sets of pumps, each boiler having a connection with the header under its row. An auxiliary header is extended over each row of boilers, these two headers being interconnected and supplied independently from the feed pumps.

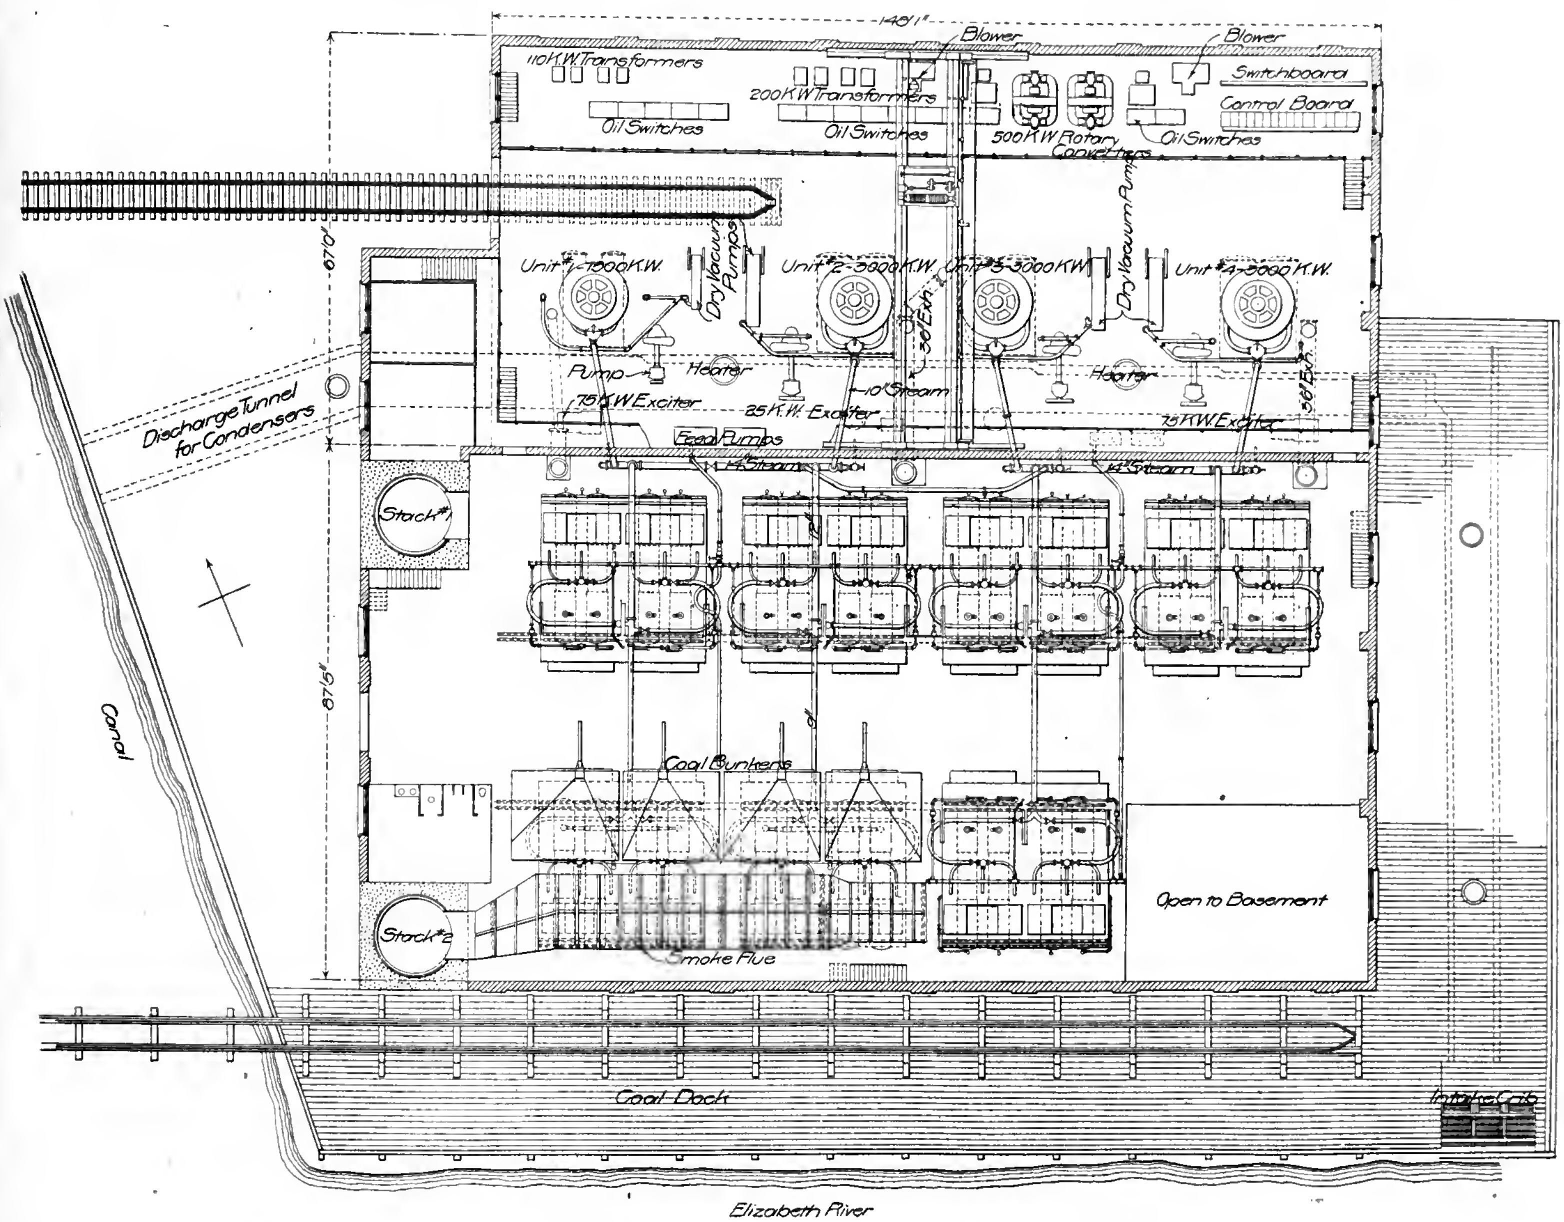
A 14-in. steam header in two sections is supported on the wall between the engine room and boiler room, the two sections being connected by an 8-in. loop. Two 12-in. branches are extended from each section of the steam header to connections with the first row of boilers and are then continued as 9-in. lines to the second row of boilers. The two drums of each boiler have a 6-in. connection with one of these branches, the connections each having a check and stop valve and an angle valve at the boiler, and a gate valve at the header.

Two of the main units in the turbine room are supplied from each of the two sections of the header, the latter having a valve at the middle by which either half of it may be operated independently. A line is extended into the turbine room basement from both ends of each section of the header to supply the auxiliaries in the turbine room, all of which are steam driven.

Extra heavy hydraulically-operated Crane gate valves are used on the steam headers and on the main connections from them. These valves are arranged to be operated from the basement of the boiler room. Water under pressure for operating the valves is obtained from connections to the supply lines leading from the feed-water pumps to the boilers, auxiliary connections also being provided. These connections are each controlled by a four-way cock, the controlling cocks being brought together in two groups on the wall of the boiler-room basement so the operator may close all of the valves on one section of the steam header and on the branches of the latter leading to the main units in the turbine room, without moving from the group of controlling valves. All the fittings and valve bodies on the main live steam connections are of cast-steel.

The four main units in the turbine room are in a single row, the 1,500-kw. unit being at the front end of the station. Between this unit and the first 3,000-kw. unit are the condenser equipments for these two units, one feed-water heater and a pair of feed pumps. The third and fourth units are arranged in a similar pair with their auxiliaries between them. The plans for the station contemplate that the building will be extended from the end which the fourth unit occupies.

The four main units have three-phase, 60-cycle, 11,000-volt, 10-pole alternating-current General Electric generators, which are each direct-connected to a Curtis turbine, and are operated at 720 r.p.m. The steam supply to these turbines is automatically controlled by an oil-operated governor in each case. The turbines all have base-condensers of the Alberger type, those on the 3,000-kw. units having 12,000 sq. ft. of



Plan of Norfolk Power Plant of the Norfolk & Portsmouth Traction Co.

surface, and the one on the 1,500 kw. unit having 6,000 sq. ft. of surface. Cooling water for these condensers is obtained from a large tunnel which connects with the river and extends the length of the building under the floor of turbine room basement. Three 20-in. Alberger volute centrifugal pumps, each direct-connected to a steam engine, are placed on the turbine room floor, one close to each of the large units, which deliver water from the intake tunnel to the condensers. A 10-in. Alberger volute centrifugal pump performs the same service for the condenser of the 1,500-kw. unit. After the circulating water has passed through the condensers it is discharged into a second tunnel, which parallels the intake tunnel and is also connected with the river, the two tunnel connections being at nearly diagonally opposite corners of the station site.

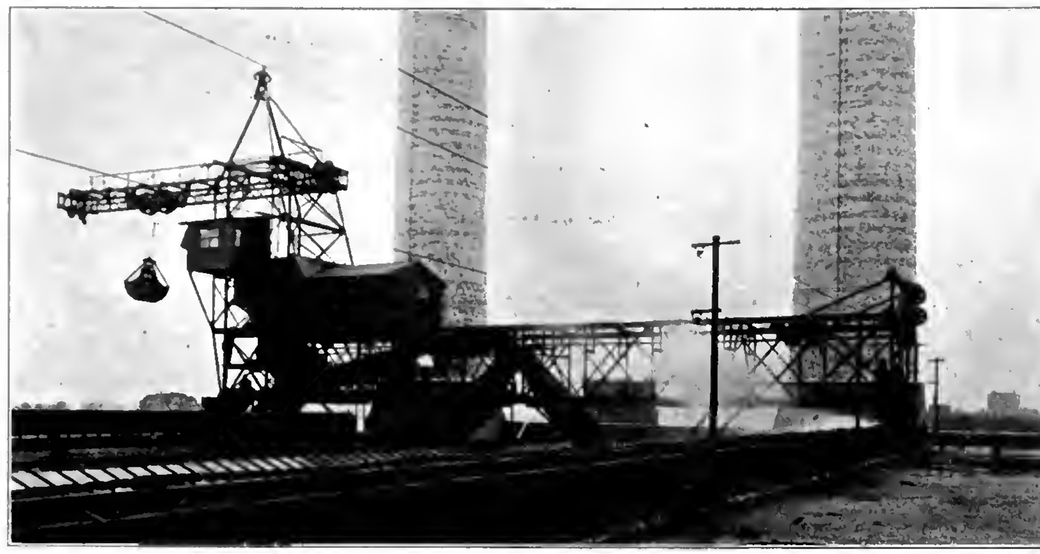
A 12x22x18-in. Alberger dry vacuum pump is used in connection with the condenser of each of the large units and an 8x20x12-in. Alberger dry vacuum pump serves the condenser of the 1,500-kw. unit. These pumps are on the floor of the turbine room, close to their respective units. Each condenser has an exhaust to the atmosphere through a riser extending above the roof of the boiler room. Each free exhaust outlet is fitted with a bronze mounted Davis turbine relief-valve, a 24-in. size for the 3,000-kw. and an 18-in. size for the 1,500-kw. unit.

The oil for the lubrication of the turbines and for the governors is supplied by four 9x5¼x3⅛x10-in. duplex, center-packed plunger Blake pumps of the differential type, one pair of these pumps supplying two turbines. These pumps take suction from a pipe supplied from the storage chamber of an oil filter in the basement, to which the oil from the bearings of the turbines is returned by gravity. The connections between the pumps and the bearings is arranged so either pump of a set may supply either turbine in each pair.

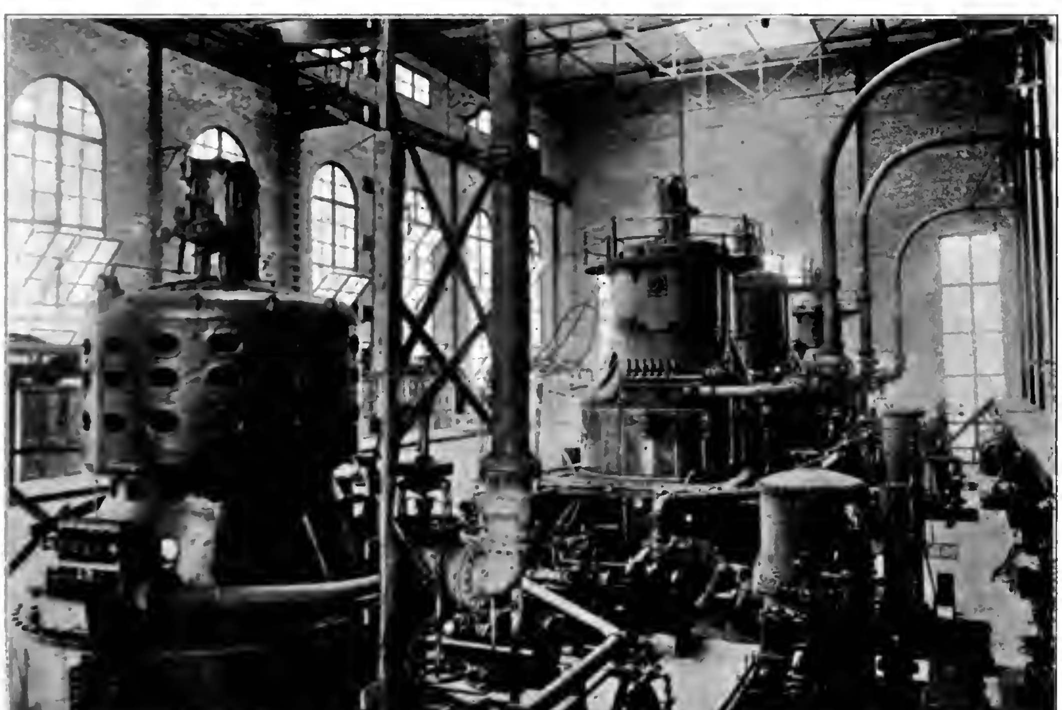
A 25-kw. and two 75-kw., 4 pole, 125-volt direct-current General Electric generators furnish excitation for the main generators. These exciters are each direct-connected to a horizontal Curtis steam turbine and operate at 2,400 r.p.m.

A part of the output of the alternating-current generators is transformed by two 500-kw. General Electric rotary converters in the engine room to direct current at 550 volts and is transmitted at that voltage for use on the street railway lines in the immediate vicinity. A large part of the remainder of the output is transmitted at 11,000 volts to sub-stations where it is transformed by rotary converters to direct current at 600 volts. The balance is stepped down to 2,300 volts alternating current and is used to supply lighting circuits.

The transformers, converters, control board, switchboard and so forth, are mounted on a concrete platform, 17 ft. 8 in. wide, which extends the length of the engine room, 8 ft. above the level of the floor of that room. The three cable leads from each main generator are carried under the engine floor in conduits to current transformers under the platform and then to motor-operated automatic 11,000-volt General Electric oil switches mounted on the platform. These switches are connected through disconnecting switches to three-phase buses in a brick compartment under the space enclosed by the platform and the wall in front of the latter. Each bus is in a separate section in this brick compartment. The buses are sectionalized at the middle by a 11,000-volt motor-operated oil switch, two generators being on each section. Three 11,000-volt feeder lines lead out of the station from each section of the bus-bars. Leads also extend from one section of the buses through disconnecting and oil switches to the primaries of two 550-kw., three-phase General Electric air-blast transformers mounted on the platform. The 11,000-volt current is stepped down to 420 volts by these transformers which deliver it to the rotary converters. The current used for lighting is stepped down to 2,300 volts by three 200-kw. and three 100-kw. single-phase delta-connected transformers, motor-operated oil switches and disconnecting switches being provided between the 11,000-volt buses and the transformers, and solenoid-operated oil switches and disconnecting switches between the transformers and the 2,300-volt buses.



Traveling Bridge of the Coal Handling Apparatus.



Interior of Turbine Room.

The oil switches, rheostats, field switches and the governors of the main generators and the switches for the 11,000-volt lines are operated by remote control switches on a switchbaord having 110 volts at the latter. This board has a panel for each generator, a tie panel for the 11,000-volt buses, a panel for each of the rotary converters, two transformer panels and six outgoing line panels.

The regulation of the auxiliary equipment, the direct-current side of the rotary transformers and 600-volt feeders, the local power and lighting circuits and so forth is controlled from a second switchboard. This board has two panels for Tirrill voltage regulators, a panel for each of three exciter units, a station lighting panel, four panels for 600-volt, direct-current feeder lines, two panels for the positive of the direct-current side of three rotary converters, a 600-volt panel for power supply around the station and three 2,300-volt feeder panels.

A switch track is extended into the engine room for a car length to expedite the delivery of heavy machinery. A 25-ton Niles-Bement-Pond traveling crane operated by three electric motors spans the turbine room and serves all parts of the latter, permitting of ready removal and installation of apparatus.

The station was designed and built under the direction of Sargent & Lundy, consulting mechanical and electrical engineers of Chicago. Messrs. J. B. McAfee, C. O. Emmons and E. C. Hathaway form an engineering committee in charge of the design and construction of the station for the Norfolk & Portsmouth Traction Co. The electrical equipment of the turbine room was furnished and installed by the General Electric Co.

AN EXHAUST STEAM TURBINE of the Rateau type at the Zollverein mine in the Essen coal district of Germany was found to require from 18.6 to 14.3 kg. of steam per kilowatt-hour when developing from 433 to 1,112 kw. The steam was supplied at 1.004 to 1.155 atmospheres absolute and the vacuum was 93.46 to 88.29 per cent. at the limits mentioned.

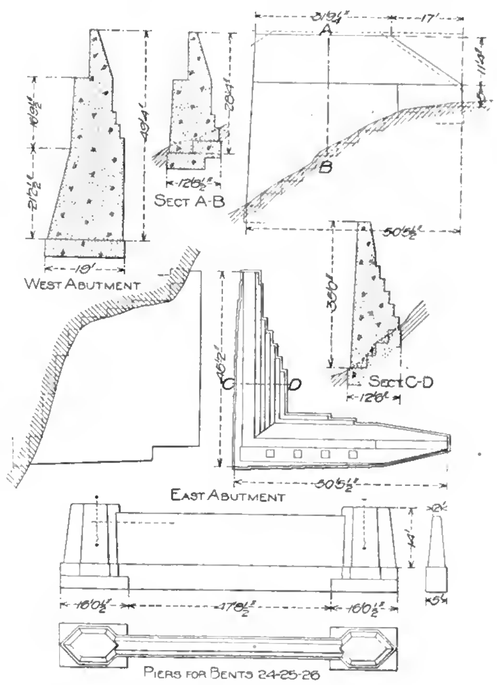
The Moodna Creek Viaduct, Erie R. R.

The Erie & Jersey R. R. now under construction is a 39-mile branch of the Erie system running from Highland Mills, N. Y., to Guymard, N. Y., and crossing the Moodna Creek valley on a tangent at a 2 per cent grade, on a steel viaduct 3,200 ft. long and 181.47 ft. above high water made of alternating 40 and 80-ft. plate girder spans supported by 40-ft. steel towers 120 ft. apart on centers. The substructure and towers are designed for a double-track superstructure but only enough girders for the single track will be erected at first, provision being made for the erection of the girders for the second track and for the reinforcement of the towers to carry the additional load at any future time without seriously increasing proportionate expense.

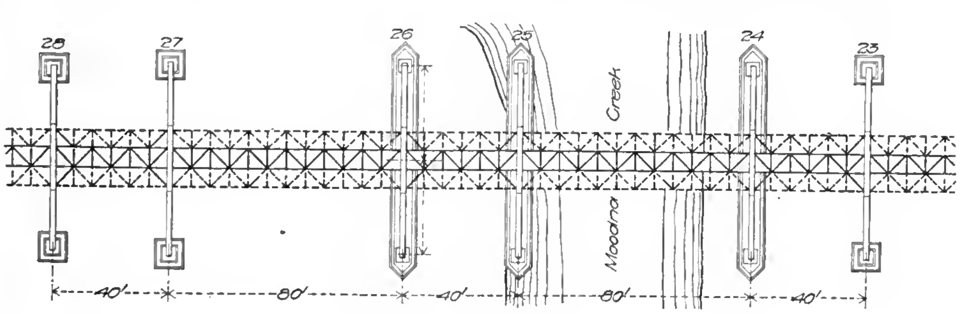
Careful estimates were made of the comparative cost of placing the reinforcement in the tower columns, now, and of deferring it until some future time, which showed that, calculating interest at 5 per cent., an economy will be effected if the reinforcement is deferred eight years or more.

The substructure is entirely of concrete without reinforcement and comprises two abutments, three intermediate piers and 98 separate pedestals for the tower columns. The footings were carried down from 5 to 10 ft. below the surface of the hard clay soil and were proportioned to load it to a maximum intensity of 5,000 to 6,000 lb. per square foot. At the west end the abutment 50 ft. high above the original surface of the ground is of the "pulpit" type without wings, and is 19 ft. wide at the base and 37 ft. long perpendicular to the bridge axis. The upper part is carried up 12 ft. above the bridge seat to form a back wall retaining the fill and the front and rear faces are battered and offset as indicated in the cross-section.

width of 11 to 12 ft. At the ends of the viaduct where the tower weights are a minimum the sides of the tops of the piers are reduced to 4½ ft. Where the distance from the base of the column to the surface of the ground is 5 ft. or less the height of the pedestal above the footing is 5 ft. In all other cases it is 8 ft. Each pier is provided with two vertical anchor bolts 2 in. in diameter and 10 or 12 ft. long, embedded in the masonry and projecting about 20 in. above its top. A shallow U-shaped bend is made in the bolt 2 ft. above the bottom, to prevent it from turning in the masonry and each end is provided with a nut and 6 in. of thread. The concrete was made 1:2½:5 with Atlas Portland cement



Details of Substructure.



Part Plan of Viaduct.

At the east end of the viaduct the surface of the ground slopes both longitudinally and transversely, and the abutment is L-shaped in plan with one long wing wall. The footings for both the wing wall and the face are built in offset horizontal courses on solid rock.

At the deepest part of the valley, where the viaduct crosses the Moodna Creek, three of the tower bents are located in or near the bed of the creek, and in order to protect their foundations from flood and drift and ice, the special hexagonal pedestals under both columns of each bent have sharp cut-waters up and down stream and are connected by a solid vertical wall 2 ft. thick at the top and 12 ft. with a base 5 ft. wide extending down to the bottom of the footings and made integral with them so as to form a long and solid pier approximately parallel to the creek, developing great longitudinal strength and preventing any driftwood or debris from lodging between the pedestals.

In all of the other tower bents each column has a separate and independent pyramidal pedestal 5 ft. square on top with battered sides, seated on two or three offset courses extended to a

and all exposed edges of piers, bridge seats and wing walls were rounded to a 3-in. radius.

The superstructure of the viaduct consists of twenty-seven 80-ft. spans and twenty-six 40-ft. spans supported on 52 transverse trestle bents, longitudinally braced together in pairs to make 26 towers, 40 ft. long, 19½ ft. wide at the top on centers, with the columns battered 1½ in. per ft. to a maximum width of about 65 ft. at the foot of the tallest towers. The towers are from about 35 to 180 ft. high and are divided into one to five stories with X-braced panels. Both columns of each bent are riveted at the top between the webs of a transverse box plate girder 10 ft. deep, with its top flange flush with the top flanges of the longitudinal girders. The upper panel has a uniform depth of 42 ft. in all bents except the single story ones, and the intermediate panels have a uniform depth of 30 ft. on centers, while the heights of the lower panels vary from 20 to 45 ft., according to the irregularities of the surface.

The columns have a 23½x26¼-in. open rectangular cross-section, made of two built-up channels having their webs parallel to the axis of the viaduct and their flanges turned inward and latticed. Wide rectangular plates riveted across the flanges of the columns project beyond the inner faces and form jaw plates receiving the field-riveted connections of the transverse struts and diagonal members. Each web has from end to end a double row of open rivet holes provided for the future connection of an I-shaped diaphragm perpendicular to them which will be made with 22x⅜-in. flange angles, and two 7x⅝-in. flange cover plates, field-riveted in the interior of the columns when it is decided to reinforce them in order to withstand the extra stresses from the added track. The cross-section of the column varies in the different stories, as indicated on the general elevation.

In the high bents the transverse width at the bottom is so great that the temperature movements make it necessary to provide a roller bearing, similar to that of an ordinary bridge truss, for the foot of one column, the opposite column being seated on a fixed pedestal. The horizontal transverse struts are built channels having their webs horizontal and their flanges turned inward and latticed. The X-braces are pairs of angles latticed together, one member being continuous in each panel and the other cut to clear it at their intersection and spliced and connected to it with two field-riveted flange cover plates. The longitudinal face of each tower is X-braced in panels corresponding with those of the transverse face but has no horizontal strut except one at the foot. The X-braces are uniform throughout, each consisting of two 12-in. channels with vertical webs and latticed flanges. One of them in each panel is continuous and the other is cut to clear and spliced across the intersection with web plates. The struts are field-riveted at the ends to pairs of vertical web-connection plates shop riveted to the columns.

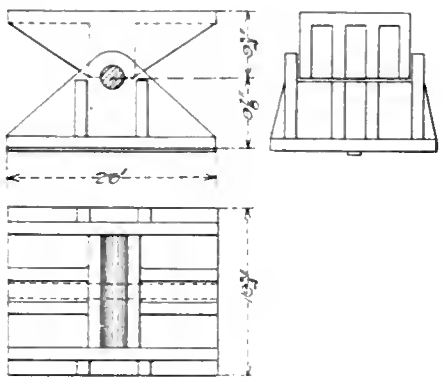
The single-track viaduct, as first erected, has two lines of longitudinal girders each 3 ft. 3 in. from the axis of the viaduct. Provision is made for adding two more duplicate lines of girders, each 6½ ft. beyond the original line, when it is decided to double-track the viaduct. The 40-ft. girders, about 5½ ft. deep over all, are all fixed at both ends where they are field-riveted to the transverse girders at the tops of the towers. The 80-ft. girders, 9 ft. deep, are similarly connected to the tower girders at the fixed ends. Expansion bearings are provided for the 80-ft. girders on both abutments and at one of every second span, making a series of portals at intervals of 240 ft. where they have sliding seats on planed bed plates. The transverse tower girders have deep web pockets to receive the sliding ends at the expansion points.

The upper ends of the top sections of the columns have very deep and wide flange cover plates, projecting a considerable distance from the inner face of the column, which in reality form the end sections of the webs of the transverse girders and are field-riveted to outside cover splices shop-riveted to the latter. This arrangement greatly simplifies the construction and facilitates the erection, allowing the location of all field-driven rivets in accessible positions. The center sections of the transverse girders are 13 ft. long and are shop-riveted complete to the webs and are connected by the top flange cover plates and by vertical longitudinal diaphragms in the planes of the longitudinal girders. The fixed and expansion end middle sections weigh 9,100 lb. and 13,800 lb. respectively, and are found to be easily handled and assembled in the field. The diaphragms are provided with manholes to make the interior of the header girders accessible for painters and inspectors after erection. The fixed ends of the longitudinal girders are field riveted to the webs of the transverse girders with 42 rivets each, driven from the outside with pneumatic hammers, sufficient space

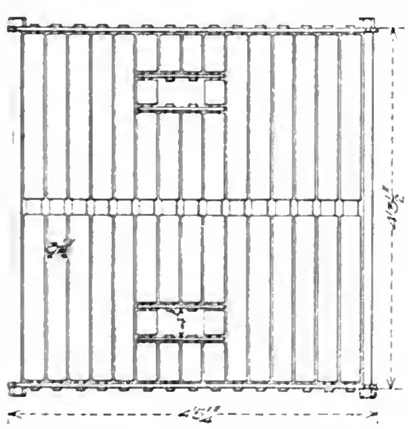
being provided betwen the webs to hold up against the heads of the rivets. The top flanges of adjacent longitudinal girders are connected across the transverse girders by cover plates field-riveted to all three girders except where they are bolted through slotted holes to the expansion ends of the sliding girders.

The longitudinal girders are braced together with transverse angle frames, top lateral struts and zig-zag angles, thus making horizontal wind trusses 6½ ft. deep on centers and 40 and 80 ft. long. In order to transmit the horizontal shear at the ends of the span to the tops of the tower columns without producing a bending moment in the transverse girders, the end transverse struts are spaced about 4½ ft. beyond the transverse girders and the lateral angles terminating there connect with horizontal knee-braced struts running directly to the column tops. These struts will be removed when the viaduct is double-tracked and an additional set of lateral bracing is put in on each side of the two center girders, as indicated by dotted lines on the plan diagram.

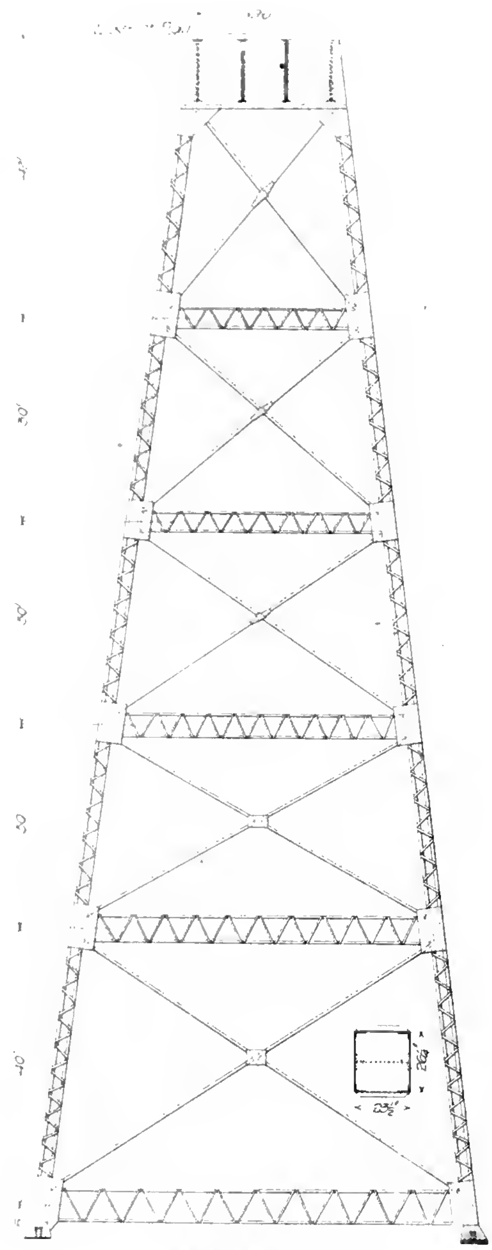
Cross ties 10 in. deep and 16 in. apart on centers are laid on the top flanges of the stringers, to which every fourth one is hook bolted at both ends. Every fourth tie is 10 ft. long with a projection beyond one side of the track to carry a 5-ft. sidewalk with 2x9-in. longitudinal plank 16 ft. long. The ends of the long ties carry a wooden lattice girder hand-rail 4 ft. deep with a 5x5-in. vertical posts 8 ft. apart securely bolted to the ends of the ties. The intermediate ties



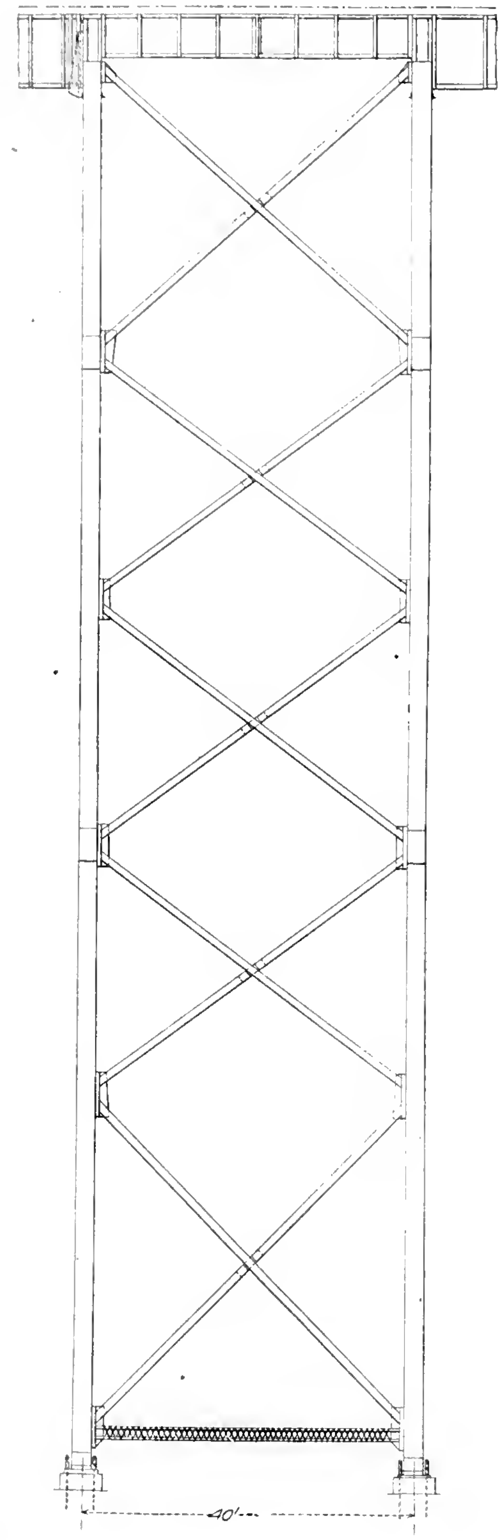
Abutment Expansion Bearing.



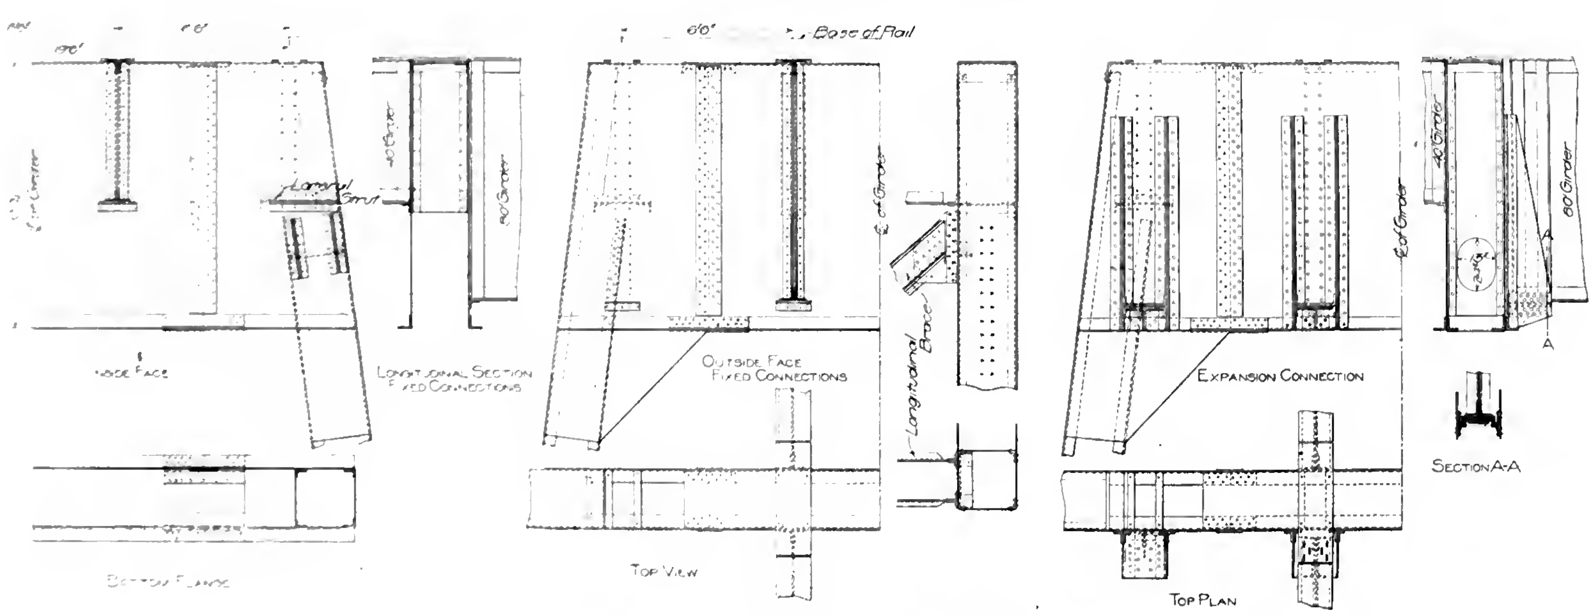
Rollers under Column.



Transverse Elevation.



Longitudinal Elevation.



Connections of Longitudinal and Transverse Girders.

are 10 ft. long and every other one is bolted to the 5x8-in. guard timbers. All high viaducts on the Erie Railroad have wooden hand rails as the appearance of their heavy lines is considered better than that of a lighter construction. An effort is always amde to accentuate the columns and the top line of the structure and to simplify the bracing, so that the main supporting elements may not be confused by a network of insignificant members.

The tower girders are 38 ft. 10½ in. long over all and their webs are two ⅜-in. plates 108 in. deep, shop-spliced with four rows of rivets in a pair of cover plates. The flanges are made of a pair of 6x6x⅝-in. angles and three 16½-in. cover plates, one of them full length. Pairs of 5x3½x⅜-in. angles with fillers divide the girders into 6½-ft. panels.

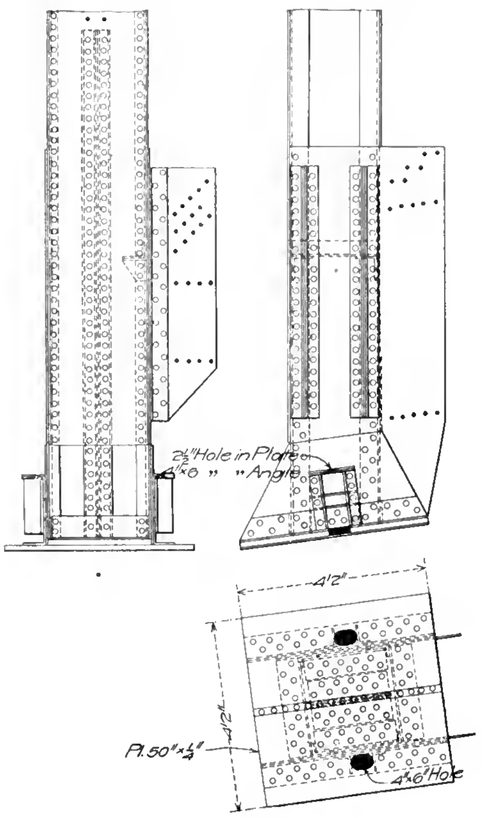
The transverse girders have 120x⅜-in. single-piece web plates 26¼ in. apart in the clear with 6x6x⅝-in. bottom flange angles. The 6x4x⅝-in. top flange angles have their horizontal flanges turned inward to clear the longitudinal girders and are shop-riveted to the 27x⅜-in. cover plates. At the ends of the fixed longitudinal girders the webs are connected by diaphragms 62½ in. deep in the planes of the longitudinal girder webs. At the expansion connections the diaphragms are extended to the full depth of the girder between flange angles, to reinforce thoroughly the pocket connections and are provided at the bottom with 18x24-in. manholes to give access to the center part for inspection, painting and riveting. The expansion bearing pockets are made of a pair of 20x⅝-in. vertical longitudinal plates 8 ft. long shop-riveted to the webs and having at the bottom an 18¾x20½-in. reinforced horizontal shelf plate with a planed upper surface to receive the lower flange of the longitudinal girder.

The feet of the tower columns have 4 ft. 2 in. x 3 ft. 9 in. base plates stiffened by vertical transverse flange plates and heavy connection angles, and provided with two 4x6-in. slotted holes just clear of the column faces. These holes receive the 2-in. anchor bolts that pass through pockets made by vertical distributing angles on the faces of the columns and through 2¼-in. holes in horizontal shelf angles fitted to the tops of the vertical angles and affording bearings for their nuts. The fixed column base plates are seated directly on the carefully dressed masonry, but the bases of the expansion columns are seated on nests of fifteen 3⅛-in. rollers 50 in. long with shoulder bearings in ordinary guide frames and center slots for guide ribs on the bottoms of the base plates and on the tops of the 50x50x1¼-in. bed plates. Four rollers in the center of each nest are made in three lengths each, with 4-in. spaces between the ends of adjacent sections of the same rollers to provide slots clearing the anchor bolts. The expansion ends of longitudinal girders have sliding bearings on all towers, but at the abutments they are provided with Standard cast-iron shoes and pedestals and the latter are seated on nests of eight 3⅜-in. rollers 22 in. long.

The superstructure contains about 4,042 tons of steel for the single track and 1,750 tons additional are required to transform it to a double-track structure.

In the present construction of the viaduct the two lines of longitudinal girders are spaced close together for a single track and are connected to the transverse or header girders near the centers of the latter. After the future double-tracking of the structure, the addition of the two outer lines of girders will very much increase the width of the roadway platform and extend it to the tops of the tower columns, thus directly transmitting to them the various horizontal stresses at track level. Meantime, in order to provide for the longitudinal traction stresses, the first panel point of each long span is braced with a heavy transverse cross strut and from its ends diagonal struts are run to the tops of the towers, as indicated in the general plan, thus directly connecting the main girders with the columns and providing for the transmission of the stresses through the tower bracing to the ground.

The Erie Railroad construction department is under Mr. J. M. Graham, vice-president, and Mr. Francis Lee Stuart, chief engineer, under whose direction the viaduct, including the foundations, was designed by Mr. Mason R. Strong, engineer of bridges and buildings, with the assistance of Mr. F. A. Howard, assistant engineer of bridges and buildings. The erection is being done by the bridge and building department under the charge of Mr. W. H. Wilkinson, inspector of bridges. The steelwork was fabricated by the McClintic-Marshall Construction Co.



Foot of Column.

Bituminous Preparations for protecting structural steel were strongly recommended by Mr. Bertram Blount at the British Engineering Conference last month. Natural bitumen is permanent but costly; coal tar boiled so that the coating shall be neither brittle nor sticky, is almost as durable and is cheap enough. Its use is limited by aesthetic considerations, but as these are chiefly based on convention, Mr. Blount believes that the engineer who insists on finishing a bridge with tar may be regarded as a poineer in the art of embellishment. Until that time bituminous materials can be freely used for all structures not too conspicuous. Where the work is exposed to boiler-gases, such as overhead bridges and station roofs, complete coating with a good layer of hot bitumen, he believes to have so much practical advantage over paint that no question of appearance should be permitted consideration. Whether paint or tar is used, the metal should be thoroughly cleaned from scale and rust immediately before the coating is applied. For structural steelwork, such as the frames of buildings or frame foundations, there is no preservative so good as lime or cement concrete, Mr. Blount said. It is essential that the concrete hould be dense and rich in cement, and that the cement or lime should be unexceptionable. Steel protected in this way need not first be cleaned from scale and rust.

Standard Test for Fireproof Floor Construction.

Reported by the Committee on Fireproofing Materials of the American Society for Testing Materials.

The test structure may be located at any place convenient to the applicant, where all the necessary facilities for properly conducting the test are provided. The test structure may be constructed of walls of any material not less than 12 in. thick, properly buttressed on all sides. The floor construction to be tested shall form the roof of the test structure. At a height of not less than 2 ft. 6 in., nor more than 3 ft. above the ground level, a metal grate, properly supported, shall be provided, covering the whole inside area of the building. In the walls below this grate level, draught openings shall be provided, as many as possible, furnishing openings with an aggregate area of not less than 1 sq. ft. for every 10 sq. ft. of grate surface. Means for temporarily closing these openings should be provided. In the wall, immediately above the grate level, a firing door, 3 ft. 6 in. by 5 ft. high, must be provided in the side of the building at right angles to the floor beams. A second door must be added when the span of the floor slab under test exceeds 10 ft.

Flues should be supplied at each of the corners, and oftener in case of a test structure exceeding 250 sq. ft. of grate surface, with sufficient opening to insure a proper draught, securely supported and disposed at the sides of the structure in such manner as not to rest on the floor under test. In no case should a flue area be less than 180 sq. in.

The horizontal dimensions of the test structure will depend upon the number and the span of the systems under consideration. The clear span of the floor beams is to be 14 ft. The distance between floor beams, or span of slab, may be varied according to the design of the system to be tested, and should be as near as possible to usual practice. The underside of the construction under test must be not less than 9 ft. 6 in. nor more than 10 ft. above the grate level.

The construction to be tested should be designed for a working load of 150 lb. per square foot, and no more. This load to be uniformly distributed without arching effect, and to be carried on the floor during the fire test. The floor may be tested as soon after construction as desired, but within forty days. Artificial drying will be allowed if desired. The floor is to be subjected to the continuous heat of a wood fire, averaging not less than 1,700° F. for four hours.

The heat obtained shall be measured by means of standard pyrometers, under the direction of an experienced person. The type of pyrometer is immaterial so long as its accuracy is secured by proper standardization. The heat should be measured at not less than two points when the main floor span is not more than 10 ft., and one additional point when it exceeds 10 ft. Temperature readings at each point are to be taken every three minutes. The heat determination shall be made at points directly beneath the floor so as to secure a fair average.

At the end of the heat test a stream of water shall be directed against the underside of the floor, discharged through a 1⅛-in. nozzle, under 60 lb. nozzle pressure, for ten minutes.

After the floor has sufficiently cooled the load on the same shall be increased to 600 lb. per square foot, uniformly distributed.

The test shall not be regarded as successful unless the following conditions are met: No fire or smoke shall pass through the floor during the fire test; the floor must safely sustain the loads prescribed; the permanent deflection must not exceed one-eighth inch for each foot of span in either slab or beam.

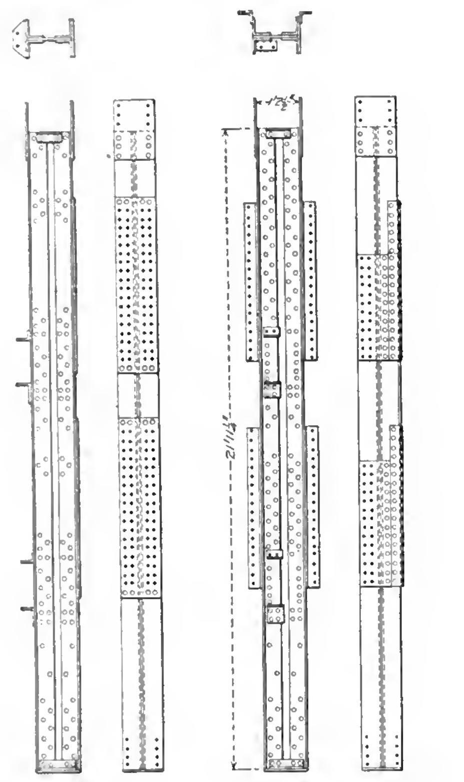
The Berger Building, Pittsburg.

The 60x90-ft., 15-story Berger Building at the corner of 14th Ave. and Grant St., Pittsburg, Pa., is an example of extremely simple and regular construction of a steel cage office building of moderate height. The plan is a parallelogram with the ends skewed 11⅛ inches on the long side. This difference is all concentrated in the end panels of the floor, so that the 12 intermediate panels are rectangular, and the six in the center of the building are all 15 ft. wide and 10 ft. long, the others varying from 15 ft. to 20 ft. 1½ in. From the basement to the fifteenth floor inclusive the beam framing is the same in each story, and is of the simplest possible description, consisting of single longitudinal and transverse I-beams on the center lines of the columns except for the wall girders which are riveted on the outer faces of the columns, and having no intermediate beams or girders whatever except in the two intermediate panels containing the elevator and stair-well. The main beam, therefore, supports the Johnson system floor arches, made with 6-in. blocks and a maximum span of 15 ft., and are proportioned for a dead load estimated at 65 lb. per square foot, and for a live load of 100 lb., on all but the roof, which is proportioned for dead and live loads of 65 lb. and 60 lb. per square foot respectively. The I-beams vary from 7 in. 15 lb. to 15 in. 60 lb., and in all cases are connected to the column with simple top and bottom horizontal flange angles.

The columns are made in two-story lengths, except in the upper section, which are three stories long. All wall columns are spliced 5½ ft. and all interior columns 11¾ in. above finished floor level. The first story is 16 ft. high and those above it are uniformly 11 ft., except the fifteenth story which is 16½ ft from the floor line to the highest point of the roof. This gives the roof a total height of 175 ft. above the first floor or 200 ft. above the sub-basement floor. All columns have an I-shaped cross-section made with two pairs of flange angles and a web plate. The lightest column section is made with four 5x3½x5/16-in. angles and a 14x5/16-in. web plate about 36½ ft. long and extends through the thirteenth, fourteenth and fifteenth stories and supports the main roof. The heaviest column section is proportioned for a static load of 554,000 lb. plus wind stress, and is made with four 6x6x¾-in. angles, one 14x¾-in. web plate and four 14x½-in. cover plates and is 30 ft. 9 in. long extending from the sub-basement floor to above the first floor. All of the other columns have a uniform length of 22 ft. and a cross-section varying between the limits already mentioned, but terminating in the basement and sub-basement stories with a uniform dimension of 12-in. flange and 14-in. web made with either 4x6 or 6x6-in. flange angles.

All columns have simple cast-iron pedestals 21 in. high seated on solid rock, except adjacent to the next building, where in order to bring them close to the party line the pedestals are seated on grillages of 10-in. I-beams 5 or 6 ft. long, which distribute the pressure longitudinally. The wall columns are enclosed in interior pilasters made by extensions of the brickwork. On the two street fronts two 10-in., 15-lb. fascia channels to support the metal cornice are carried about 2 ft and 3½ ft. beyond the centers of the wall columns by cantilever girders each of which consist of a pair of 10-in., 15-lb. channels back to back with a solid web gusset plate riveted between their inner ends to give connection to the face of the column.

The exterior walls are carried at every story by plate girders made with a 20¾-in. web plate and four 3½x3½-in. flange angles, both webs and angles varying slightly in thickness to correspond with the different surfaces. The lower outside flange angle is made full length, the other three flange angles of each girder are cut to clear the columns and the web plates are field riveted across the column flanges except in four cases where the corner columns have connection angles to receive the girders at right angles to their flanges. In all cases below the thirteenth floor the girder web is made in three sections with the short end pieces projecting from two to four feet above or below the top or bottom flanges of the girder to form gusset-plate knee-braces in the corners of the panels made between the columns and girders. The inclined edges of the knee brace plates are stiffened with pairs of 3x3-in. angles below the tenth floor in two sides of the building and below the third floor in the third side. Those of the fourth side on the 4th Ave. front not being stiffened at all. On the party side of the building the knee braces are placed on the under sides of the girders in the sub-basement, basement and first story. Otherwise they are throughout as above described. Exposed braces are carried across the court at the eighth and thirteenth floors and roof.



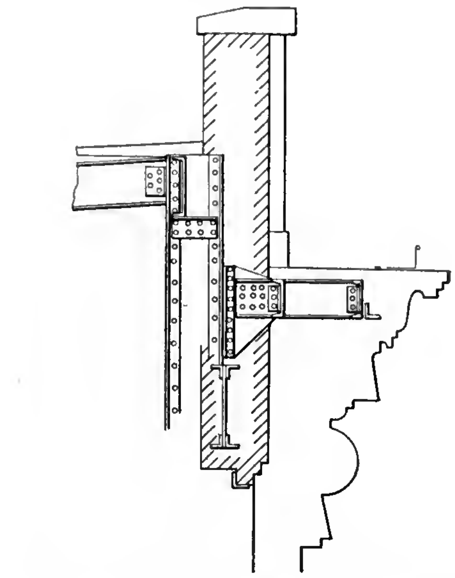
Column with Wind Bracing Connections.

The building contains about 950 tons of structural steel which was fabricated at the Ambridge plant of the American Bridge Co. Mr. S. S. Beman was the architect, and Mr. N. Ronneberg was the structural engineer.

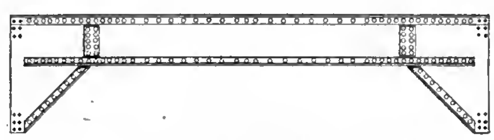
BITULITHIC PAVEMENTS may be laid in Iowa cities under a decision recently made by the Supreme Court of that State in Saunders v. Iowa City et al., 111 N. W. Rep., 529. The court rules that the bitulithic monopoly cannot be considered odious in the eye of the law. The field for the use of paving materials and methods is limited, the court considered, and if cities may not avail themselves of new discoveries in this line, little encouragement will be given to invention, and we must depend upon the cobblestones of our forefathers. If the material for a pavement selected in a legal way is wholly or partly patented, there cannot be absolutely free competition, and where that is impossible, the court decided, the Legislature never intended that improvements should cease or antiquated methods only be adopted.

Sampling Coal for Government Buildings.

The methods adopted by the Treasury Department in purchasing coal for use in federal buildings were described in the Engineering Record April 6 and formed the general subject of three papers read at the recent convention of the American Society for Testing Materials, as reported in the Current News Supplement of this journal on June 29. An important lesson of the experience gained to date in purchasing coal on the thermal unit and ash basis is the necessity of taking great care in sampling coal, so as to obtain a fair average. This was particularly shown in the paper presented to the convention by Messrs. J. A. Holmes and D. T. Randall, of the U. S. Geological Survey, based on three years' experience in comparing samples obtained in the mine and from cars. Two methods of



Support of Cornice and Parapet, Berger Building.



Wind Brace, Berger Building.

sampling have been tried. In one the sample is taken and impurities discarded in accordance with instructions to miners for separating foreign matter from the coal. This method, when checked by samples taken from coal shipped in cars under ordinary working conditions, shows that mine samples are usually considerably better than the actual delivery, due to the failure of the miner to fully carry out instructions. This difference may be indicated by comparison of the ash content of the coal in the two cases. The average results show for run-of-mine coal 30 per cent. more ash in the coal delivered than in the mine sample. The other method of mine sampling follows as nearly as possible the actual methods which the miners follow, regardless of what their instructions may be. By this method samples may be secured by an experienced inspector which correspond very closely with the car deliveries, but considerable time is required for observing the work of the miners in different parts of the mine, and the judgment of the inspector is depended upon to secure the result.

In both methods the following precautions are taken by the inspector to secure a correct sample. A vertical cut is made over the face of the coal and the cuttings are caught upon a waterproof blanket which is spread upon the floor of the mine. Impurities are rejected, in accordance either with the instructions or with the usual miners' practice, and after being crushed to ½-in

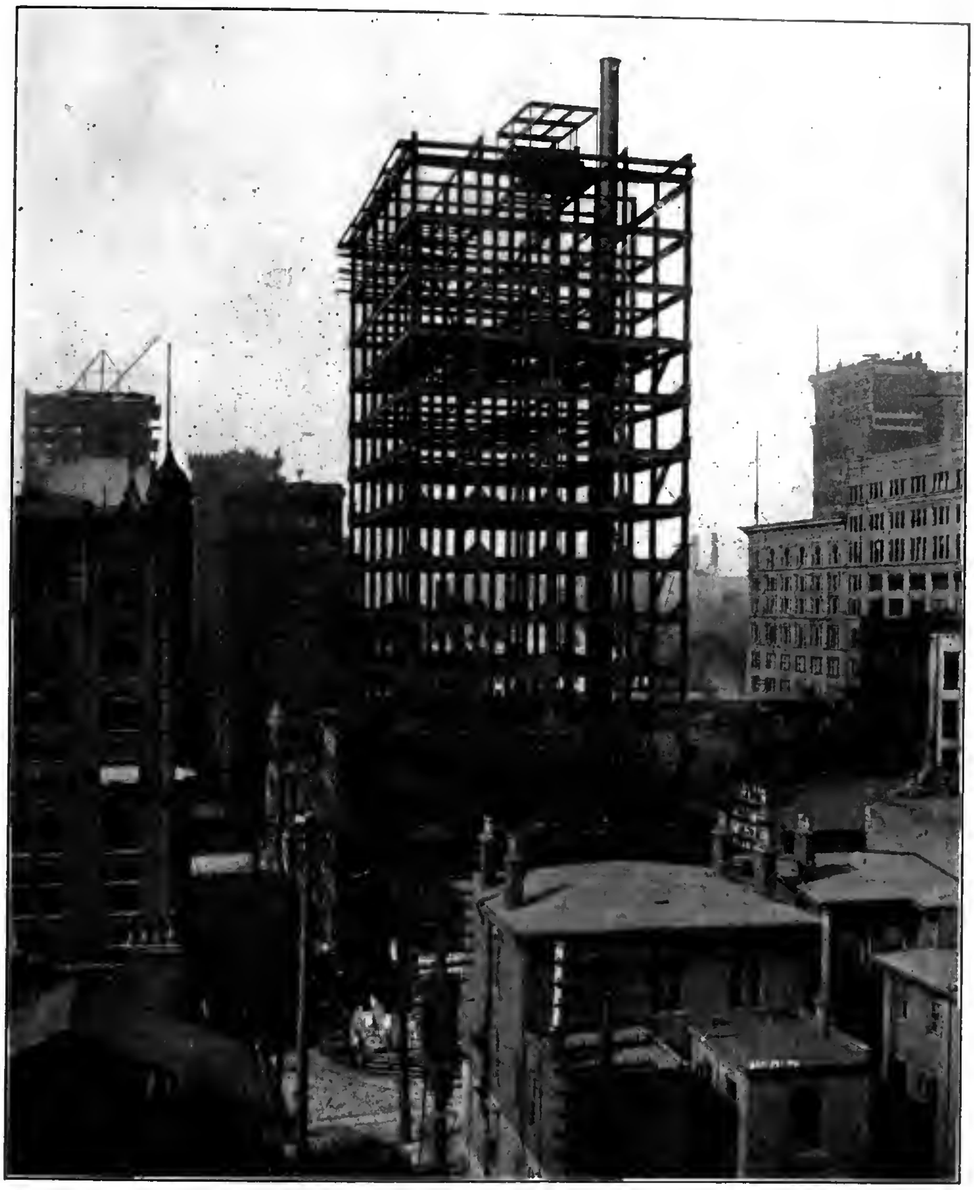
pieces or smaller, the coal is thoroughly mixed. It is then quartered down and the resulting sample is placed in a metal can holding about one quart and sealed air tight. All of this work is done in the mine where the sample is taken and as rapidly as possible to avoid loss of moisture. A full description of these methods and results may be found in the Geological Survey Bulletin No. 290.

Samples as usually furnished from mines are not to be depended upon as representing the coal which will be delivered. This difference is mainly due to failure of the miners to obey instructions regarding the rejection of impurities, to differences in the quality of the coal in different parts of the mine, and to the fact that different beds of coal are often mined at the same time and the output mixed. Lack of cars in mining and in preparation of coal for the market explains in a great measure the variation in the amount of ash in the coal delivered from the same mine at different times. In sections of the country where coal is washed variation in the quality may be considerable, due to the carelessness of the attendant in charge of the washery. The tendency with persons inexperienced in sampling is to select a sample much better than the average product. In many cases samples are taken by selecting a nice looking lump, breaking it down and shipping it in a cloth sack, thus allowing the moisture to evaporate. Such a sample, of course, represents the best coal in the mine and (unintentionally, in most cases) establishes a much higher value than can be commercially delivered.

The mine sample, if properly taken, does, however, establish the general character of the coal and indicates what may be expected under favorable circumstances.

During the past winter samples of coal from several of the Government buildings in Washington were secured by members of the Fuel-Testing Division of the Geological Survey and the analyses were made by the Chemical Laboratory conducted by this division under direction of Prof. N. W. Lord, of Ohio University. Samples were usually taken from the coal as it was being unloaded from the cars or from wagons. In the case of car deliveries it has been found that it is necessary to take small quantities from many parts of the car as it is being unloaded, in order to obtain a fair sample, for the reasons that the coal is often brought to the car from different parts of the mine, and in transit the heavier portions of the coal tend to settle to the bottom. The analysis of samples from the top and bottom of cars often show very considerable differences in the percentages of ash. In case coal is delivered to the buildings in wagons and stored in bins, it is preferred to obtain the sample by taking a small quantity from each load or at regular intervals as the wagons are being dumped into the bins. In cases of small deliveries of anthracite coal it has been found satisfactory to take samples from a number of points over the surface of the coal when it has been impossible to channel through the bin, which is preferred when practicable.

These samples vary from 100 to 500 lb., according to the amount of coal delivered. The coal is collected on shovels in such a manner as to represent the delivery as closely as possible, and is placed in closed cans, each holding about 60 lb., which are locked when filled. These samples are then sent to the laboratory crushing room in the Geological Survey Building and crushed in a small rotary crusher to ⅛-in. pieces or smaller. The crushed coal is automatically divided into quarters by passing through a special sampling tube designed by the chemical division. The resulting sample is further reduced by quartering until a quart sample is secured. Precaution is taken throughout the work to prevent loss of moisture.



Complete Steel Framework, Berger Building.

Waste Heat Boilers for Copper Smelting Furnaces.

An interesting smoke flue boiler installation has recently been made at the smelting plant of the Colusa-Parrot Mining & Smelting Co., at Butte, Mont., for the utilization of waste heat from the copper smelting furnaces. The installation follows in general lines the practice that has been customary in steel mills for the utilization of heat from reverberatory and similar furnaces, but in plants where chemical processes are involved, the difficulties attending the use of the smoke flue boilers have prevented its more general adoption. While in furnaces for heating metals for forging and working, the waste gases of combustion carry little soot and dust, where chemical processes like smelting and ore roasting are involved, such large amounts of dust and friable matter are carried over from the ore that considerable difficulty is usually experienced in the operation of the boiler, owing to the rapid accumulation of this flue dust on the boiler tubes, with consequent reduction of their heat-absorbing capacity. Especially in the case of copper smelting furnaces is this difficulty encountered, so that only boilers whose heating surfaces may be quickly and effectively cleaned while in operation, are adaptable, and those of the water-tube type with inclined tubes have been found in practice to be the more desirable. Moreover, this dust and friable matter carries a considerable quantity of metal, so that its recovery by deposition in any manner is both desirable and profitable.

There are three matte furnaces at the Colusa-Parrot smelters, each having chimney flues 32 x 45 in. in cross section, which were formerly connected directly into tall stacks. The furnaces are all of the reverberatory type, with 5x10-ft. grates, and are fired with coal, the waste gases formerly passing to the stacks at temperatures ranging from 1,500° to 2,000°. In the application of the waste-heat boilers to the furnaces, it was the desire so to arrange the flue gas connections that a by-pass might be secured for use in case it might be necessary to take the boilers out of service, and accordingly provisions were made for the boilers at the front corners of the furnace settings, on the opposite sides from the by-passes. The matte furnaces are located 51 ft. apart between centers, which allowed fully 24 ft. between the settings; at the front and above these spaces at one end substantial platforms 17 x 24 ft. in size were erected upon which the boilers are supported. The platforms are elevated about 7 ft. above the main floor level in order to bring the heating surfaces of the boilers at a convenient level above the flue gas connections. The platforms consist of four latticed posts under the corners of the boilers, upon which are carried 12-in. I-beams transversely, that support six 10-in. I-beams, 24 ft. in length, three under either side of each boiler. The platform is extended about 3½ ft. on all sides of the boiler and is fitted with a railing to form a working gallery.

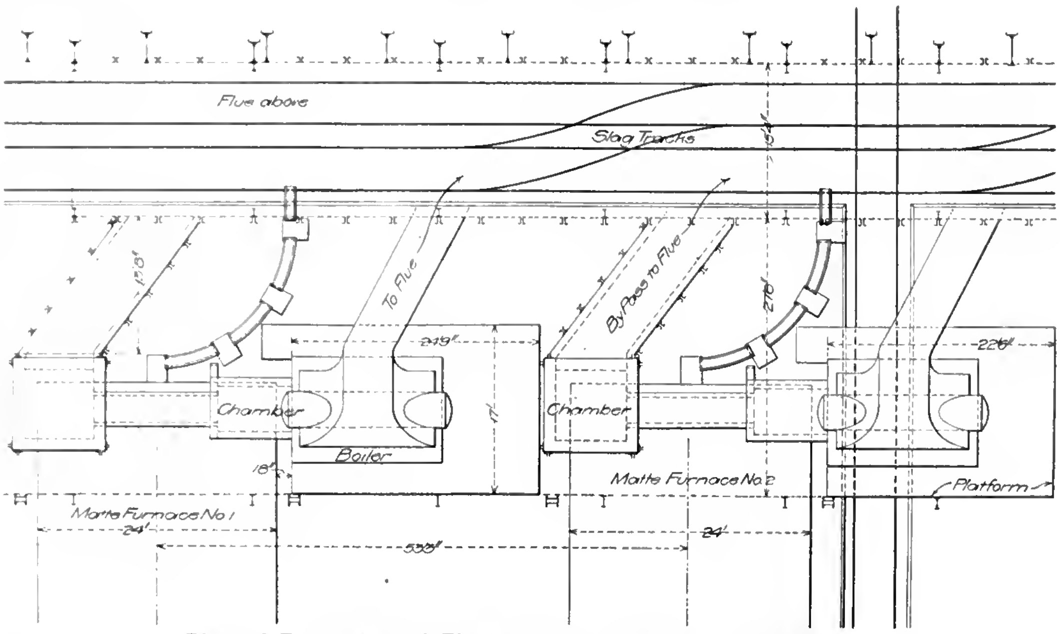
The details of arrangement of the flue connection to the boiler are shown in the accompanying drawing. From the furnace a flue outlet, 32 x 45

in. in section, is carried up directly to the combustion chamber of the boiler, directly above this is located the boiler. The course of the waste gases is from the furnace through the flue to the combustion chamber under the boiler and thence upward through the heating surface of the boiler and discharging through a special breeching which extends to a flue leading to a settling chamber and stack. The settling chamber is a brick duct, about 50 ft. wide x 19 ft. high inside and several hundred feet in length. The chimney is a circular brick stack, 352½ ft. in height, which is substantially built on a heavy slag foundation, the reinforcement of the latter being of steel rods and bars, around which the slag was poured while in molten state.

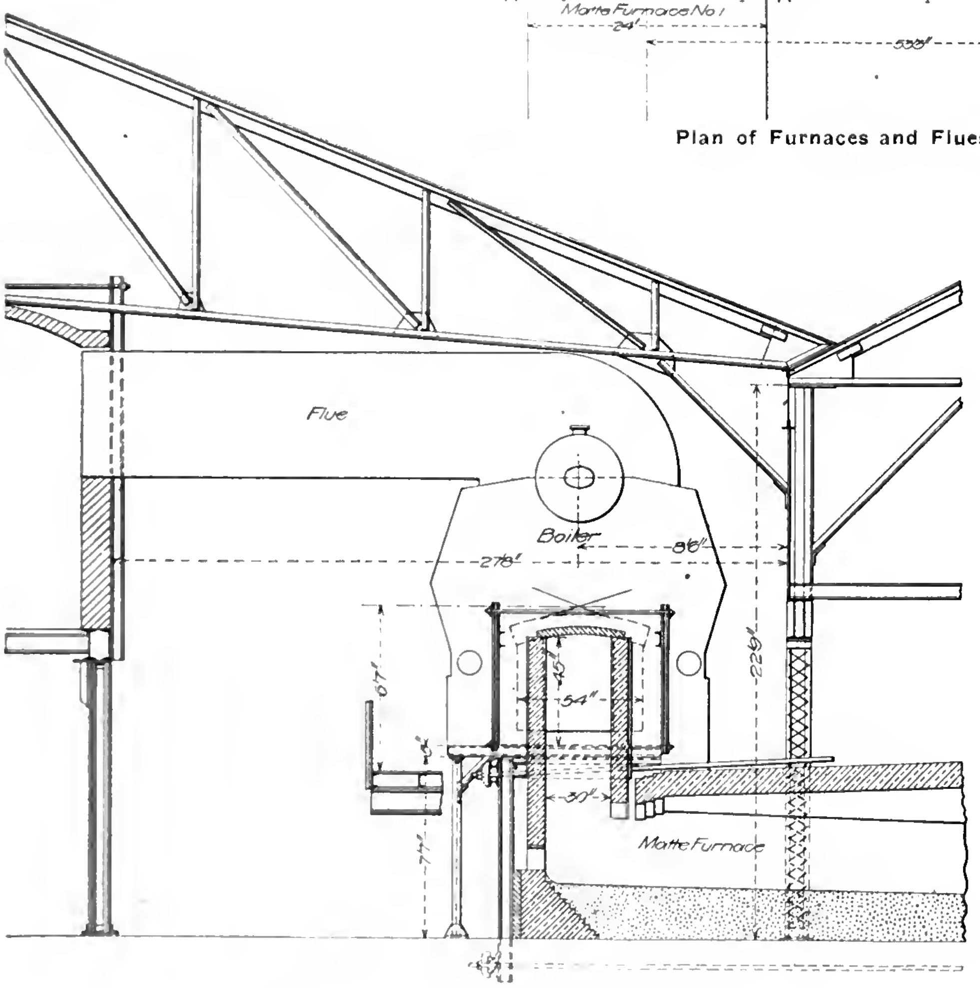
The boiler used with each Matte furnace is a 315-h.-p. unit of the Worthington type, built by the New York Safety Steam Power Co., which has a specially designed casing rendering it well adapted to this class of service. It embraces the usual Worthington construction, consisting of a centrally located horizontal steam drum with inclined banks of tubes, the steam drum being 42 in. in diameter by 20 ft. long. There are 61 sections of water tubes, each with eight full-length tubes and one shorter tube connecting with the lower side of the drum, making 549 tubes in all. The tubes are 3 in. in diameter and 10 ft. in length, the total heating surface presented in each boiler being 4,635 sq. ft. Apart from its size the boiler presents no unusual features with the exception of the casing, which is of special design to permit cleaning while in service, not only for the purpose of keeping the heating surface free from dust and matter deposited from the furnace, but also to enable this material to be reclaimed for return to the smelter.

The entire outer casing of the boiler, which is of the usual sheet metal construction, is formed of hinged doors, of which there are two on each end and six on either side, to facilitate the cleaning of the heating surfaces. The by-pass flues permit any boiler unit to be cut out of service at any time desired in order to enable this cleaning to be done, but the spaces between the tubes may be kept free from accumulations through slotted openings in the lower doors at both front and back, through which bars may be inserted. The slots are 2 x 10 in. in size, cut through the doors in line with the openings between the headers of the boiler, and are covered by small flap doors, hinged and held by buttons on the main doors. Each flap door covers only five of these openings, so that it will be seen that by opening but one of these doors at a time, the boiler may be cleaned while it is in operation without sensibly interfering with the draft. The operation of the cleaning bar through the slot openings keeps the boiler free from any deposit between the tubes vertically, while the side doors permit the introduction of a nozzle to blow the dust from the tubes horizontally.

In operation the waste heat boiler units have been very successful, it having been found that, with this arrangement of flue connections, there is no diminution in the capacity or economy of the matte furnaces, and sufficient steam is produced for the operation of the entire plant, without the use of the boilers that were formerly operated for steam production. While the waste gases formerly went to the stack at temperatures of from 1,500° to 2,000° Fahr. they are now discharged at a temperature of about 500°; in order to provide ample draft, a tall single stack was erected to replace the independent stacks that formerly served each of the furnaces separately. The boiler settings are also found effective as settling chambers, considerable amounts of the metal-bearing material carried over from the furnaces being reclaimed from the combustion chambers under the boilers, for return to the furnace or smelter.



Plan of Furnaces and Flues at the Colusa-Parrot Smelters.



Connection between Boiler and Furnace Flue.

Traction in the Detroit River Tunnel.

Traction in the Detroit River Tunnel now under construction will be conducted at first with six 100-ton direct-current locomotives of the swivel truck type, with geared motors. Each locomotive is designed to haul a 900-ton train up a 2 per cent. grade at a speed of 10 miles per hour. Current for operating the motors will be taken from a third rail by contact shoes. Power for the operation will be purchased from the Detroit Edison Co., and will be delivered at a substation at a potential of 4,400 volts and a frequency of 60 cycles. At the sub-station two 1,000-kw. synchronous motor-generator sets will be installed for supplying direct current to the third rail. The yards and approaches to the tunnel will be lighted by arc lamps while the tunnel itself will be lighted by incandescent lamps. Alternating currents from the main power supply at a frequency of 60 cycles will be used on the lighting circuits. For draining the tunnel there will be five sumps, each fitted with a pair of centrifugal pumps driven by induction motors. The sub-station will be provided with a regulating storage battery to carry the fluctuations of the load. The electrical equipment of the tunnel will be furnished by the General Electric Co.

A 22-Degree Curve on the Canadian Pacific Ry., between Golden and Field, B. C., known as Kicking Horse Pass curve, has recently been replaced by a new cut-off with maximum curvature of 8 deg., which involves a tunnel 693 ft. long. The old curve was on a detour line around a bend in the Kicking Horse River, which had been made necessary by the caving in of the old "Mud Tunnel" 20 years ago; the detour was 2,880 ft. long, 755 ft. of which was curved to a radius of 262 ft., so that no elevation of the outer rail was possible on account of "cornering" of passenger coaches. The cut-off shortens the line 1,192 ft.

The New Settling Basins and Other Improvements to the St. Louis, Mo., Water-Supply System.

The water supply for the city of St. Louis is drawn from the Mississippi River at the Chain of Rocks, 10 miles above the business section of the city. At this point a tunnel extends under the river to an intake tower in the channel of the latter, and is connected at the shore end to low-service pumps in a station building 500 ft. back from the edge of the river bank. These pumps deliver at present to a series of six large settling basins immediately downstream from the pumping station, the six basins having a combined capacity of 180,000,000 gal. From these basins the settled water flows by gravity through a horseshoe-shaped brick and masonry conduit, 11 ft. wide at the springing line of the arch and 9 ft. high, to two high-service pumping stations, known as the Baden Station and the Bissell's Point Station, which are approximately 4 and 7 miles, respectively, down the river from the low-service pumping station at the intake.

In order that the facilities for supplying and distributing water to the city should keep pace with the exceptionally rapid growth of the latter, additions to and extensions of the supply and distribution systems had become an immediate necessity. Two new settling basins at the Chain of Rocks, a 7-ft. steel pipe flow line paralleling the existing conduit from these reservoirs to the Baden high-service pumping station, and a storage reservoir at this station are the most important features of the additions and extensions to the supply system that have been undertaken. A large building containing storage space for the coagulants used in the clarification process employed in the settling basins, the machinery necessary in mixing these coagulants and applying them to the raw water, and a new high-service pumping station are among other improvements to that system that are to be put under construction soon.

The six existing settling basins are each 400 x 670 ft. in plan and are placed side by side, a masonry division wall separating the adjacent basins. The side walls of these basins are of stone masonry and their bottoms are concrete, embankments being placed around the walls. Under normal conditions of operation the raw water enters the upstream basin through four 3 x 3-ft. openings controlled by sluice gates. It flows from this basin over the dividing walls between the successive basins and is drawn into the brick and masonry conduit from the downstream one of the six basins, known as Basin No. 6. Supply and effluent connections are made, however, so the water may be admitted to or drawn from the various basins in practically any combination of the latter, in order to provide for cleaning and for emergencies of operation. The bottom of each of these basins is sloped from both sides to a trench along the longitudinal center line, to facilitate the removal of the sediment that is deposited from the raw river water. A 24-in. sewer outlet controlled by a gate valve in a gate house in the embankment extends from the end of this trench to the river, about 500 ft. distant.

The two new basins are being built between the existing basins and the river, covering together an area 400 ft. wide by 1,660 ft. long. They have reinforced concrete side and end walls backed by earth embankments, their bottoms being lined with 9 in. of concrete. The two basins are separated by a division wall, consisting of two reinforced concrete walls spaced apart and filled between with puddle, the total thickness of the walls and puddle being 9.5 ft. The bottom of each basin is sloped to two transverse trenches under which is laid a 30-in. sewer leading to the river. The basins are each 400 x 800 ft. in plan and have an average depth of about 21 ft., their combined capacity being 75,000,000 gal. The total capacity of the eight basins will be 255,000,000 gal., which is increased to 394,000,000 gal. when the new basin at the Baden station, four basins at Bissels Point Station and a distributing reservoir on Compton Hill in the city are considered. As the average daily consumption is approximately 72,000,000 gal., five and one-half days' storage capacity is provided.

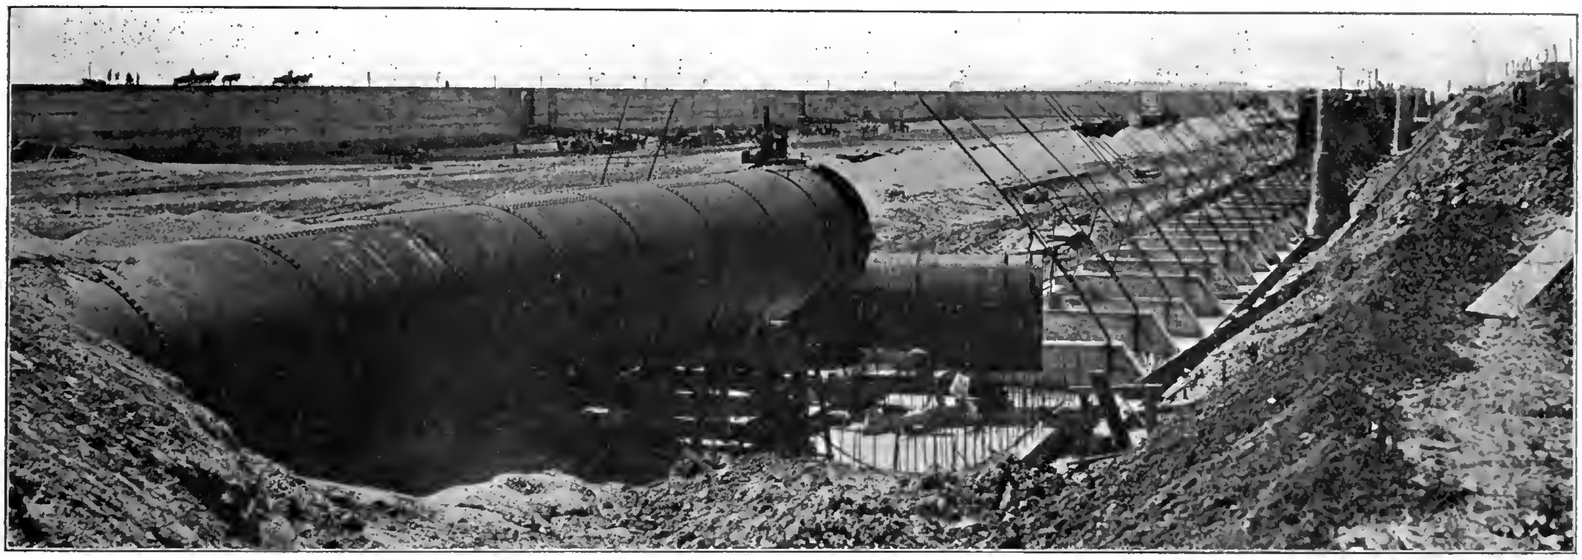
A by-pass consisting of a double 4x7-ft. reinforced concrete box conduit has been laid between the six existing and the two new basins in order that one or more of the eight basins may be cut out of service if desired; the two new basins are each connected with this conduit from which they may be supplied separately. The downstream one of the new basins, known as Basin No. 7, is connected with the downstream basin of the six existing ones, called Basin No. 6, so that water may be diverted from the former into the latter. The new basins are interconnected and have independent connections with the brick and masonry flow-line conduit leading to the high service pumping stations. Basin No. 7 also has a connection with a gate chamber from which the new 7-ft. steel flow line will be supplied.

The usual method of operation when the new basins are placed in service will be to pass the water through the existing basins in the normal manner, then through Basin No. 7, into Basin No. 8, and thence into the brick and masonry flow-line conduit, from which it may be diverted into the 7-ft. steel flow line at the south end of the system of basins. The various connections that have been provided, however, provide for a number of different combinations of the basins, making the sequence of operations entirely flexible. The connections between the various basins and between the latter and the by-pass and conduits are all controlled by sluice gates and valves. These gates and valves are placed in concrete gate chambers, built with the walls of the basins as their outer sides. The walls of the chambers are carried up to the tops of the basin walls and are to be covered with removable cast-iron floor plates.

A gate chamber at the inner downstream corner of Basin No. 7 is called Chamber No. 1. It contains two compartments, one 10 ft. square and the other 10x12 ft. in plan, which are separated by a 4-ft. concrete wall. The connection between Basin No. 6 and Basin No. 7 is a reinforced concrete conduit, having a 4 x 8-ft. rectangular cross-section. This conduit terminates in the larger compartment of chamber No. 1, 10.25 ft. above the bottom of the latter, in which it is controlled by a 4x8-ft. sluice gate. The outlet from this compartment is a two 4x4-ft opening in the opposite side of it, leading into the basin. A 6x7-ft. opening in one side of the other compartment of this chamber connects the latter with the basin, the opening being controlled by a sluice gate. The outlet from this chamber is a 7-ft. steel pipe which connects through the terminal conduit chamber nearby with the new 7-ft. flow line.

A connection from Basin No. 7 to the by-pass is made about midway in the side of that basin, terminating in a 10x15-ft. gate chamber known as Chamber No. 2. The connection with the by-pass is a double reinforced-concrete box conduit, each part of which is 5 ft. square in cross-section. The outlet from the chamber is a 6x7-ft. opening fitted with a sluice gate of that size.

The third one of the gate chambers, known as Chamber No. 3, is at the inner end of the dividing wall between Basins No. 7 and No. 8. This chamber has two compartments, each 10x13.5 ft. in plan, which are connected by an arched opening in the wall between them. A connection with the by-pass, of the same type and size as the one in Chamber No. 2, ends in one of these compartments and is controlled by two 5x5-ft. sluice gates. A 7-ft. steel pipe extends from the other compartment to the brick and masonry flow-line conduit, and is controlled by a 7-ft. circular sluice gate. A 6x7-ft. opening in one chamber connects the latter with one basin and the second basin is connected with the other compartment by an



General View of New Basins During Construction.

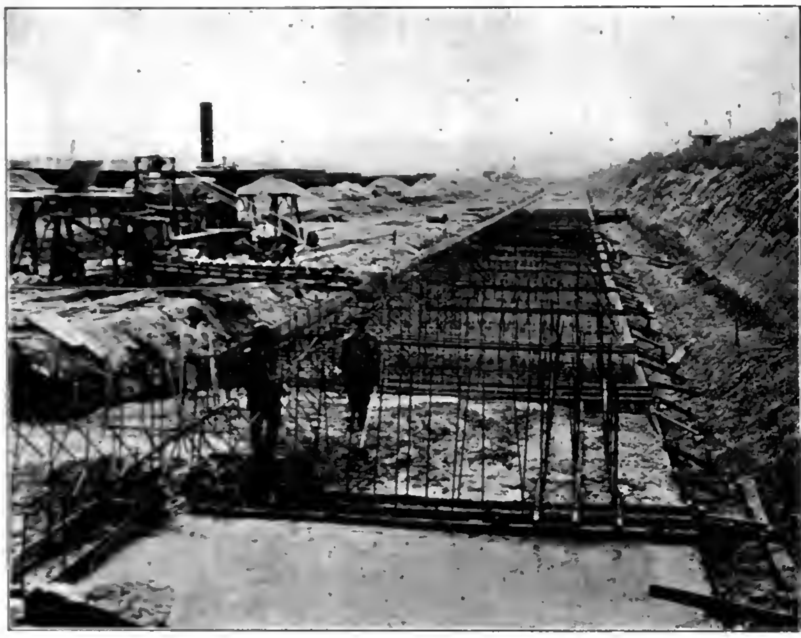
opening of the same size. With this arrangement the two basins may be connected, either or both basins may be supplied from the by-pass and either or both basins may discharge into the brick and masonry flow-line conduit through this conduit.

A fourth gate chamber, known as Chamber No. 4 and similar to Chamber No. 1, is placed at the inner upstream corner of Basin No. 8. This chamber has two independent compartments, one 10 x 10 ft. and the other 10 x 15 ft. in plan. A 7-ft. steel pipe line from the receiving chamber which supplies raw water to Basin No. 1 leads into the larger compartment, which also has a connection with the by-pass, of the same size and type of those already mentioned, and has a 6x7-ft. opening into the basin. The two supply connections are each controlled by gate valves. The smaller compartment has a 6x7-ft. opening connecting it with the basin and a 7-ft. steel pipe connection with the brick and masonry conduit, the opening into the basin from it being controlled by a sluice gate.

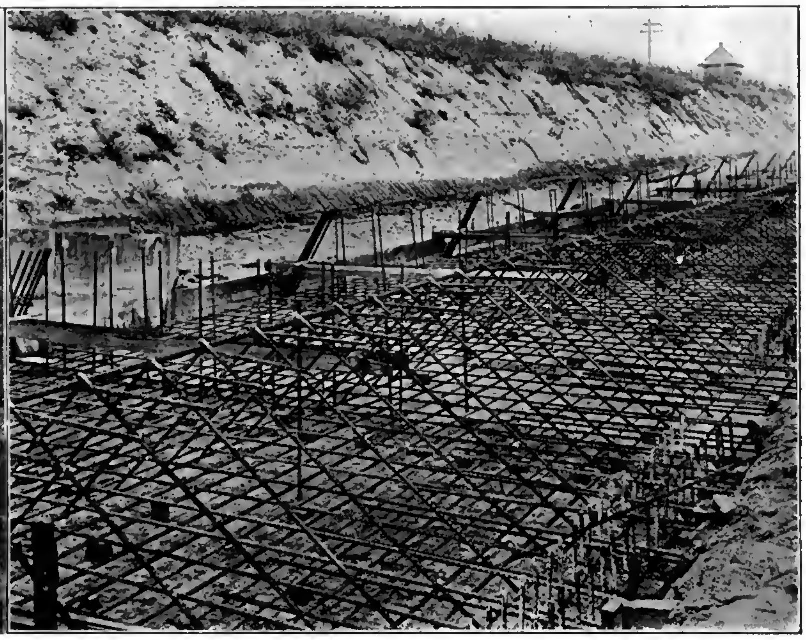
Three 30-in. cast-iron pipe lines are laid across each new basin under the floor, and at one side bottom is placed. The latter has a minimum thickness of 9 in. and is laid in 8x8-ft. blocks, the surface being troweled to a smooth finish. The blocks are separated to their full depth by ½-in. joints, which are filled with an asphalt cement filler. This filler is required to remain pliable at zero Fahr., and to have a melting point of not less than 210° Fahr. In addition to containing at least 92 per cent. pure bitumen it must be free from any coal tar products.

The footings of the reinforced concrete side walls of the basins are 25 ft. wide and 18 in. thick, the walls rising to a height of 22.5 to 24 ft. above them, depending on the elevation of the bottom of the basin at the point in question. The base of the wall proper is 2.5 ft. thick, the footing being stepped down to that width. The front face of the wall is vertical, but the rear face is battered slightly, the thickness at the top just below the coping being 18 in. The wall is designed as a buttressed retaining wall capable of resisting the forward overturning moment brought about by the fill against its rear face, as well as a backward overturning moment caused by the pressure of the water on point, 20 in. in diameter at the top and 20 ft. long. They were built by sinking two concentric steel shells together with an ordinary land pile driver having a 2,000-lb. hammer falling 5 ft.; then pulling the inner shell, which is collapsible and much the heavier, and filling the outer one with concrete. Each pile was reinforced with six ¾-in. corrugated bars. This method is controlled by the Raymond Concrete Pile Co. of Chicago, and has been described at length in this journal. The maximum load on the footing where these piles are used is about 2,800 lb. per square foot, the maximum load on the piles being 35 tons to a pile.

The details of the reinforcement of the footings, walls and buttresses are shown in one of the accompanying illustrations. Johnson corrugated bars are used in all cases where the concrete is reinforced in connection with the work on the basins, ¾-in. rods being employed chiefly in the footings, walls and buttresses. The footing is a horizontal beam 18 in. thick, which is designed to resist upward stresses, as well as the load brought on it. The walls and buttresses are thoroughly tied into the footing, and the



Concrete Mixing Plant Used on Footings of Walls.



Reinforcement Bars in Place for Wall Footings.

of the trenches in the latter. They replace the 24-in. vitrified pipe sewers which formerly served the existing basins. The trenches in the floors of the new basins are each connected with them at three places through 24-in. pipes having 24-in. non-rising steam valves placed in concrete chambers built in the trench. One of these connections is at the river side of the basins and the other two are at equal distances apart across the latter. A steel tower carrying a working platform above high-water level in the basin will be placed over each of the valve chambers not against the side wall in order that these valves may be operated from the stands when the basins are filled.

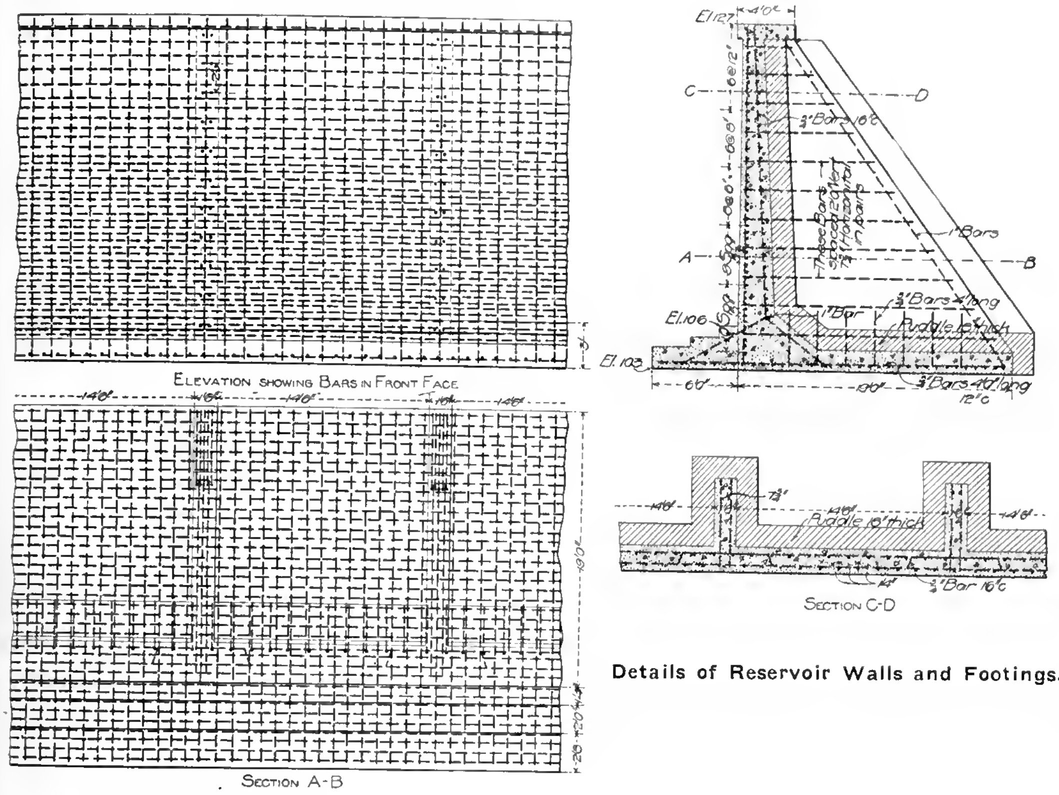
The site of the two new basins is a strip of the river bank from 725 to 825 ft. wide between the existing basins and the river. The greater part of the natural surface of this site is 2 to 5 ft. above high water. The basins are being built partially in cut and partially with embankments against the back faces of the concrete walls which form their sides. The greater part of the walls, however, is above the level of the natural surface.

The bottoms of the basins are being built almost entirely in excavation, a mixture of river silt and sand being uncovered over a large portion of their sites. A layer of puddle, having a minimum thickness of 18 in., is placed over the bottom of the excavation before the concrete its front face. The buttresses against the back face are placed 16 ft. apart on centers and are built continuously with the wall and footing, the latter extending at its full width for the full length of the wall. The walls are entirely without expansion joints, the reinforcement being designed to provide against cracks due to temperature changes. A continuous wall 1,600 ft. long is thus made on each side and one 400 ft. long at each end of the two basins. The wall on the river side has nearly all stood through three changes of seasons during the construction without having shown any cracks due to temperature.

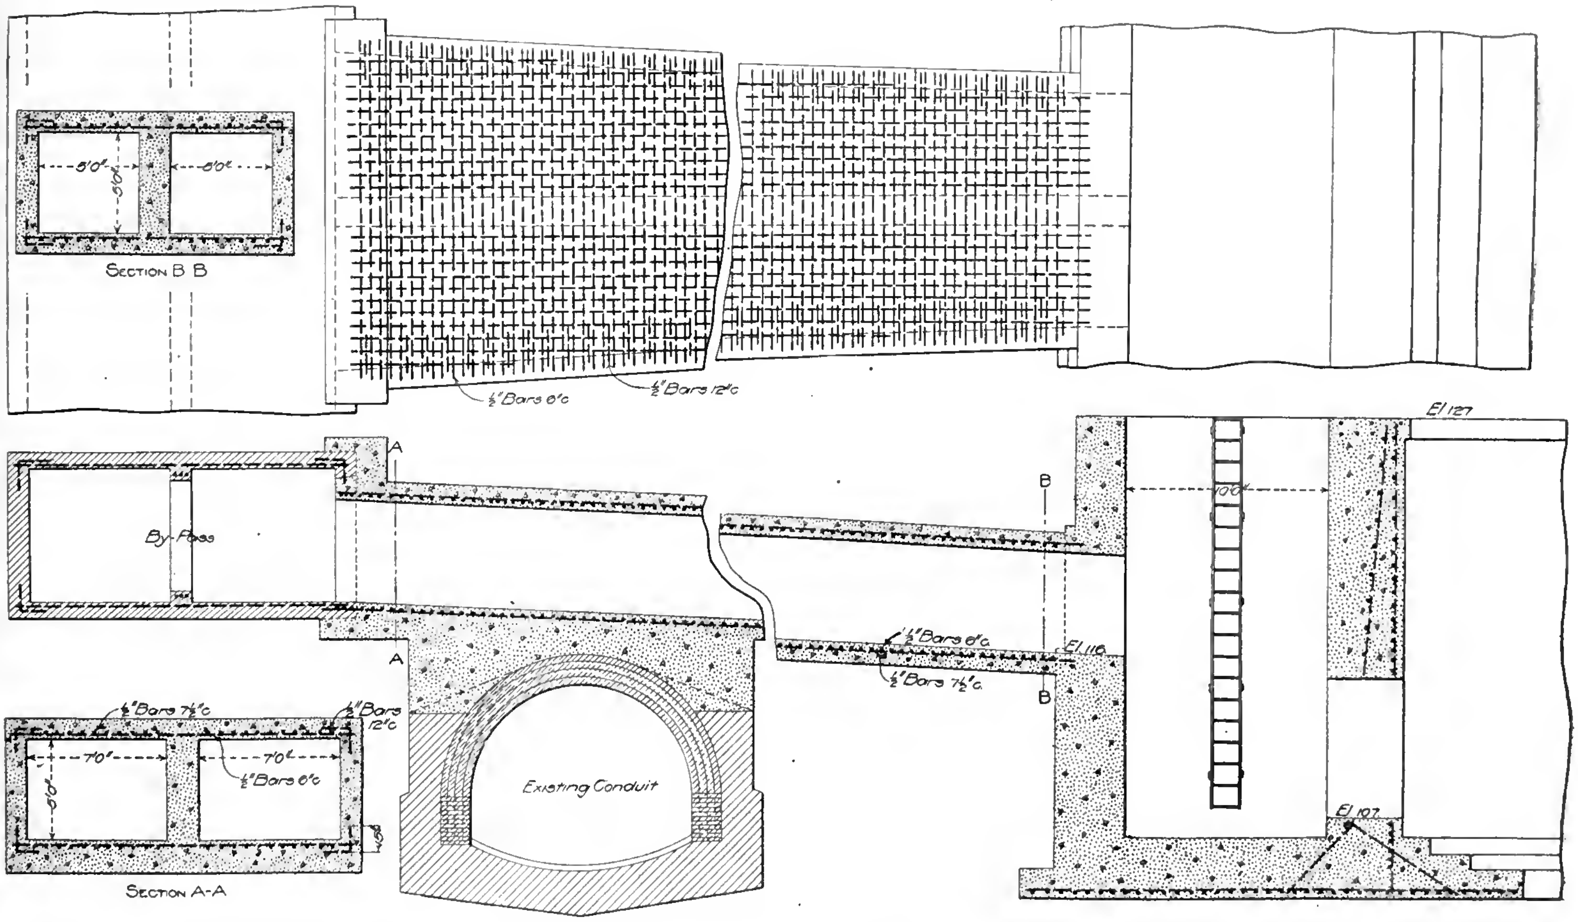
The soil of the site has sufficient sustaining capacity to carry the walls on the regular footings except at the outlets of the three sewers in each basin leading from the latter to the river. A heavy concrete wing wall is placed on both sides of these outlets and the excavation for the trench leading up to the outlets had to be carried considerably below the level of the remainder of the basin floor, with the result that extremely poor soil was encountered. In order to insure the stability of the walls on the poor soil at these outlets, a section of the wall footing about 64 ft. long is carried by seventy Raymond concrete piles at each outlet. The piles are placed in five rows of fourteen each, the rows being 5 ft. apart on centers, and the piles in the rows from 4 ft. 3 in. to 5 ft. 4 in. apart on centers. The piles are each 6 in. in diameter at the buttresses into the wall by reinforcement bars. The wall proper is designed as a continuous beam placed on edge, with the buttresses as points of support. The principal reinforcement is therefore laid horizontally and extends longitudinally near the faces of the wall. Shorter horizontal bars are also placed at the buttresses, as shown, to provide for the stresses set up at those points. Vertical bars are placed in the same plane as the horizontal bars in order to tie the wall together and to cause it to act as a uniform beam. The coping on the top of the wall is 12 in. thick and 4 ft. wide, and is reinforced sufficiently to carry its overhanging portion between the buttresses, and to prevent cracks.

Two classes of concrete are used in the construction of the basins and the various structures connected with them. One of these is specified to be made in the proportions of one part cement, three parts sand and six parts broken stone, by measurement, a barrel of cement being considered as 3 cu. ft., which actually produces a 1:2¼:4½ mixture, as proportions are ordinarily stated. The proportions of the other class, as specified, are one part cement, four parts sand and eight parts broken stone, or one part cement to nine parts of a mixture of sand and gravel, also by measurement, the barrel of cement again being considered 3 cu. ft. The 1:4:8 or 1:9 concrete is used for

lining the floors of the basins; in all other concrete construction the 1:3:6 mixture is employed. Red Ring Portland cement is used in all of the concrete, over 50,000 bbl. being required. This cement is subjected to tests approximately the same as the standard tests recommended by the American Society for Testing Materials. Clean, sharp river-channel sand, free from loam and dirt is required. Sound, clean limestone, crushed and screened, is used, the pieces ranging in size from those that would be retained on a ¼-in. screen to those which would pass a screen with 1½-in. meshes. The gravel used is dredged from the Meramec River, and is washed and screened before being delivered.



Details of Reservoir Walls and Footings.



Details of Typical Reinforced Concrete Conduit.

Construction of the Basins.—The Water Department of St. Louis operates an electric railway, 7 miles long, from the Bissells Point high-service pumping stations in the city to the low-service pumping station at the Chain of Rocks. This railroad connects with steam railroads in the city, and over it all of the supplies for the work are delivered by a steam locomotive owned by the city. The main railroad track traversed longitudinally the site of the two new basins and practically the first construction work done on the latter was to relocate this track on the river side of the site. Two side tracks from this main track were then laid the full length of the site from the upstream end of the latter, one adjacent to each longitudinal wall of the basins. The materials for the work can thus be delivered directly in cars to within 75 ft. of the point where they are to be used.

The first work that was done on the basins themselves was to excavate the trenches for the footings of the walls on the river side and the downstream end. These footings were then laid the length of the walls, which were built later, reinforcing bars and keyed recesses serving to tie the new concrete to the old, although the latter was also well cleaned before any fresh concrete was laid on it. Meanwhile, work was started on the footings for the walls on the other side and end of the basins, the footings for these walls being completed in time so the work on the walls resting on them could be carried forward without interruption when the first walls were finished.

As the top of the footings are in all cases at or below the natural ground level of the site, the concrete did not have to be elevated to them. On the other hand, since the footings contain a comparatively small amount of concrete per linear foot of wall a stationary central mixing plant from which the concrete could be delivered in cars, or by other means, to the position it was to occupy was impracticable. The requirements governing the method of constructing the wall proper, as will be described later, were also against the use of a central mixing plant. Two portable self-propelling concrete mixing and conveying outfits, built by the Drake Standard Machine Works, of Chicago, were accordingly designed for the work of the footings.

Each of these outfits consists of a standard Drake continuous mixer with its 20-h.-p. engine and boiler mounted on a four-wheel truck, which is fitted with a traction gear driven by the engine. A boom, 25 ft. long, carrying a 20-in. traveling belt conveyor is supported from the front end of this truck in such a position that the concrete is discharged on the belt directly from the mixer, and as the boom can be swung through an arc of 90 deg., concrete is delivered into the

footings from the mixer by the conveyor. The sand, gravel and cement for the concrete were delivered in barrows from storage piles and cars along the branch railroad tracks extending the length of the site, to the machines and elevated by super-hoppers into the mixer troughs. The mixing outfits were moved on 4x16-in. plank runways laid on the ground along the walls. Each of these mixing outfits could place on an average about 100 cu. yd. per 10-hr. day, with 25 men, allowing for delays, time of moving, and so forth.

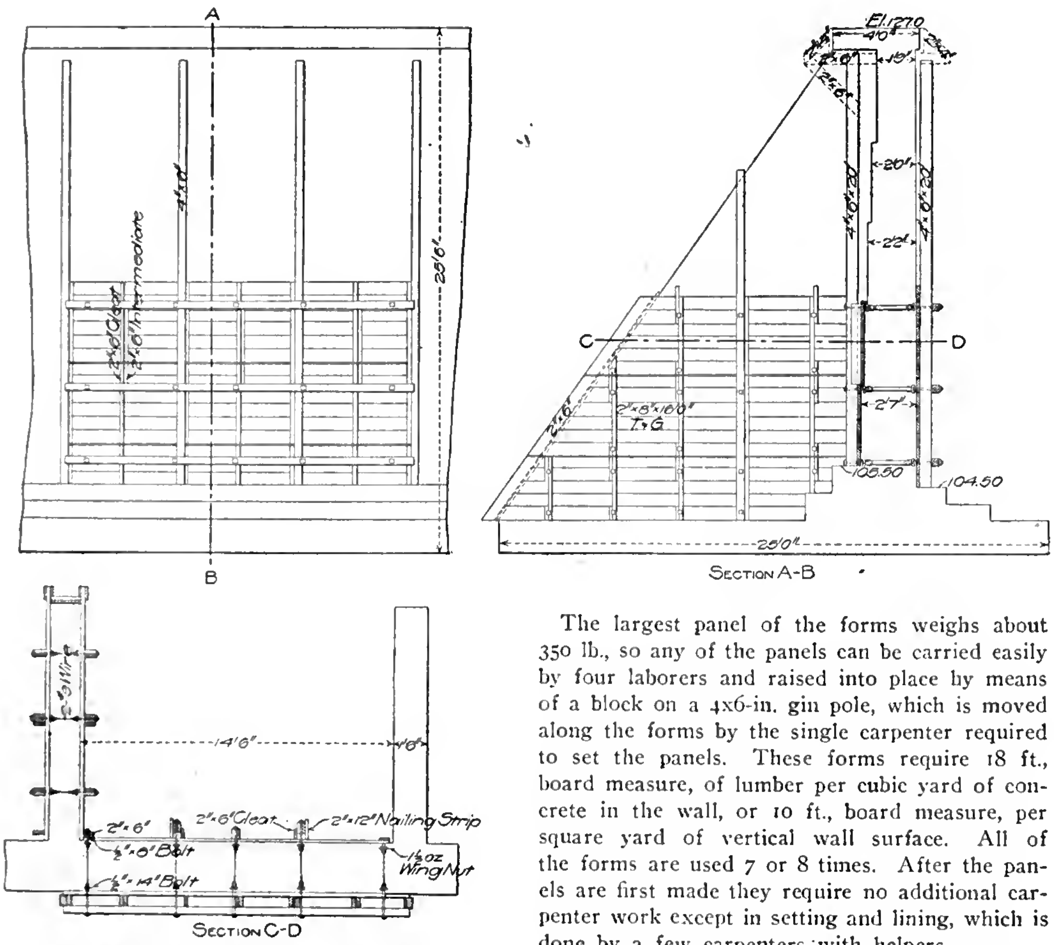
The type of the mixing outfit employed on the walls was governed entirely by the design of the walls, the manner in which they were required to be built, and the design of the forms. At the same time the design of the walls and buttress forms was controlled materially by the following considerations: The concrete was required to be placed in layers not exceeding 4 ft. in depth; provision had to be made in building the 4,920 linear feet of walls to permit the work to be stopped with keyed bulkheads, at the end of each day's work, in a form so narrow and so filled with reinforcing bars that a man could not work within it; and longitudinal reinforcing bars had to be placed after each layer of concrete had been laid.

The solid concrete wall with counterforts, forming a structure capable of resisting pressure from either face suggested the possibility of designing a hollow self-contained and self-sustaining timber wall, without bracing, for the forms. A form of this type was accordingly adopted, and is designed so it can be taken down in sections and erected again with a minimum amount of labor. In fact, in detailing the forms attention was devoted to minimizing the amount of lumber necessary by using the latter repeatedly, to the construction of sections of the forms of such size and weight that they could be placed and removed rapidly, and to simple methods of fastening and to the reduction of skilled union carpenter labor at 60 cents an hour as compared with unskilled helpers at 22½ cents per hour.

The lagging for these forms is made of 2x8-in. tongue and groove planks, faced on one side. This lagging is converted into panels, 3 ft. 2 in. to 4 ft. in height when placed vertically in position, and of different lengths, depending on the portions of the wall for which they are made. The panels on the front face of the wall are all uniformly 16 ft. long, extending from the center of one wall buttress to the center of the next; those for the back face of the wall are 14 ft. 2 in. in length extending from the forms for one buttress to those for the next; the panels of lagging for the buttresses have one beveled end and are gradually reduced in length from the bottom to the top of the buttresses to correspond with the slope on the back of the same. The planks forming each panel are cleated to 2x6-in. uprights, placed 30 in. apart on centers to prevent warping. The bottom panel of both the front and rear faces of the wall form rests on offsets in the footing of the wall. The remaining panels of the front face of the form are set on the lower panels later, but the succeeding panels of the rear face form each rest on a 2-in. offset in the back face of the wall. These offsets are spaced so their inner corners fall outside a line drawn to the batter proposed for the back face of the walls in the original design. The amount of concrete in the walls is thus increased only about 100 cu. yd. on all the walls by the change, while the saving attained in building the forms was very great. The panels of the front face of the forms are held in position by vertical 4x6-in. timbers, 20 ft. long, which are spaced four to a 16-ft. front panel. The rear face panels have two of these 4x6-in. uprights at the quarter points, their ends resting against the forms for the buttresses. The alignment of the front face forms is preserved by a horizontal 4x4-in. timber to each 4-ft. panel, these horizontal pieces being placed against and bolted to the 4x6-in. uprights.

The two faces of the forms are tied together by wires which are attached in such manner by means of bolts and wing nuts, that, as compared with the usual method of binding the wires around the uprights of the forms and cutting them when the latter are removed, only half the number of holes need be bored, the labor of wiring is diminished and wire is saved. At the same time, by turning up the bolts an even strain can be brought on all the wires holding a panel thus preventing the forms being broken out when the concrete is poured. The wires are held by ½-in. bolts, with ⅛x2¼-in. wrought-iron washers and ½-in. wing nuts. The bolts are placed through the uprights of the forms, the nuts being inside the latter. The bolts are placed in pairs, one bolt in the front face and the other in the rear, two No. 9 wires holding together the wing nuts on each pair of bolts. These wires are prepared in advance for the various lengths required at different heights of the wall. They have loops on their ends to fit over the wing nuts, these loops being made by holding the loose end of the wire in a vise and twisting the other end with a small rod so as to crimp both strands at the loop and prevent slipping. As shown in the accompanying sketch of the forms, intermediate 2x6-in. cleats are slipped along the cleats on the panels of the front face of the forms to reach the 4x4-in. longitudinal below the level to which the concrete has already been carried. These intermediate cleats reduce the number of wires and permit the upper wires of each panel to be raised so they can be reached from the top of the form, which method is required by the narrowness of the forms. When the forms are to be removed the bolts are screwed out of the wing nuts and the small holes resulting in the face of the concrete are filled with mortar. The walls are not given a mortar face, the only finishing done being to spade the concrete against the forms, but a good smooth surface is secured in this manner.

The walls and buttresses are carried up about 4 ft. at a time over a section 20 to 30 panels of the forms in length, depending on the working conditions. The 4x6-in. uprights of the forms are first set true to line and then the lowest panels of both faces of the forms are placed over the length of the wall in which concrete is to be laid in a continuous section. After the concrete has been filled in to the top of this lower panel for this length of wall, the next panels of both faces are placed over this length and a second longitudinal layer of the wall is built. The forms are thus erected and the walls built continuously in horizontal sections. These sections are selected of such length that work on the forms can be in progress on one end of this horizontal section while concrete is being placed at the other end of the section without interference.



Forms for Building Reservoir Walls.

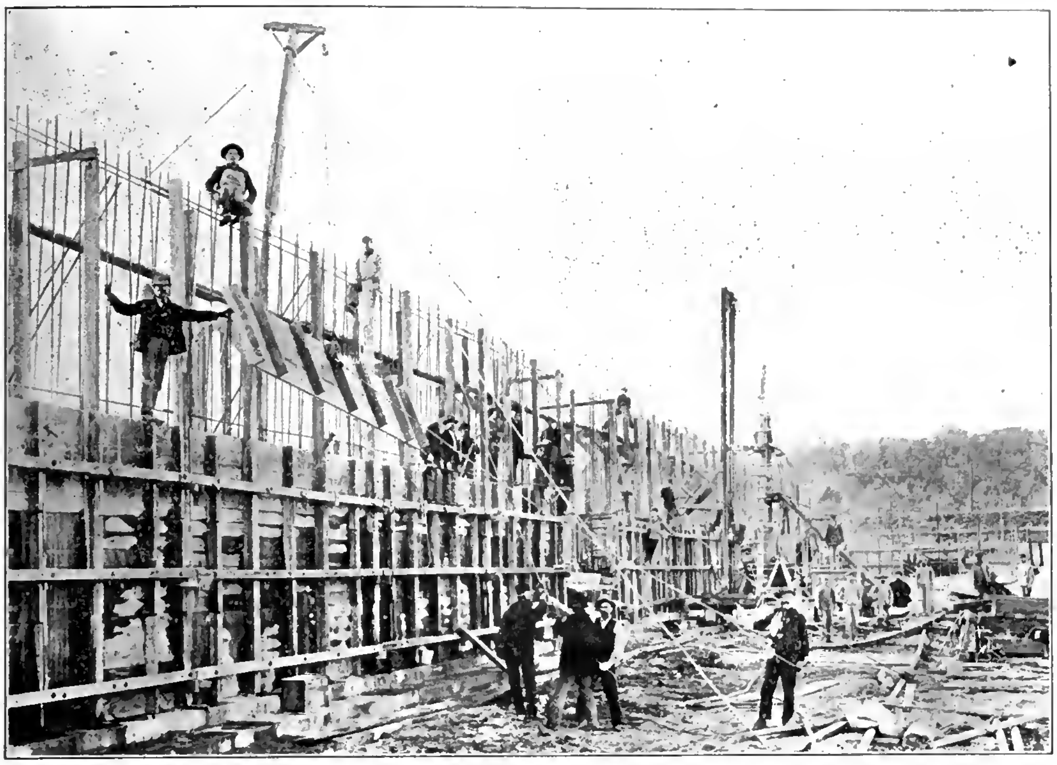
The largest panel of the forms weighs about 350 lb., so any of the panels can be carried easily by four laborers and raised into place by means of a block on a 4x6-in. gin pole, which is moved along the forms by the single carpenter required to set the panels. These forms require 18 ft., board measure, of lumber per cubic yard of concrete in the wall, or 10 ft., board measure, per square yard of vertical wall surface. All of the forms are used 7 or 8 times. After the panels are first made they require no additional carpenter work except in setting and lining, which is done by a few carpenters with helpers.

A portable concrete mixing and elevating outfit entirely different from those employed in building the footings is used in constructing the walls. This outfit consists of a 11 cu. ft. improved Chicago cubical mixer mounted, with a 20-h.p. electric motor which drives it on a platform carried by a truck having four flat-rim castor wheels running along planks laid on the bottom of the basin. This mixer is equipped with an automatic charging hopper, which is loaded, about 2 ft. above the level of the bottom of the basin, from wheelbarrows and holds one batch of materials for the mixer. The concrete is discharged from the mixer into a specially-arranged automatically-dumped hoisting bucket operating in a pair of vertical leads at the front of the platform on which the outfit is mounted. A chute, also operating in the leads carrying the hoisting bucket is set at the height at which concrete work is in progress, the concrete being dumped from the hoisting bucket through this chute into the forms. The machine is moved along the wall by a rope in a block and fall attached to an anchor at one end, and at the other to a winch head on the hoisting drum driven by the mixer motor.

As this outfit can be moved readily, and as

concrete can be placed by it at any height of the wall, it is particularly adapted to building the wall in the horizontal sections as required. Under these conditions an outfit can place on an average 80 cu. yd. of concrete in the wall and buttresses in a 10-hr. day.

The 230,000 cu. yd. of earth required to be excavated from the bottom of the basins was handled with New Era grading machines, drawn by 26-h.-p. traction engines, or by 12 mules, each, when the ground was soft. These graders loaded the excavated materials into three-horse contractors' dump wagons in which it was hauled through openings left in the walls and filled in behind the latter on the layer of puddle which had already been placed against the wall.

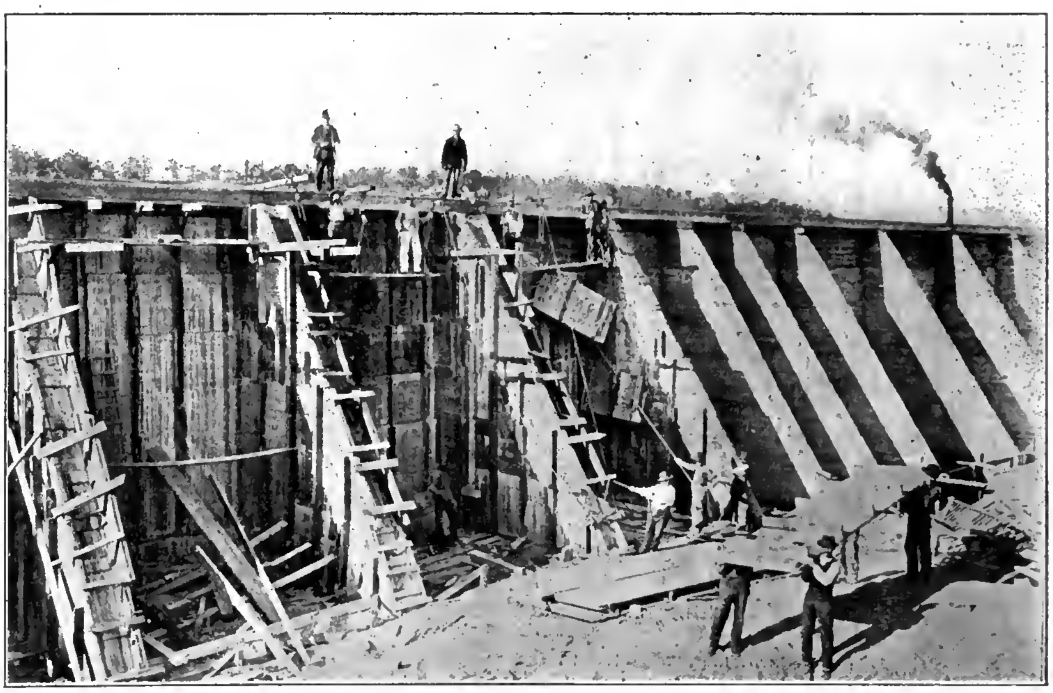


Concrete Mixing Outfit and Forms for Basin Walls.

Some puddle has been placed and the concrete lining laid over a portion of the bottom of the basins. The same concrete mixing outfits used in building the footings for the walls are being used in placing the concrete bottom lining. The bottom is laid in blocks 8x8 ft. in plan, and with ½-in. joints between them, as required. These blocks are placed continuously, ½x9-in. by 8-ft. iron plates forming the joints. These plates are greased with paraffin and tallow to aid in pulling them, the pulling being done with a light lever jack at each end.

The construction of the basins, according to the plans, requires approximately 50,000 cu. yd. of puddle under the concrete lining of the bottom and as backing for the walls. This puddle is made from a very excellent deposit of yellow clay excavated from the top of a high bluff back of the low-service pumping station, and about half a mile from the transverse dividing wall of the basins.

A very complete plant for excavating, mixing and delivering the puddle has been installed. A New Era elevating grading machine, drawn by a 26-h.-p. traction engine, is used in excavating the clay and loading it into three-horse bottom-dump contractors' wagons. The clay is hauled in these wagons to pug mills at the edge of the bluff. Three of these mills, 8 ft. long, and of the Freeze & Co. type are used as dry granulators into which the clay is dropped from the wagons through three traps in a platform over the mills. The granulators each feed the clay into one of the pug mills proper, which are 12 ft. long, where water is added in a fine spray. The wet mills discharge at the ends into 3-yd. dump cars on a 36-in. gauge track. This track has two branches just below the pug mills, which branches drop down the side of the bluff on a grade varying from 6 to 33 per cent. for a distance of 1,000 ft., part of this grade being on a trestle over a highway. The dump cars are operated on the incline in trains of three by a cable railway, the descending loaded cars assisting in pulling the empty ones to the top of the incline. The tracks at the bottom of the incline connect with tracks leading to the basins, the cars being handled in trains of 6 to 9 over 2½ per cent. grades by 9x14-in. locomotives running on 30-lb. rails.



Removing Forms from the Rear Face of the Basin Walls.

The cars in which the puddle is delivered are designed specially to handle this material. They are side-dumping and tilt to an angle of 55 deg. The bottom of each car extends out 1 ft. on each side farther than is usual in such cars, in order to cause the puddle to slide beyond the ends of the 6-ft. ties in the tracks. The bottoms of the cars are lined with No. 12 sheet steel to prevent the puddle from sticking. The cars were furnished by the Western Wheel Scraper Co., of Aurora, Ill., and have given satisfactory service in handling the wet, sticky puddle used on the work.

The puddle back of the basin walls is dumped into place from cars operated on a narrow-gauge track laid on top of the walls. These cars are hauled out on top of the walls in trains by the locomotive and dumped with no more difficulty than is experienced in dumping ordinary material in the same manner from cars of the usual type. The puddle for the bottom of the basins is hauled into the latter, on the narrow-gauge tracks, in the cars in which it is delivered and is dumped directly in place from these cars.

The construction of the two new basins and the improvements directly connected with them are about 60 per cent., completed, and it is believed they can be finished and placed in service by the end of 1907. The principal quantities of materials required in their construction are as follows: 230,000 cu. yd. of excavation; 49,700 cu. yd. of puddle; 40,150 cu. yd. of concrete; 17,000 ft. of ½-in., 1,103,000 ft. of ¾-in. and 35,000 ft. of 1-in. Johnson corrugated reinforcing bars; 4,100 ft. of permanent standard-gauge railroad track; and 3,050 ft. of sewers.

Mr. Ben C. Adkins, water commissioner, of St. Louis, has general supervision of the improvements which are being made by the water department. Mr. Edward E. Wall, assistant water commissioner, has charge of the engineering work for the department. Mr. Arthur I. Jacobs is engineer of the supply and purifying division of the water department in which division the improvements described are being made. The basins are being built by Messrs. Fruin & Colnon, general contractors of St. Louis, for whom Mr. A. P. Greensfelder is superintendent in charge of field operations at the Chain of Rocks.

Rail Corrugations were discussed at considerable length by Mr. Joseph A. Panton, in a paper before the Institution of Electrical Engineers, in which these corrugations are attributed to lateral play in weak trucks, the weakness being intensified by unsymmetrically driven axles. In the discussion of the paper, Mr. H. M. Sayers suggested that a considerable part of the trouble might be due to slipping of wheels on curves or when braked.

A New Impact Test.

A paper read before the American Society for Testing Materials by L. W. Page, director of the Office of Public Roads, Department of Agriculture.

The essential parts of this impact machine, like all others, are a hammer and an anvil. The nature of the work for which it is designed, however, has made it necessary to introduce a number of devices not before employed in impact tests.

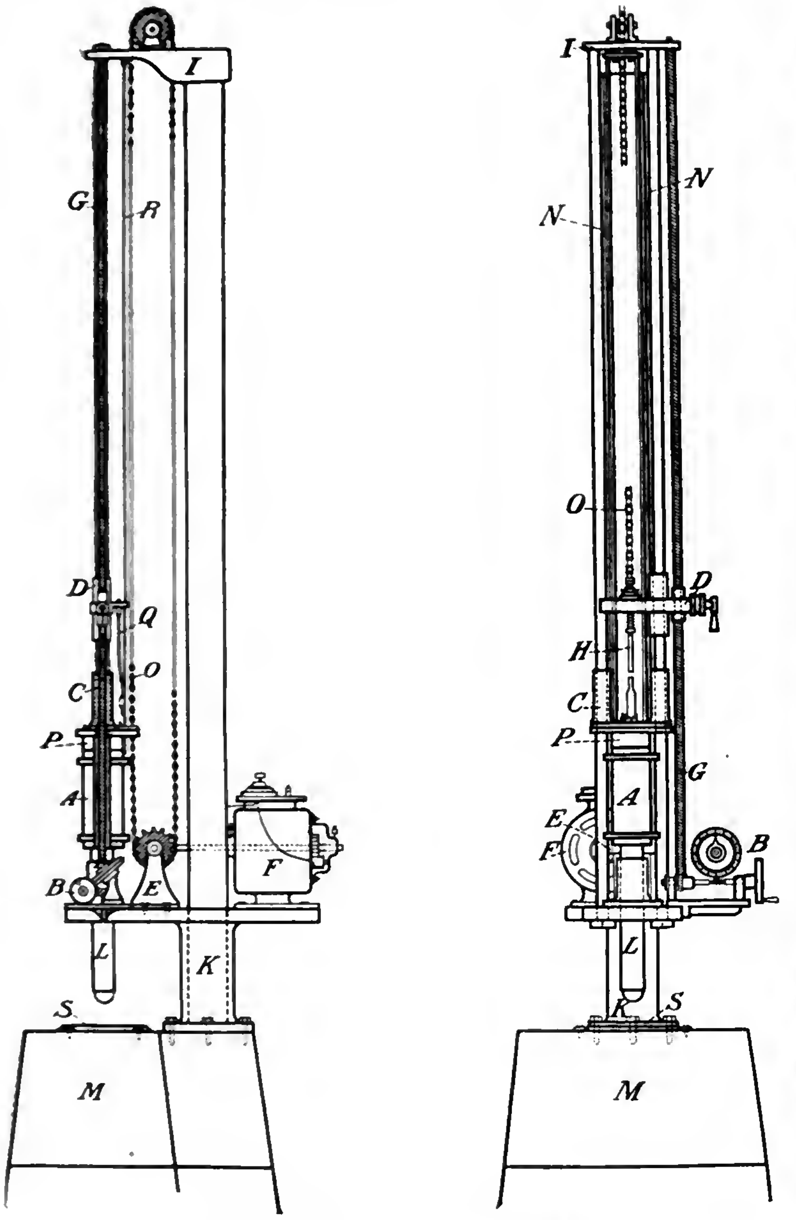
The main object of the test is to determine the relative toughness of road-building rocks. In the consideration of road materials toughness is understood to mean the power possessed by a material to resist fracture under impact. As the surface of a road is continually subjected to the pounding of traffic, it can be seen that toughness is an important property from the standpoint of the road builder. From the laboratory standpoint the problem is not altogether a simple one, and considerable difficulty has been found in designing a suitable test for measuring the degree to which a rock possesses this property. With homogeneous, structureless, brittle materials, resistance to impact may be due to a relatively low modulus of elasticity combined with high elastic limit. Provided a blow is delivered on such a material by a flat striking head with small local damage, toughness will be almost wholly due to elasticity. In this case there will be a critical energy of blow below which the specimen under test will not be broken by an indefinite number of blows, and in excess of which it will be broken by a single blow. The toughness of a road material in this instance will vary directly as the square of the elastic limit, which equals the ultimate strength, and inversely as the modulus of elasticity. In testing such materials under impact it is necessary to apply a number of blows of successively increasing energy and note the blow causing failure. The machine which I am about to describe involves this principle, and is the result of about fourteen years' work on the subject.

Instead of the hammer falling directly on the test piece it strikes an intervening plunger and the energy of the blow is conveyed through this plunger to the test piece. As comparative values are sought rather than physical constants, the end of the plunger bearing on the test piece is spherical in shape, thus rendering the energy of the blow splitting in its effect. At present we have in the laboratory of the office of public roads two of these machines, one having a 2-kg. hammer and a 50-kg. anvil, photographs of which are given here. This machine is used for making routine tests on the toughness of road-building rocks, and has a few special devices for this work. The other machine has a 10-kg. hammer and a 500-kg. anvil, and is used for larger tests, especially on paving blocks. A front and side elevation of this machine are also given. In describing this test I will confine my remarks entirely to the smaller machine, as it has all the essential parts of the other and a few improvements.

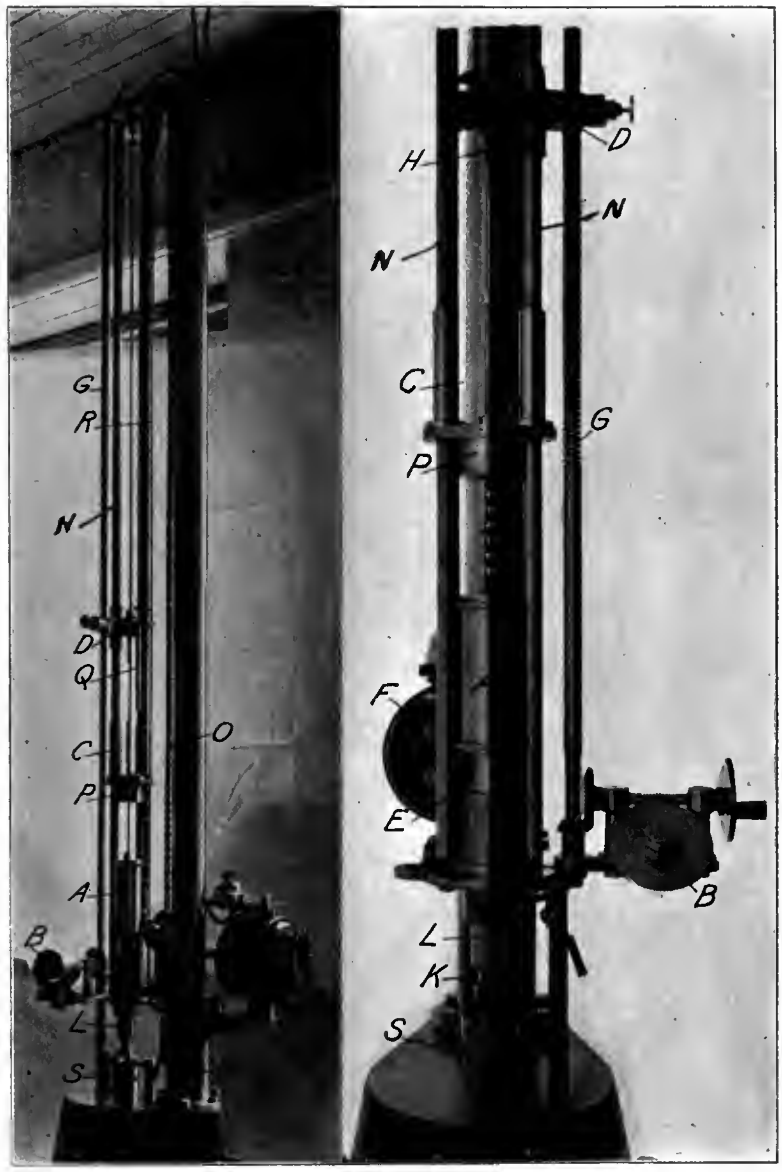
The test for toughness is made on 25x25 millimeter rock cylinders, which are cut with a core drill. It can be seen that the blow as delivered through a spherical end plunger approximates as nearly as practicable the blows of traffic; besides this, it has the further advantage of not requiring great exactness in getting the two bearing surfaces of the test piece parallel, as the entire load is applied at one point on the upper surface. The test piece is adjusted so that the center of its upper surface is tangent to the spherical end of the plunger, and the plunger is pressed firmly upon the test piece by a spring. The test piece is held on the anvil of the machine by a device which prevents its rebounding when a blow is struck by the hammer, and which keeps the test piece centered.

The hammer, which weighs 2 kg., is raised by a sprocket chain and released automatically by means of an electromagnet. The test consists of a 1-cm. fall of the hammer for the first blow, and an increased fall of 1 cm. for each succeeding blow until failure of the test piece occurs. The number of blows required to destroy the test piece is used to represent the toughness of a sample. The variation in results on the same material is very low; only in rare instances does a variation of more than one blow occur.

The machine consists of a 2-kg. hammer, *A*, which is guided by two vertical rods, *N*. The upper end of the hammer has a small cone set in it, which fits snugly into a concentric electromagnet, *P*, the latter being attached to the lower side of a crosshead, *C*, which slides freely on the guide rods, *N*. This crosshead is provided with a slot on its rear side through which a sprocket chain, *O*, passes. This sprocket chain is supported on two sprocket wheels which are attached to castings at the top, *I*, and near the base, *K*,



Large Machine for Impact Tests.



Small Machine for Impact Tests.

of the machine, which project sufficiently to support the guide rods, *N*, and other attachments. The lower sprocket wheel is directly connected by a worm gear to an electric motor, *F*, placed at the rear end of the lower casting, *K*. The sprocket chain is provided with two small lugs, which, when it is being driven by the motor, engage a spring bolt attachment, which projects inward on either side of the slot on the crosshead, *C*. This raises the crosshead until tripped by a rod, *O*, projecting downward from an upper crosshead, *D*. When this takes place the crosshead, *C*, which holds the electro-magnet falls until it comes in contact with the hammer, *A*. The electro-magnet, *P*, is supplied with current from the same circuit running the motor. The current is conveyed through two small conducting rods running parallel to the guide rods, both being insulated from the rest of the machine. The current passes from one of these conductor rods through a small carbon brush to a make and break attachment, *H*, on the upper crosshead, *D*, and thence down one of the guide rods through the electro-magnet back to the other conductor rod.

When the crosshead, *C*, is raised by the lugs on the sprocket chain and the current turned on the magnet, the hammer is lifted until the crosshead, C, comes in contact with the make and break, *H*, on the crosshead, *D*, and thus releases the hammer, which falls, striking a plunger, *L*. This plunger is made of armor-piercing steel which has the maximum temper at its lower end, which is spherical in shape. The test piece rests on a counter anvil, S, of hard steel, the plunger resting on its upper surface, which is tangent to it at its center point.

The upper crosshead, *D*, is raised through any desired height by means of the long revolving screw, *G*, which is geared at its lower end to a dial, *B*, on which the height of the make and break attachment, and, therefore, the height of the hammer drop may be read direct. By means of the revolving dial and screw the height of the crosshead may be adjusted by very close approximation to within 1 millimeter.

In order to prevent the crosshead, *C*, which holds the electro-magnet from striking too hard a blow on the hammer when falling a dash-pot was first used, but we have found that a few drops of cylinder oil on the lower end of the guide rods completely prevents this difficulty.

A point of interest in connection with this test is the fact that many of the test pieces are split into three pieces. Just why this takes place I am unable to explain.

The highest result yet obtained was on a sample of diabase from Pennsylvania. One test piece of this sample broke at a drop of 54 cm. Three months later another operator cut and tested another test piece, which broke at 58 cm. drop. The next highest result was on a fine grained sandstone from Virginia. One test piece broke at 49 cm. and the other at 50 cm. drop. I give these results only to show the small variation in results on the same materials. In rocks of low toughness there is generally no variation.

Several series of cement briquettes, of the same size as the rock cylinders, have been broken in this machine, with practically no variation in the results. It was necessary in these tests to use a ½-kg. hammer to give high numerical values to the results. This test has also been found most useful in grading asphalt surface mixtures. Some interesting penetration tests have also been made on wood paving blocks.

In concluding, I may state that a very interesting series of tests are at present being made to determine the detonating points of the high explosives. It has already been ascertained that more energy of blow is required to detonate nitroglycerine than a number of the other high explosives. It is very easy with this machine to determine the detonating point of an explosive at a given temperature within 1 cm. fall of the hammer. Nitroglycerine, for instance, detonates at 30 cm. drop at 29°, 31 cm. at 28°, 34 cm. at 24°, 35 cm. at 23°, 67 cm. at 11°, and 95 cm. at 8°.

Foundations of the American Bank Note Building, New York.

The new 66 x 44-ft. office building for the American Bank Note Co., New York City, will be a fireproof steel cage structure at the corner of Broad and Beaver Sts. Above the street level the floors are entirely unobstructed by columns and, together with the roof and walls, are carried on 16 steel wall columns. Eight of these columns in two opposite sides of the building have separate rectangular piers from 6½ to 7 ft. square. On a third side of the building the four columns are carried in two pairs, each on long, narrow piers, and on the fourth side, where the columns are located close to the wall of the adjacent building, they are supported on separate still smaller and narrower piers close to the footings of the old building. All of the piers are of concrete carried down by pneumatic caisson process through quicksand and some clay to a solid stratum of hardpan from 30 to 37 ft. below the curb. The column loads are distributed on the tops of all of the larger caissons by double grillages consisting of a lower tier of I-beams and an upper tier of pairs of channels riveted together back to back to give larger web sections than can be secured in I-beams of the same depth.

The self-supporting brick wall of an adjacent four-story building on one side of the lot was underpinned by seven 12-in. wrought-iron sectional pipes driven to hardpan by the Breuchaud method before the excavation was commenced. The pipes were received in 6-ft. lengths and were sunk in the usual manner with a hydraulic jet and a 50-ton hydraulic jack, reacting against the wall of the building. They were forced down to refusal against the hardpan, the interior was thoroughly washed and pumped out and filled with concrete, and the work was completed without entering the interior of the old building or causing any settlement or cracks in its wall.

The site was excavated by hand to a depth of about 11 ft. below the curb and the spoil was removed at first in wagons driven into the excavation and afterwards by derricks and buckets. The sides were retained by 2-in. tongue-and-groove sheet-piling braced by inclined struts as the excavation was carried down and afterwards left permanently in position and faced up on the inside with a concrete wall reinforced by steel rods ⅞ in. in diameter. Ground water was encountered at a depth of about 9 ft. below the curb and was drained by syphons to one of the caissons, which was left unfilled until the last to act as a sump and was emptied by a 4-in. centrifugal pump driven by an electric motor.

One one side of the lot a working platform at street level was built on falsework bents and on it was mounted a stiff-leg derrick with a 50-ft. boom of 15 tons capacity which commanded all portions of the lot and unloaded the caissons of a maximum weight of 7 tons from wagons in the street and delivered and set them in their required positions in the excavation. The derrick was operated by a 7 x 10-in. double drum Lidgerwood hoisting engine with independent boiler and sufficed to handle all materials involved in the construction of the substructure. Underneath the derrick platform were set two 10¼-in. class E Ingersoll-Sergeant air compressors and their receivers, and the remainder of the space there was utilized for storage and workshops.

The 8 regular piers were sunk with standard rectangular wooden caissons very simply constructed with 3-in. vertical sheeting with caulked joints, bolted to inside rectangular horizontal frames made of 4 x 12-in. planks spaced from 16 to 34 in. apart vertically in the clear. A deck of two crossed courses of 3-in. planks, 6 ft. in the clear above the cutting edge, is supported on the upper edge of one of the interior frames and another frame was bolted in contact with its upper surface. A steel airshaft 3 ft. in diameter was fitted to the deck and provided with the usual air-locks and connections. The lower horizontal frame was made of 6 x 10-in. timbers and being placed 6 in. in the clear above the cutting edge served to reinforce the latter which was formed simply by bevelling the lower ends of the wall sheeting which were not shod or otherwise strengthened. The vertical sheeting was made in 18-ft. lengths continuous over the working chamber and the cofferdam.

When this did not suffice, the cofferdam was extended by a separate 8-ft. section constructed in the same manner and connected to it by ¾-in. vertical bolts through the top frame of the lower section and the lower frame of the upper section which thus acted as flanges. The sheeting in the lower section extended about an inch above the upper edge of the upper cross frame and thus formed a socket to receive the lower edge of the lower frame in the upper section, the sheeting for it being cut short to correspond and bringing the joint over the solid timber of the lower cross frame in the upper section. Two of the caissons about 19 ft. long and 4 ft. wide were made in substantially the same manner except that the long side frames were braced by two sets of equidistant 3 x 10-in. horizontal transverse struts. The smallest caissons, 3 ft. 8-in. x 8 ft. 4 in. outside, were constructed substantially like the regular caissons except that in order to increase the clearance for the airshaft made with 5-ft. sections of 3-ft. cast-iron cylinders with inside flanges, sections about 2 ft. long were cut out of the center of each of the long sides of the inner horizontal frames and the remaining end pieces were spliced together with single 8 x ⅝-in. plates 46 in. long, thus increasing the effective width of the caisson nearly 6 in. The caissons were filled with 1:3:5 concrete made with Atlas Portland cement hand-mixed and completed in 25 days with an average force of about 90 men.

Kirby, Petit & Green were the architects. Mr. Chas. H. Nichols, consulting engineer, and the Hedden Construction Co. general contractor. The Bryson-Gamble Co., was the contractor for the sub-structure work above described.

THE PRESERVATION OF TIES by crude oil has been tried successfully by the Atchison, Topeka & Santa Fe Ry. In the fall of 1901 the company treated a few thoroughly seasoned New Mexico, Arizona and Texas pine ties with California crude oil containing about 75 per cent. asphaltum base, the remainder being light oils, the greater part of which vaporized when heated. The oil was heated to 180° Fahr. and forced into the wood under a pressure of 150 lb. per square inch, the ties taking up from 4 to 8 gal. each. They were placed in an experimental track on the Gulf, Colorado & Santa Fe Ry., where an untreated loblolly tie will not last over two years, and an untreated long leaf tie not over three years. The ties were examined by the Santa Fe officers after they had been in service four years and nine months and were found perfectly sound. Those that were sawed through or bored were found to be in excellent condition, and the spikes were not only as good as the day they were driven, but seemed to hold better than in untreated ties. The company has therefore decided to use oil for ties, and to continue creosoting for bridge timbers and piling.

Aqueduct Bridges on the Illinois and Mississippi Canal.—II.

By Fred W. Henens, M. Am. Soc. C. E., Junior U. S. Engineer.

Methods of Construction.—Aqueducts 1 and 9 were built entirely by hired labor, as were also the piers and abutments of Aqueducts 2 and 3, and the trunks, including the reinforced concrete linings, of all of the aqueducts.

The foundations of Aqueducts 2 and 3 were constructed by Cogan & Pound, contractors, and the foundations of Aqueducts 4 to 7, inclusive, were put under contract twice, it being finally necessary for the Government to complete the work by hired labor. The foundation of Aqueduct 8 and the piers and abutments of Aqueducts 4 to 8, inclusive, were constructed by Page & Shnable, contractors, of Chicago. The latter contract was completed during the season of 1906.

Unless otherwise stated, the methods of construction described were those used at Aqueduct 9. The methods used at Aqueduct 4 are typical of the work done on the Western Section and will be referred to frequently. Junior Engineers H. E. Reeves and A. O. Rowse were the resident engineers in charge of construction of Aqueducts 4 and 9, respectively.

Aqueduct 9 is located about 11 miles from Tampico, Ill., its nearest railroad station, and 24 miles from Rock Falls, Ill. A narrow-gauge railroad was previously constructed by the Government for riprapping the banks of the canal, and was later extended to the Aqueduct. All of the materials were received at Rock Falls, and transported to the aqueduct with a construction train. There is a siding from the Chicago, Burlington & Quincy Ry. on the canal right-of-way at Rock Falls.

Aqueduct 4 is located about 2 miles north and east of Mineral, Ill., which is a station of the Rock Island Ry.

The canal runs almost due south at Aqueduct 9, making an angle with Green River, such that during construction, an abutment and the upper end of one pier were on the south side of the river, two piers were entirely in the river, and an abutment and the lower end of one pier were on the north side of the river.

A cofferdam about 110 ft. long was built parallel to and about half way between the first and second piers, from the north, with a wing on the upstream side that returned to the river bank. In the same way a dam was built between the third and fourth piers with a wing on the downstream side that returned to the south bank, thus leaving a channel about 65 ft. wide for the passage of the river.

The coffer dams consisted of two lines of sheeting, 2 x 12-in. by 8 ft., placed 6 ft. apart, filled with a sandy loam, the only available material.

Each line of sheeting was supported by two 6 x 8-in. by 16 ft. horizontal waling timbers, placed about 4 ft. apart. Vertical 6 x 8-in. posts were placed outside at the ends and center of the wales, through which the coffer-dam was tied together at top and bottom with $\frac{5}{8}$-in. rods, 8 ft. 6 in. long.

After all of the work inside of the two enclosures, including the excavation for the channels, had been finished, the wings of the dams were removed and the ends of the main or longitudinal portions were connected with cross-dams, thus enclosing the second and third piers and forcing the water through the two side channels.

Twice it was necessary to flood the pit on account of high water. This was accomplished through a sluice or trough about a foot square, with a gate, constructed in the cofferdam about 2 ft. above the ordinary water line. The gate was kept closed until it was seen that the dam was in danger, when it was opened, allowing the pit to flood.

Owing to the sandy bottom of the river, the cofferdams were not entirely satisfactory. Twice the water went under the sheeting, doing no particular damage except to delay the work for a few days. On later work a pile coffer-dam was used.

Such a coffer-dam was constructed at Aqueduct 4 by driving a row of round piles 7 ft. apart, through the center of the creek between the second and third piers, to which was bolted 6 x 8-in. waling timbers.

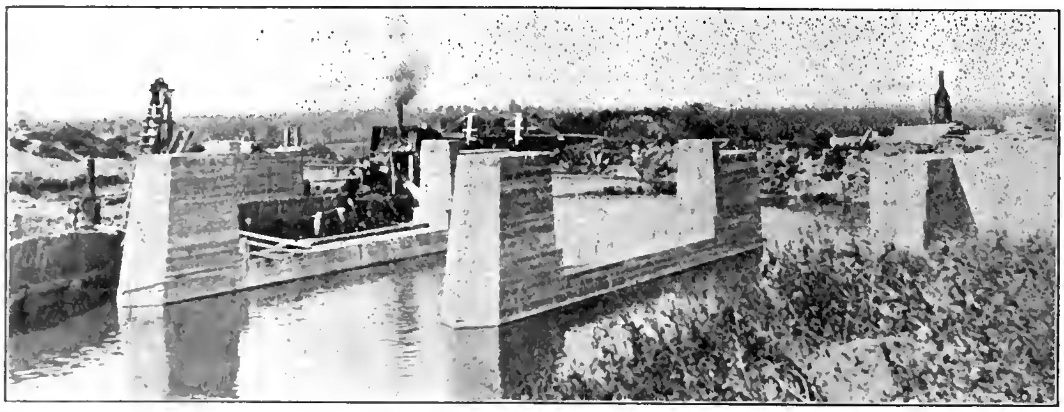
Triple-lap sheet piles made of 2 x 12-in. by 16-ft. lumber were driven about 8 or 9 ft. and spiked to the wales. At each end of the pit a similar dam was constructed across the channel, sluiceways being left on each side of the center coffer, which could be closed with planks when it was desired.

The materials excavated at Aqueduct 9 were sand and sandy peat with some clay. The work was done with teams and scrapers, except the sand in the middle section, which was excavated with a 6-in. sand pump. The materials were wasted between and back of the canal embankments, which had been previously built, the bottom grade of the canal being several feet above the natural surface of the ground.

At each aqueduct, channels were excavated across the canal right-of-way, being the full width between abutments except where it joined the original channel.

The first contract for excavation and building foundations for Aqueducts 4 to 7 inclusive on the Western Section, was dated March 20, 1902. The only work done at Aqueduct 4 under this contract, was the excavation of about 11,000 cu. yd. of materials.

The work was relet on Oct. 12, 1903, but no work was executed at Aqueduct 4 under this contract. When the United States began work by hired labor, in the spring of 1905, to complete these contracts, the pit was found to have from 7 to 9 ft., about 7,000 cu. yd., of silt deposited in it. This deposit stood at a slope of about 1 to 4, and was gummy and sticky, being exceedingly hard to dump from the cars.



Right-Hand End of Aqueduct No. 4.

Left-Hand End of Aqueduct No. 4.

The hired labor work was done with a $\frac{3}{4}$-yd. Page scraper bucket operated by a stiff-legged derrick mounted on a frame with a 12-h.-p. hoisting engine and vertical boiler, which furnished the power. The dredge was moved about on rollers.

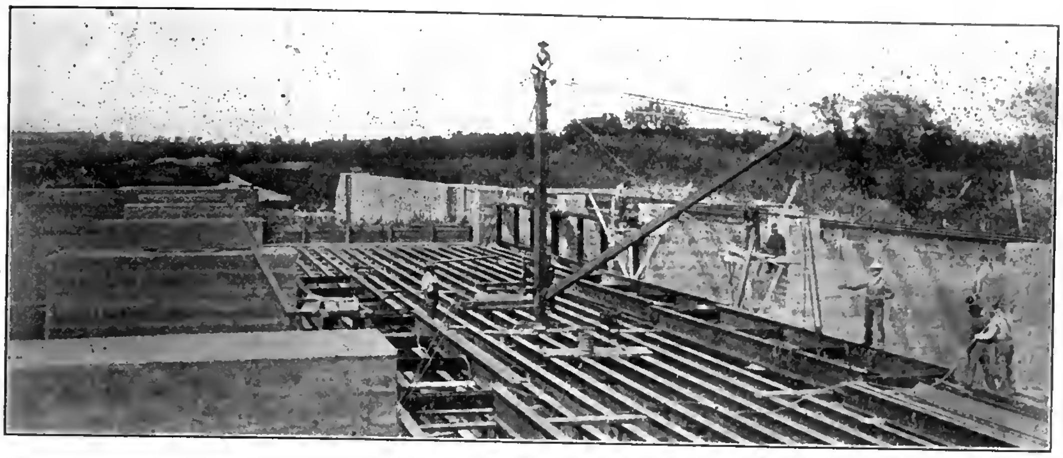
The excavated materials were dumped into $1\frac{1}{4}$-yd. dump cars, which were pulled to the top of the canal bank with a cable by a 15-h.-p. hoisting engine. The cars were operated in trains of three cars each. At the top of the embankment, the train was taken by a team and drawn down the canal where the materials were dumped back of the canal bank. A force consisting of 2 enginemen, 1 fireman, 1 team, 6 laborers, and a foreman, operated the plant. The output was about 15 cu. yd. per hour.

Both round and sheet piles were driven with a driver having a 2,000-lb. hammer, aided where necessary by a water jet. The round piles were about 16 ft. long and 12 to 16 in. in diameter at the large end, the average driven length at Aqueduct 4 being between 14 and 15 ft. A sheet pile was made of three pieces of $1\frac{1}{2}$-in. white oak 8 ft. long, fastened at the top and bottom with three 5 x $\frac{1}{4}$-in. boat spikes, making a tongue and groove $2\frac{1}{2}$-in. deep. The sheeting was driven about 7 ft. below the bottom of the foundation, and was imbedded about 6 in. in it. The round piles were cut off at grade, the longitudinal timbers placed and the spaces between timbers filled with concrete. The cross timbers were then laid and concrete filled between them.

At Aqueduct 4, the concrete was made with Utica natural cement, the proportions being 1 part cement, 2 of Mississippi River sand and 4 of crushed limestone from quarries at Moline, Ill. The concrete was mixed with a one-half yard Smith mixer, and dumped into the pit,

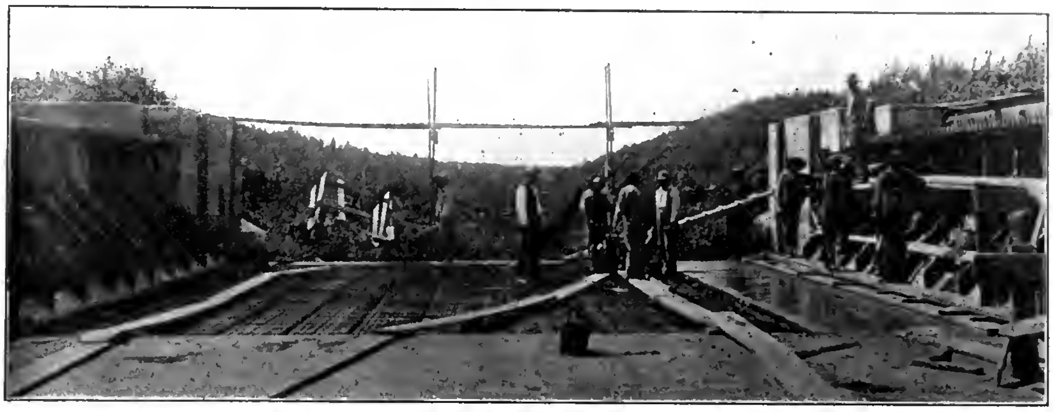
where it was distributed in the foundations with wheelbarrows. The materials were placed in the mixer with wheelbarrows.

At Aqueduct 9, Portland cement was used almost exclusively, most of it being the Marquette brand. The sand contained about 20 per cent. of pebbles and was obtained from excavations from the canal prism. The crushed rock was obtained from the Government crushing plant at Rock Falls, being screened to remove dust and rock too large to pass a 2-in. ring. The concrete in the foundation consisted of 1 cement, 3.5 sand, and 4.5 crushed rock, and was mixed with a half-yard Smith mixer as later described for piers and abutments.



Assembling Steel at Aqueduct No. 8.

The concrete materials for the piers and abutments of Aqueduct 9 were the same as for the foundations and were hauled to the site of the aqueduct in dump cars. The track was on top of the canal bank from which the cars were dumped on the outside of the bank, the slope being covered with a grass sod. Enough sand and crushed rock was delivered before any construction began to complete all of the concrete work. The materials were distributed along the bank for a distance of about 400 ft. An accompanying illustration shows the general layout of the mixing and hoisting plants.



Placing the Concrete Lining at Aqueduct No. 9.

A warehouse with a capacity for storing about 2,000 bbl. of cement was rebuilt about 1,500 ft. from the aqueduct and a shed was built over the track at the aqueduct site large enough to shelter a flat car loaded with cement. All cement was received in sacks.

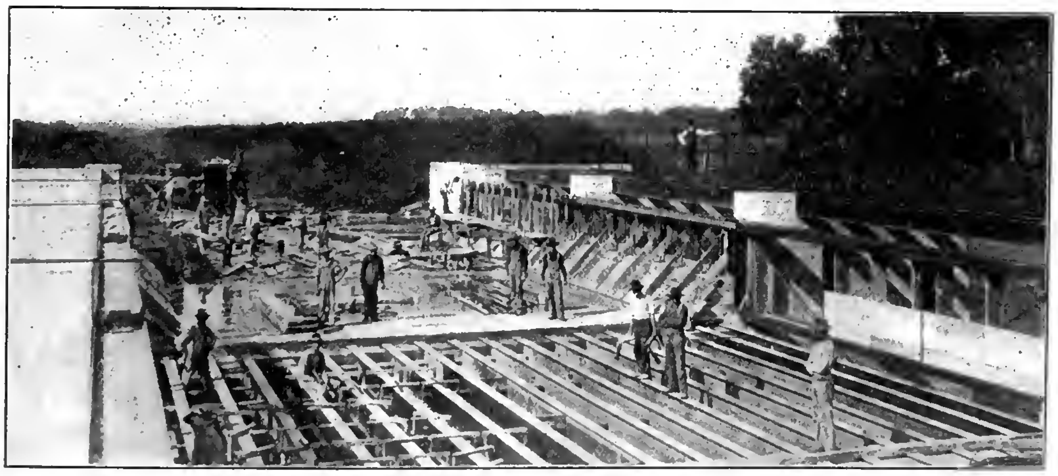
The concrete was mixed in a one-half yard Smith mixer mounted on a frame with an engine and vertical boiler, the concrete proportions being 1 cement, 3.5 sand and 4.5 crushed rock. The materials were loaded into a car, in which they were measured, the sand being placed in the bottom and the rock on top, with the cement sandwiched between. The car was designed and built for use on the concrete work on the canal. It consists of a wooden hopper lined with sheet steel, having a slide in the bottom for dumping, mounted on two pairs of trucks of 36-in. gauge. Its capacity is about 20 cu. ft. The car was pulled up an incline by a single horse to a platform above the mixer, where it was dumped through an extension chute into the machine and mixed.

The concrete was dumped from the mixer into one of the concrete cars described, which was pushed onto an elevator and hoisted to a trestle where it was pushed by two men to the form where the concrete was deposited. In order to provide a passageway for cars without using switches, a track just long enough to hold one concrete car was constructed, at the same elevation as, and on the opposite side of the elevator, from the track leading to the forms. Two cars were used for carrying the concrete, one car being at the mixer when the other was on the upper concrete track. The cage of the elevator would be left at the top, making a continuous track over the elevator, and the car from above would be run over it to the passageway. The cage would then descend, the car of concrete be placed thereon, and raised to the upper track. As soon as the loaded car was pushed off, the empty one was pulled on and lowered to the mixer, and the operation repeated. For every load of concrete taken to the forms, it was necessary to raise the cage twice. In this way, the elevator man also acted as switchman.

The mixer was placed about 50 ft. below the downstream end of the piers and a trestle was built from the elevator, which stood just in front of the mixer, to the forms, a track being laid on it extending from end to end of the several piers and abutments.

The forms were built with posts of 6 x 8-in. timbers and the lagging of 2 x 12-in. pine plank, surfaced on two sides. The posts were placed opposite on the two sides and 4 ft. between centers. They were tied together at the top about 2 ft. above the concrete with a 3 x 12-in. plank and at two intermediate points between top and bottom by ⅝-in. rods. Planks were spiked to the grillage timbers to catch the heels of the posts, and the upper tie carried the concrete track.

The piers were divided into two sections by a bulkhead at about the center of the forms. The abutments were built in six sections, the two parts of the breast wall being first, the canal retaining walls next, and the wing walls last.



Progress View during the Work of Lining Aqueduct No. 7.

The work was carried on by two shifts of 8 hours each. No special effort was made to complete the work as a monolithic structure, but at the close of work on the second shift, the concrete was leveled and tamped as nearly horizontal as possible. The masonry was not faced, the concrete being thrown up against the sides of the form, allowing the coarser parts to rebound, and the crushed rock was omitted from the last batches on top.

The piers and abutments at Aqueduct 4 were built with natural gravel and the Chicago AA brand of Portland cement. The specifications for cement were those formulated by a Board of Army Engineers and published as "Professional Papers No. 28, U. S. A."

The following extract is from the specifications for concrete, and proved to be quite effective:

"Abutments and piers of aqueduct bridges shall be built of Portland cement concrete so proportioned that there are no voids when compactly rammed, and shall contain on an average, for each section of wall, one and one-tenth barrels of Portland cement per cubic yard in place, including facings, copings, and bonding layers, as hereinafter described. In no case will a greater proportion of sand than three parts sand to one part cement be permitted to be used. In case the number of barrels in any piece of masonry falls below the average stated above, then the price per cubic yard shall be reduced in proportion to the reduction in amount of cement used. Prices of concrete will not be increased if greater

quantities of cement than specified above per cubic yard are used."

The gravel contained about 55 per cent. of pebbles and the proportions for concrete were made 1 cement to 5½ gravel.

The concrete was mixed in a 1¼-yd. Page mixer, an invention of Mr. J. W. Page, one of the contractors. It is an open drum batch mixer mounted on the end of a shaft inclined at an angle of 52 deg. with the vertical plane. It is operated by spur and bevel gearing by a 20-h.-p. two-cylinder vertical reversing engine. Its capacity is about 15 batches per hour.

A platform was built around the drum of the mixer, on which the cement was unloaded. The gravel (27 cu. ft.) was loaded into a 1¼-yd. side-dump car and pulled up an inclined track by a 20-h.-p. double-drum hoisting engine, onto the platform in front of the mixer, where it was dumped into the drum with five sacks (5 cu. ft.) of cement.

The concrete was dumped through a door in the side of the drum into a hopper concrete car with bottom dump, and hauled to the forms by a cable operated by the second drum of the hoisting engine previously mentioned. A small trestle was built from the mixer to the form and the concrete car was pulled up an incline, about 22 ft. long with a rise of about 10 ft., to a track on top of the form. This allowed the distribution of the concrete along the entire length of the pier or abutment.

The forms were built about the same as at Aqueduct 9. The form for the nose was built in two pieces, which were left intact when wrecking the forms. The short planks in the nose were beveled to fit the corners and were spiked to 6 x 8-in. posts. The two pieces of the nose forming were fastened together where they met by bolts through the posts. The posts were also supported by diagonal braces from the ground.

The concrete would be considered a wet mixture. All of the exposed surfaces were faced with a mortar of 1 cement to 2 Mississippi River sand, 1½ in. thick.

The piers were divided into two sections, each of which were built in one day.

The materials for the concrete lining for Aqueduct 9 were the same as used for the piers and abutments, although crushed rock was not used except for the concrete over the piers. Marquette Portland cement was used exclusively.

The same one-half yard Smith mixer was used for mixing the concrete, but with an entirely different set up. The mixer was placed at the bottom of the canal between the embankments, and a short track for a material car was constructed over it. Over this track and at a height sufficient to clear one of the concrete cars, a hopper having a capacity of 6 or 7 cu. yd. was built. The hopper was about 9 ft. square at the top and had a 12 x 18-in. cast-iron chute with steel slide in its bottom which was opened and closed by a lever. The hopper was placed adjacent to the track on the canal bank. The sand or gravel, which had been stored on the opposite side of the canal bank the previous year, was loaded into 3-yd. dump cars and hauled with the narrow gauge locomotive by a circuitous route to the hopper, where it was dumped. From here the gravel was dumped into the material car where it was measured and pushed by hand to and dumped into the mixer. The concrete was dumped from the mixer onto a platform, where it was shoveled into wheelbarrows and wheeled to the forms.

The ends of the floorbeams and trusses are embedded in concrete, 4 ft. wide and 18 in. thick, over which the joint in the lining between the adjacent bays is made. This joint was made by placing a piece of house siding between the two pieces of concrete when it was built, subsequently removing it and filling the joint with coal tar pitch. As just indicated, the lining for each span was built separately, the floor and those parts of the side up to the top of the triangular reinforcement being built one day and the balance of the sides later.

For the floor forming, 2 x 12-in. by 8-ft. pine planks were laid horizontally between, and were supported from, the flanges of the floorbeams by small horses or brackets.

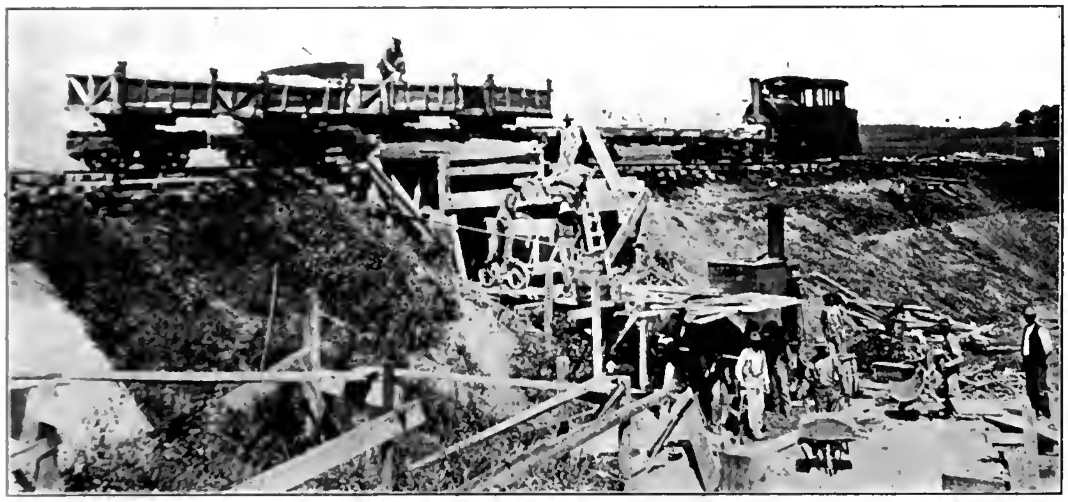
For the side forming, vertical posts were securely fastened between the two beams of the side truss every 4 ft., and 2-in. lagging nailed to them. To form the triangular portion, diagonal posts of 3 x 8-in. pine were nailed to the top of the vertical post, extending downward to the top of the floor lining, and were wired to the opposite side of the form. The lagging was placed under these diagonal posts as the concrete was deposited.

All of the reinforcing bars in the floor were laid in position and wired together the day before the concrete was deposited. At the same time, the vertical reinforcing bars for the sides were bent to a template and were wired at the top to a 2 x 4-in. strip. The horizontal bars were laid in position as the concrete was deposited.

Operations were begun on one of the sides, the first layer of concrete extending several feet beyond the side into the floor, on which a working platform was built. This consisted of three lines of 3 x 12-in. plank laid close together parallel to the side and on top of the fresh concrete with 2-in. strips laid crosswise thereon and a fourth plank carried on the strips.

A runway for filling the sides was supported from this plank. As the concrete was being deposited in the side, a second smaller gang of men kept the floor bond alive. This was done by placing a 2 x 4-in. strip on edge over the center of the floorbeam and depositing concrete between it and the concrete previously deposited with which it was bonded. The strips were 2 ft. 3 in. wide and extended the full length of one span of the aqueduct. When the first side had been completed to the top of the triangular section, the same operation was repeated on the other side, and a third small force kept the floor bond alive on that side. As soon as the second side had been completed, the entire force was concentrated on the floor.

Concrete Plant and Trestles at Aqueduct No. 9 in 1904.



Mixing Plant Used in 1905 for Lining Aqueduct No. 9.

The concrete was a wet mixture and was finished with a wooden float, no additional mortar being used.

At Aqueduct 4, 1.8 bbl. of Marquette Portland cement were used with 1 cu. yd. of bank gravel. The Smith concrete mixer was placed at the bottom of the canal with its hopper against the inside wall of the abutment. It was charged by one-horse dump carts from the top of the abutment walls.

The method of construction was practically the same as previously described. The concrete was deposited the middle of December, in freezing weather, the lowest temperature being 12° Fahr. The water for concrete was heated to about 130° Fahr., the exhaust steam from the mixer engine was discharged into the mixer, and the concrete was deposited at a temperature of 70° to 90° Fahr.

After the concrete was deposited, boards were laid on the fresh concrete to support carpenters' horses. Planks were placed between the horses, the entire area over the lining was covered with inch boards, and the space heated for about 48 hours with live steam.

The concrete deposited in freezing weather was apparently as good as any of that deposited in mild weather.

Each of the piers at Aqueduct 4 contain 191.5 cu. yd. of concrete and each abutment 350.5 cu. yd., a total of 1,467 cu. yd. There were 1,801 bbl. of Chicago AA cement used in the concrete besides 113 bbl. in the mortar for facing. The splay walls at the ends of the aqueduct contain 119.88 cu. yd. of concrete and required 159 bbl. of Chicago A A cement in their construction. The contract price for Portland cement concrete was

$7.07 per cubic yard. The total cost of the masonry, including splay walls, was $11,219.24.

The unit costs for materials and labor for the earthworks, foundations, piers and abutments at Aqueduct 9 amounted to 31 cents for 16,471 cu. yd. of excavation, 25.1 cents for 7,000 cu. yd. of back-filling, $5.92 for 632 round piles, $64.75 per thousand feet for 18,616 ft. B. M. of sheet piling, $38.81 per thousand feet for 40,050 ft. B. M. of grillage, $6.66 for 3,612 cu. yd. of concrete, and $3.70 per linear foot for cofferdams. In addition $1,645.15 was spent for engineering connected with these items, $1,663.85 for pumping and $1,485.92 for the emergency gates set in place. The unit costs for the superstructure, splay walls and lining at the same structure were 2.3 cents for 427,889 lb. of steel in the superstructure, $6.217 per yard for 206 cu. yd. of concrete in splay walls, $8.702 per yard for 329 cu. yd. of concrete in the lining and 2.32 cents for 30,924 lb. of reinforcing metal. The engineering cost $715.

The following is the scale of wages for the above work, 8 hours constituting a day: Overseers, $100 per month; locomotive enginemen, $90; pump enginemen, etc., $60; stokers, $60; watchmen, $45; teamsters with teams, $3.50 per day; capenters, $2.50; laborers, $1.75; waterboys, 60 cents.

The average cost of 35 spans of the reinforced concrete lining of the aqueducts is $756.87 per bay, and the average cost of the concrete is $9.48 per cu. yd.

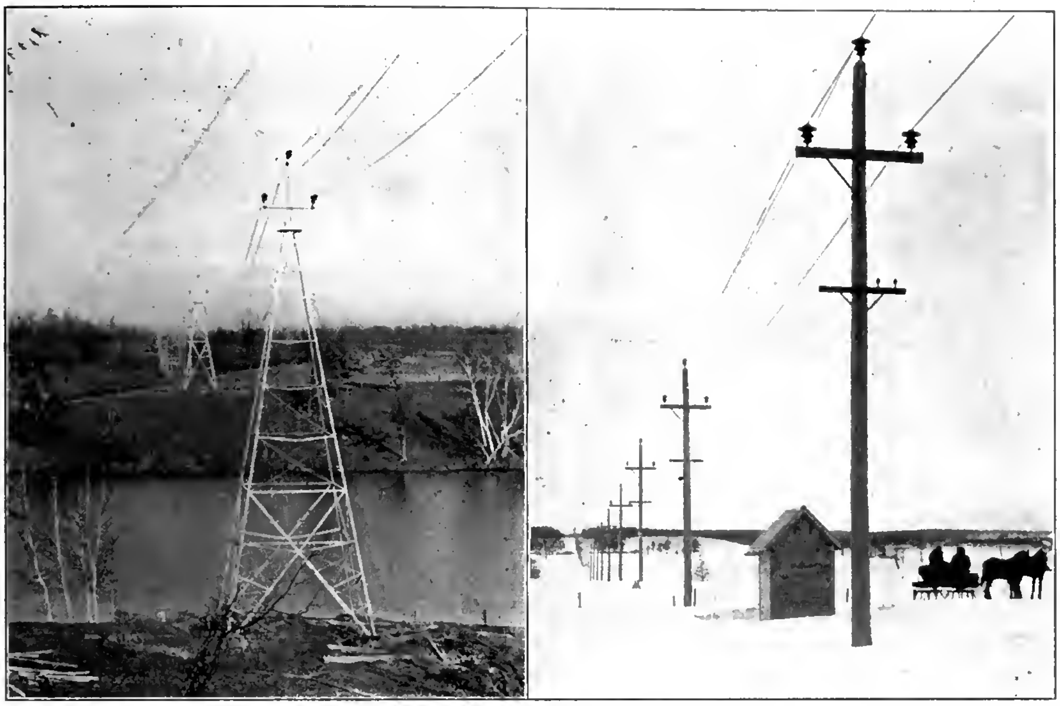
The work of construction of all work on the feeder and Western Section of the canal has been in charge of Assistant Engineer L. L. Wheeler, and that on the Eastern Section in charge of Assistant Engineer J. C. Long. Major W. L. Marshall, Major J. H. Willard, Major C. S. Riché, and Lieut-Col. W. H. Bixby, Corps of Engineers, U. S. A., have had supervision successively of the work in the district in which the canal is located.

My thanks are due Messrs. Wheeler, Rowse and Reeves for help in preparing this article.

A High-Voltage Third-Rail Interurban Line is under construction in California between Marysville and Nevada City and Auburn, using a protected under-running conductor rail on private right of way and overhead wire and pantagraph trolley in public streets. The operating voltage is 1,200 volts direct current.

The Taylor's Falls, Minn., Water Power Development.—II.

Transmission Line.—At present one transmission line has been built on private right-of-way from the power station to the step-down sub-station at the city limits of Minneapolis and St. Paul. The right-of-way is practically straight and in general is 60 ft. wide, being laid out for a pole line 10 ft. from each boundary line. The present line, which is 40.6 miles long, is of 4/0 semi-hard-drawn copper cable carried on wooden poles, with the exception of certain long spans across swamps, lakes or other obstructions where Aermotor steel towers are used. The standard pole of the transmission line is of Idaho cedar, 45 ft. long, carrying 5 x 7-in. cross-arm, 7 ft. 4 in. long, and a small cross-arm 7 ft. below for the telephone line. The transmission wires are carried on four-part porcelain insulators of special design, which are arranged on a 72-in. equilateral triangle with the apex at the top of the pole. The top insulator is cemented to a bracket pin swedged out of extra heavy 2-in. iron pipe, while the cross-arm insulators are carried on pins of the same material set into the arm in the usual manner. The cross-arms are bolted to the poles, braced with a single angle iron on one side and fitted with bolts through and on each side of each pin to hold the pin firmly and to prevent splitting of the arm. The standard span on pole construction is 140 ft., the spans on the tower construction reaching up to 600 ft.

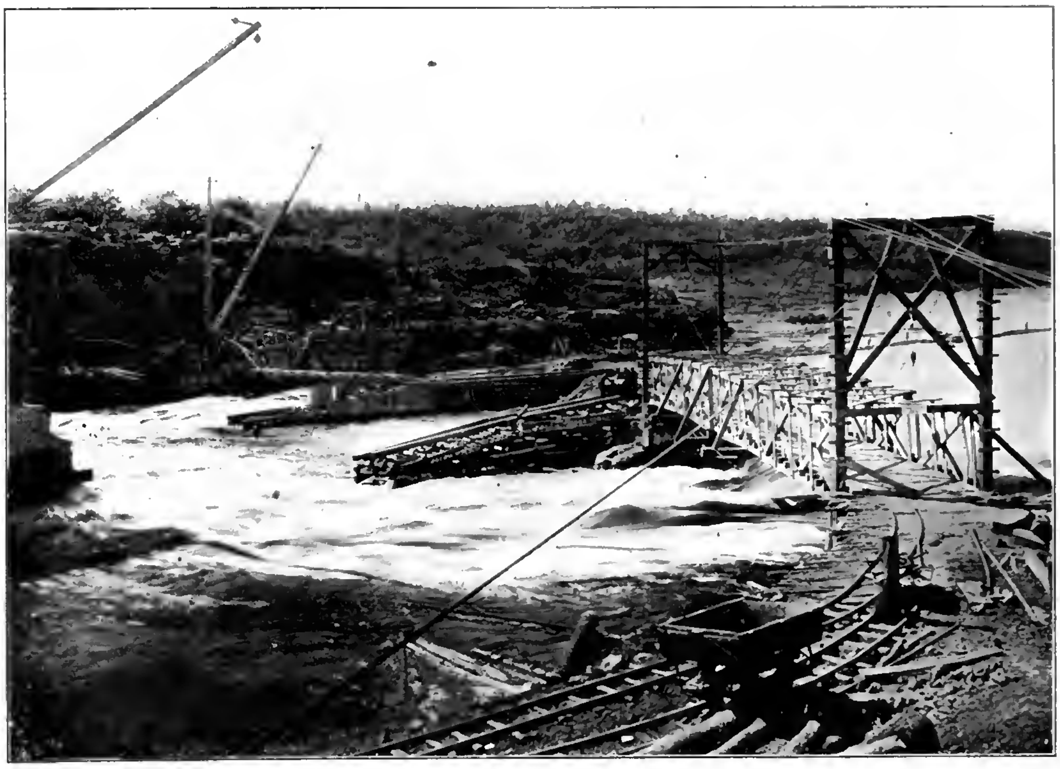


Two Typical Transmission Line Views, Taylor's Falls Development.

The telephone line consists of two No. 10 copper wires connecting permanent instruments at each power station and at a patrolmen's cottage at the centre of the line, and with temporary connections in booths arranged along the line for the use of the patrolmen. The telephone instruments and connections are all arranged with high insulation repeating coils to protect the attendants against possible shock from induction from the transmission line.

Owing to the prevalence of thunder storms over the middle portion of the transmission line, this part is protected by several different experimental constructions of overhead grounded wires, lightning rods on the poles and also on separate poles arranged alongside and reaching above the transmission line. The Westinghouse Co. standard low equivalent arresters are used to protect the station apparatus at both ends of the line and in addition three types of horn arresters and other special devices have been put up.

Main Step-Down Sub-Station.—The step-down sub-station is built of brick and steel with reinforced-concrete floors, and has a timber framework to support the wiring, which is open throughout. The building is divided into two rooms, one containing the transformers and the other the switchboard and wiring. The transformer room is screened off by a brick wall with a reinforced-concrete floor overhead. The entrances of present and future transmission lines are at one end of the building, while exits for three 13,000-volt outgoing lines are provided along each side. Three banks of transformers duplicating those at the power station are now installed with provision for three additional banks in future. These transformers are now connected for stepping down from 47,500 to 13,800 volts.



Cofferdam Used in Building Closing Section of Spillway.

Arrangement of Construction Plant for Taylor's Falls Station.

The wiring consists of two high-tension busses and two low-tension busses to be joined in the future in each case by a junction switch at the end of the building. The transformers and incoming and outgoing lines are controlled by Westinghouse oil switches mechanically connected to lever handles on the switchboard, which is arranged on the second floor across the building near the transmission line end. The oil insulated choke coils, instrument transformers and high-tension lightning arresters are arranged on a reinforced-concrete gallery at the end of the building and the arresters and oil switches controlling the outgoing lines are arranged on the second floor and gallery above. The transformers are provided with an oil treating system similar to the one at the power station. Water for cooling the transformers is pumped from a deep well and circulated by motor-driven turbine pumps and finally discharged over a cooling screen into an artificial pond outside the building. The cooling coils of each transformer are provided with Venturi meter tubes and gages to indicate the amount of cooling water used at all times and each gage is provided with electric contacts which ring an alarm and indicate by lamps in case the flow in any transformer falls below a given amount.

Construction.—The construction of the dam and power house was handled with considerable difficulty, owing to the swiftness and volume of the stream; the frequent changes in the stage of the river; the necessity of sluicing logs during the spring and summer months; the extreme toughness of the trap rock encountered in the excavation and the heavy flow of ice during the spring freshets.

The materials and equipment required in building the two structures, excepting the sand and stone used in the concrete, were brought in over a standard-gauge spur track about 1½ miles long, that was built especially for the purpose from the Minneapolis, St. Paul & Sault Ste. Marie R. R. This track extended from the end of that railroad at the village of St. Croix Falls on the Wisconsin side for about ¾ of a mile upstream to a switch back and from there back about ¾ of a mile downstream to the power house site. It ended about 150 ft. from the upstream side of the power house and was back about 250 ft. from the straight section of the spillway of the dam, parallel to the stream and 40 to 50 ft. above the bed of the latter.

The dam and power house were both built on the solid trap rock which underlies the entire site on the Wisconsin side of the river. The foundation of the power house was excavated out of this rock in the downstream side of the ledge through which the forebay canal was dug. The straight section of the dam at the power house and the downstream end of the spillway were built on this ledge after it had been stripped down below any fissures. The balance of the spillway was built on the trap rock which formed the bed of the stream after all loose rock and sand had been removed. The bear trap dam and log sluice on the Minnesota side of the river were also built in excavation made in the solid rock bank.

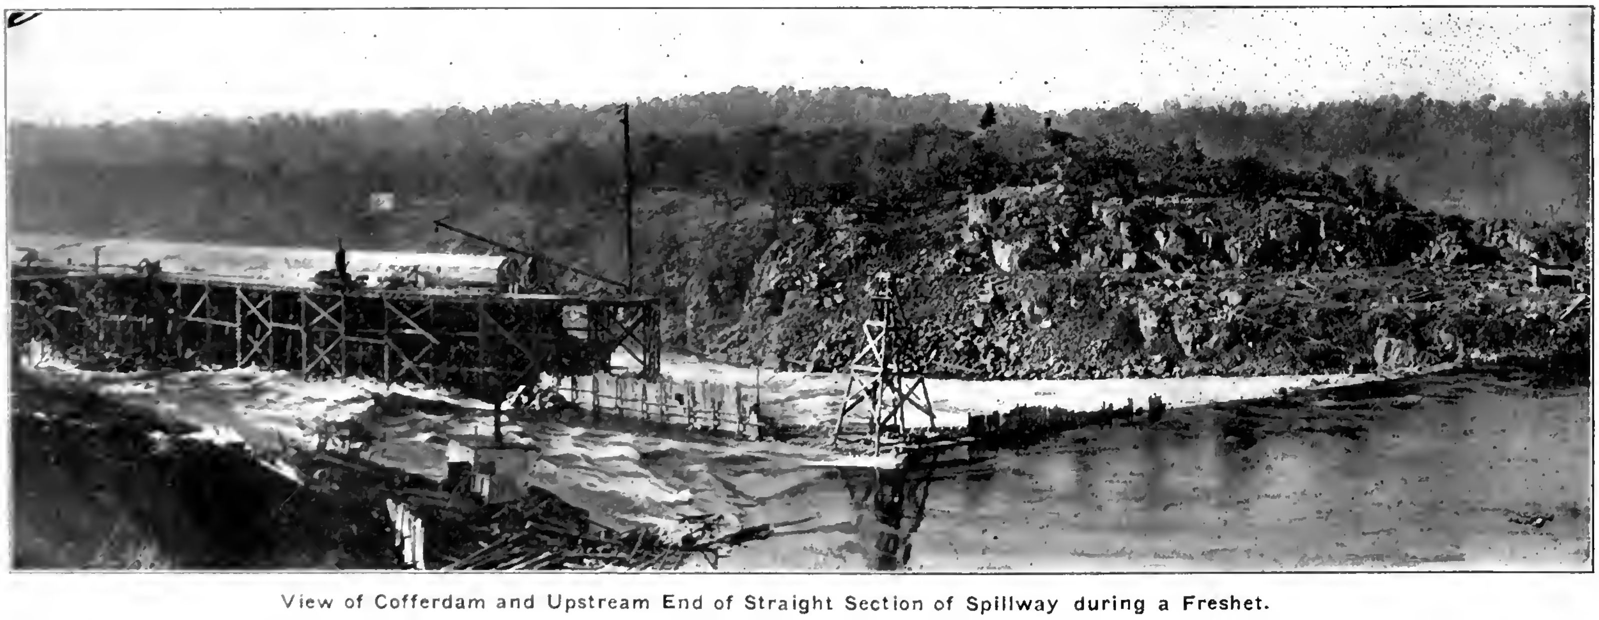
Concrete and Concrete Mixing Plants.—The mixture of concrete used for the greater part of the work was one part Atlas Portland cement, three parts sand and five parts broken stone. The sand was obtained from a bank 1,500 ft. from the site of the work. It was brought to the mixing plants in cars run by gravity on a track laid from the sand bank to the two mixing and crushing plants. After they had been dumped the cars were hauled back to the pit by horses.

The trap rock excavated from the canal and power house site was crushed to a size that would pass the meshes of a 2½-in. screen and then stored in bins to be used in the concrete. Large pieces of trap rock taken from the excavation, varying in size from those that could be handled by one man to those containing about one cubic yard, were placed in the green concrete of the dam and power house foundations. These pieces of rock were placed at least 1 ft. apart and 1 ft. from the surface.

A concrete mixing plant was set up beside the standard gauge spur track nearly in line with the junction of the curved and straight sections of the spillway and 150 ft. back from the latter at the top of a sharp drop in the river bank. This plant contained a 1-yd. Smith concrete mixer set on a platform about 4 ft. above the ground. Over this mixer were measuring hoppers for sand and stone, and above these the storage bins for those materials.

The rock was brought to the plant from the excavation on a narrow-gauge track which ran up an incline to the level of the crushers. It was first passed through a McCully gyratory crusher and then elevated to a 2½-in. mesh screen over the rock bin; all pieces that would not pass through this screen were returned to a No. 3 McCully crusher, which also delivered to the elevator. All rock that would pass through the screen fell into the storage bin for crushed stone.

The storage shed for cement was erected alongside the spur track; cement was delivered from this shed to the charging platform of the mixer on push cars. The straight section of the spillway was built from tracks on a temporary trestle about 15 ft. below the top of the dam. This trestle carried three tracks; one of standard gauge on the dam side, a 36-in. gauge next, and a 24-in. gauge on the outside, with extra rails



View of Cofferdam and Upstream End of Straight Section of Spillway during a Freshet.

provided in the outer tracks and arranged so that a 24-in. and a 36-in. gauge track were also made on that side. These tracks were connected with the mixer by a trestle which ran from it to the main trestle. The standard-gauge track carried two cars, each mounted with a guyed derrick having a 60-ft. boom. These derricks handled the rock excavated from the site of the dam; the forms for the concrete and the skips in which the concrete was delivered on the cars from the mixer.

What little coffer-dam work was necessary for this portion of the dam was done with gravel brought from an adjacent gravel bank. This section of the dam contained at the base three pairs of 9x12-ft. arched openings which were left to provide for the passage of the river while the closing section of the dam was being built.

After the work had been in progress for a few months a second crushing and mixing plant, a duplicate of the first, was erected on the river bank above the site of the power house and 300 ft. downstream from the first plant. A trestle connected this second plant with the main trestle along the dam.

The second portion of the dam crossing the bed of the river was a more serious proposition to construct than the first, owing to the liability of sudden and rapid changes in the stage of the stream. The cofferdam to turn the river while this portion of the dam was being built was constructed of log crib work, weighted down with rocks taken from the excavation. Sheet piling was placed on the upstream side of the crib work and gravel and clay were used to fill the interstices of the rock in the cribs. Large quantities of brush were also placed outside of the sheet piling and clay and gravel dumped over them, this method of construction being found very effective in the swift curent of the congested channel.

The concrete for this portion of the dam was brought to position in dump cars running on a track blocked up on top of the completed portion. An elevator brought the dump cars of concrete to position on this track from the lower level of the trestles running from the two mixing plants. From the dump cars the concrete was placed through chutes extended to the work from the end of the track. As the dam was completed the latter was gradually extended. This method of placing the concrete was found to be faster than the use of derricks, and gave excellent results.

The foundations of the power house were largely put in in the winter with the temperature at times as low as 20° below zero, Fahr. For this winter work one of the mixing plants was fitted up so that live steam could be run through the sand and rock bins and into the water tank. In very cold weather salt was also used in the water. The concrete thus made was found to be hot enough to get its initial set before it could freeze and the results obtained were uniform and excellent.

The concrete for the bear trap dam and sluiceway for logs was procured from a separate plant set up on the Minnesota side of the river. This plant consisted of a ½-yd. Smith mixer placed on the river bank immediately above the site of the work. Most of the concrete supplied by this mixer was put in position through a chute running directly from the latter to the point where concrete was being laid. In such portions of the work as could not be reached in this way the concrete was handled by a derrick set in the lower end of the sluiceway.

The dike on the Minnesota side of the river was built of gravel concrete on a stratum of hardpan and sandstone. A separate concrete mixing plant was installed for this work, using the same ½-yd. Smith mixer which was employed in the construction of the bear trap dam. A trestle ran from this mixer immediately above the dike and on this trestle the concrete was handled in dump cars from which it could be put directly in position. The sand and gravel were obtained from a bank near by which was connected with the plant by narrow-gauge tracks.

The plans for the Taylor's Falls development were prepared by Messrs. Stone & Webster, of Boston, Mass., and the construction work and installation of the machinery in the power house were executed under their direction. Messrs. Dean & Main, of Boston, were the consulting engineers in connection with the preparation of the plans for the hydraulic features of the development. Messrs. Loweth & Wolfe, of St. Paul, Minn., conducted the preliminary hydraulic investigation.

Gasoline Motor Service on the Union Pacific Ry.

An interesting innovation in railway passenger transportation in this country will be inaugurated next month, when, it is announced, the Union Pacific Ry. will place in service twelve gasoline rail-motor cars. The cars are intended for branch-line traffic, where the fast and frequent service required cannot be maintained by ordinary trains except at a loss.

The lastest type of these cars developed at the Omaha shops of the Union Pacific makes 60 miles an hour with a 200 h.-p. engine, reaches high speed within six car lengths, and can be stopped within 120 ft. With these advantages the cars can be put on a much faster schedule than is possible with the steam locomotive.

Outwardly the newest of the cars, which are built entirely of steel, resemble a turned-over racing yacht. The forward end tapers sharply, and the roof and rear are rounded off to reduce the air resistance and avoid the vacuum produced by a square car. Rounded windows give to the passengers a wide range of outlook, and increase the nautical appearance of the car.

In cold weather the cars are to be heated by hot water from the cylinder jacket. They are lighted by acetylene gas shining through opalescent panels.

For sanitary reasons the floors of the cars are built so that they can be thoroughly cleaned by flushing with hot water. The familiar system of ventilation has been replaced by roof ventilators which exhaust the inside air by suction, fresh air being taken in from the car roof in front. Vibration is reduced to a minimum by the way in which the motor is balanced.

The cost of operating the cars varies from ten to twenty cents a mile, according to the density of the traffic, but the records kept indicate that the rail-motor car will make possible great improvements in handling branch-line passenger traffic.

THE FREEZING PROCESS of sinking shafts has been successfully employed at a colliery at Seaham, England. At this place there is a deep bed of limestone under which is a 92-ft. stratum of water-bearing sand. The limestone also carries much water. Twenty-eight bore holes were marked off in a circle 30 ft. in diameter around the shafts and were sunk to a depth of 484 ft. Pipes were placed in these holes and connected with apparatus producing a circulation of brine, which formed an ice wall in 185 days. The sand was struck at a depth of 371 ft. after the freezing had been completed, and was found to be so hard as a result of the process that blasting was necessary in places. When the shaft had been sunk through the water-bearing materials, the ground was thawed by circulating warm brine through the freezing tubes.

The Quebec Bridge Superstructure Details.—II.

Vertical Bents on Main Piers—Pedestal.—The 166,000-lb. pedestal is seated on the bolster and is pin-connected to the foot of the main post. It is a 11x13-ft. frustum of a rectangular pyramid and is about 8 ft. high. The construction, although of a simple type corresponding with that of the ordinary pedestal for a bridge truss bearing, was rendered very difficult on account of the great thicknesses required for the different bearings, the necessity of securing perfect contact between the webs and base, the provision of satisfactory connections for such large stresses in oblique directions and the arrangement of details to avoid costly operation and make the shop work conform to regular standing. The construction, involving a great number of pieces, made it necessary to provide numerous plans, elevations and sections, to show their relative positions and the numerous dimensions and notes required for their proper construction. The shop drawings, at 1-in. scale cover all of a 39 x 130-in. sheet and occupied an expert draftsman seven months. It is therefore obvious that it is impossible within the limits of this description to fully show the drawings; so only enough typical plans and elevations are here given to show the general character of the construction and the great care and accuracy with which it was designed.

The base plate 3 in. thick is planed on both sides and is made with three pieces with a planed butt joint on the longitudinal center line of the pedestal. To it are riveted five vertical longitudinal webs bored for the 24-in. pin 7 ft. long, which receives in them a total bearing nearly 3½ ft. long, thus reducing the pressure on the metal to the allowed unit stress of 28,000 lbs. per sq. in. All of the webs are built up of 1-in. intermediate plates and 1⅛-in. outside plates, riveted together to make up the required thicknesses. The outside webs are made with 6 plates each and the intermediate webs with 10 plates each. In the outside webs all plates receive full holes, but in the intermediate webs the two outer plates on each side of each web terminate on the center line of the pin so that they only have half-hole bearings while the inner plates have full holes. The webs are connected to the base plates with special angle sections made by cutting off one flange of a 15-in. channel, thus leaving a vertical leg 15 in. long, through which 5 rows of rivets are placed while only a single row is driven through the comparatively narrow lower horizontal flange. The webs are stiffened and connected by five lines of transverse vertical diaphragms of different types according to the clearances required for the pins and connecting members. Each diaphragm is made with four 6 x 8-in. angles, two of them riveted back to back on the face of one diaphragm to form a T-bar section and the other two riveted to the opposite diaphragms with their outstanding flanges separated far enough to clear and engage the outstanding flanges of the first pair. The interlocking flanges are connected by bolts close together since the space does not permit driving rivets through them. The outer webs are located about 3½ ft. clear of the edges of the base plate and are provided on their outer faces with five heavy vertical transverse diaphragms in the plane of the interior diaphragms, which help distribute their load and stiffen the base plates to transmit the pressure uniformly over its entire surface. The inclined edges of all the diaphragms are stiffened with pairs of 6 x 8-in. flange angles. Most of the webs are single 1-in. plates, but in the two diaphragms nearest the center one the webs are

made of three thick plates and the two outer plates are bent at the inner edge to form flanges riveted to the main web instead of connecting angles. Angles with one long and one very narrow flange are made by cutting off one flange of a 10-in. channel and partly cutting off the other and are riveted to the inclined outer edges of the main web to receive cover plates put on to give them a neat finish and exclude water from the open joints.

The pedestal is provided with horizontal and inclined transverse connection plates forming pairs of jaws field riveted to the ends of the lower chord sections and bottom lateral members. As very heavy stresses are transmitted through these connections great care was taken in designing them; they were accurately fitted in the shop to large details accompanying the general drawing as shown in the sketch herewith reproduced. The pedestal is connected to the bolster by seventy-six 1⅛-in. vertical bolts. The spaces between the webs are closed as much as possible to exclude rain, snow and rubbish; drainage holes are provided in the upper transverse plates and in the lower edges of the outside cover plate to permit the melted snow and rain to escape as much as possible. The dimensions of the pedestal are so great that it was found impossible to ship it from the shop to the bridge site on an ordinary car or in an ordinary manner. It was therefore transported as noted in The Engineering Record of September 16, 1905, on a special steel car, built for the purpose with an unfloored frame-work of heavy girders, from which the pedestal was suspended by a heavy box girder passing through its pin hole and allowing it to be suspended with its lower edge 6 inches clear of the top of the rails.

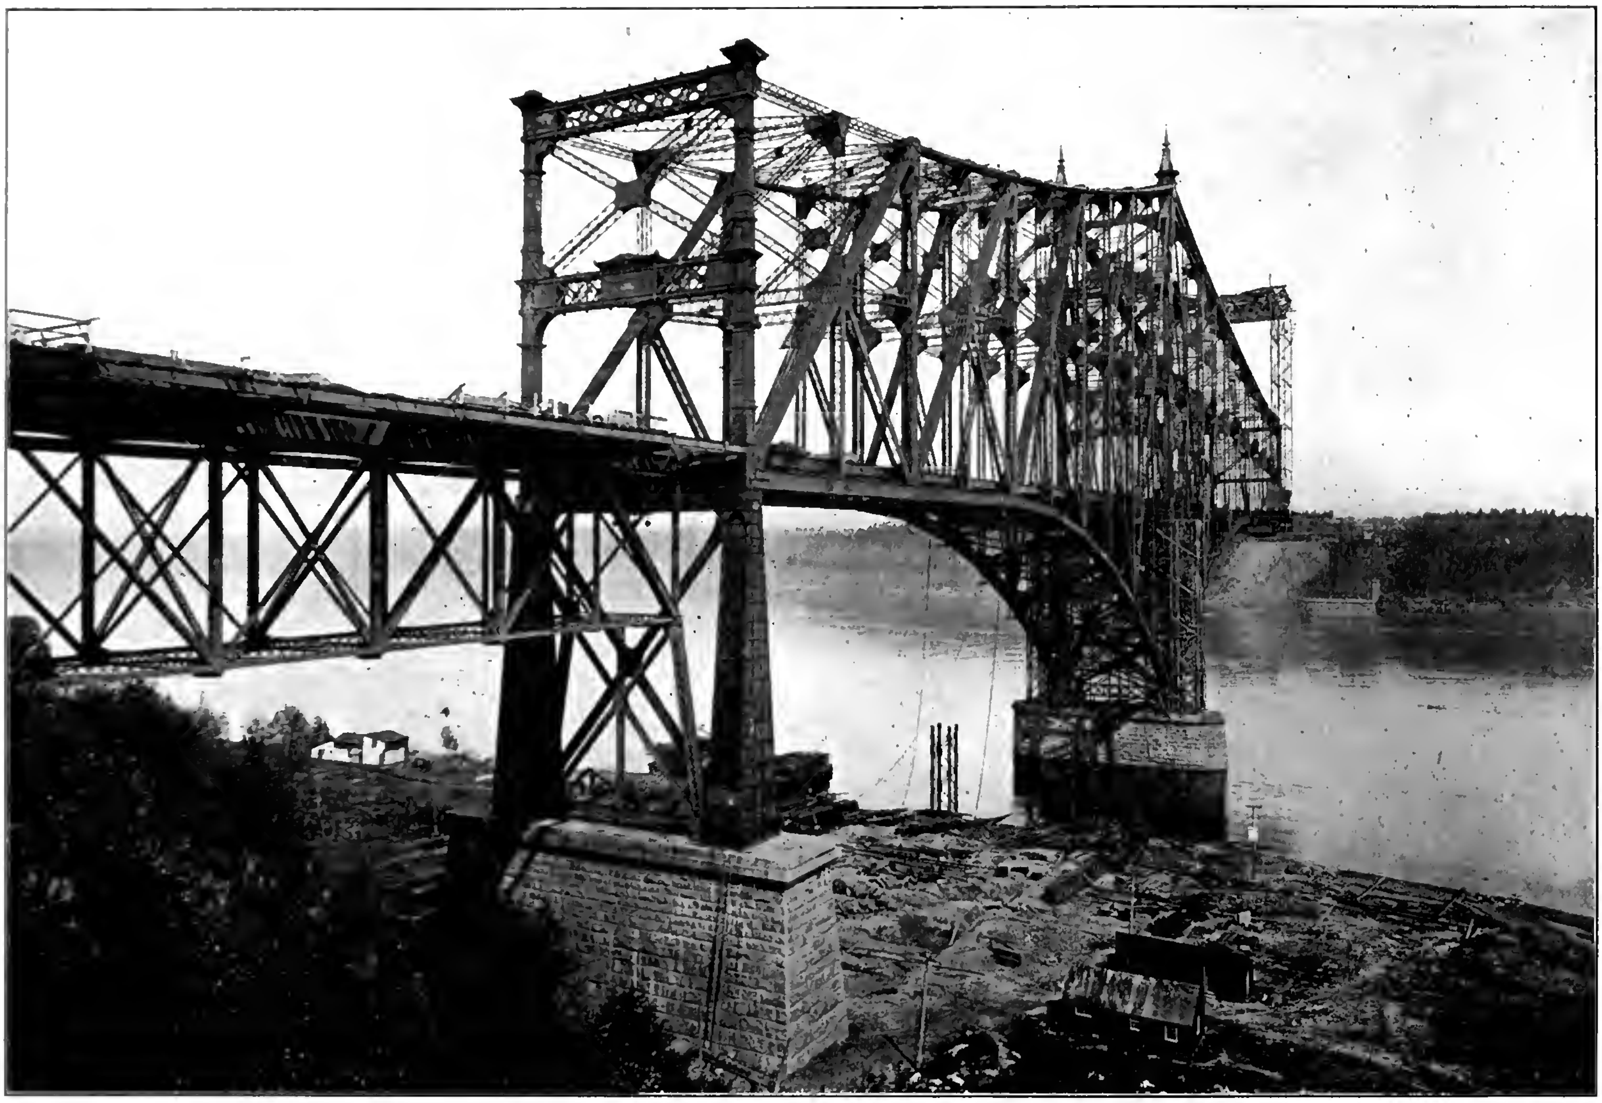
The vertical post is the most important single member connected to the pedestal and it has a special shoe riveted to the lower end with four vertical longitudinal webs engaging the 24-in. pin which locks it to the pedestal. The shoe is 9 ft. high and weighs 67,000 lbs. The 5½ x 10-ft. horizontal upper surface, corresponding to the base plate of the pedestal, is made with a single 1¼-in. plate, planed on both sides and secured by about 200 field rivets to the corresponding horizontal plates in the bottom of the lower section of the vertical posts. The four webs clear those of the pedestal and are each 6¾ in. thick, thus providing a combined bearing 27 in. long for the transmission of the 10,000,000 lb. stress in the post to the pedestal. Each web is built up of four ¾-in. plates, three plates being cut off on the center line of the pin so as to afford half-hole bearings and the fourth plate being extended to receive a full hole and thus lock the shoe to the pin. The webs are connected by four lines of inclined diaphragms, those between the outer pairs being made like those described for the pedestals with two pairs of engaging angles back to back riveted to their adjacent faces. The space between the inner webs is sufficient to enable their diaphragms to be made in the usual manner with a ¾-in. web plate and two pairs of 8x8x¾-in. flange angles. Between the flange angles the web plates are reinforced by pairs of ¾-in. cover plates, giving them a uniform thickness throughout of 2¼ in.

The shoe is provided, like the pedestal, with horizontal and inclined transverse plates perpendicular to its web which engage the upper flanges of the lower chord sections and are thoroughly field riveted to them. The connection plates are shop riveted to the outside webs and are reinforced in the center by heavy brackets with their lower ends faced to bearing against the plates.

The main lower chord pin which connects the pedestal and shoe is 24 in. in diameter, about 7 ft. long and weighs 10,000 lbs. It is doubtless the largest pin yet constructed for a bridge truss; it is made from open hearth steel of about 70,000 lbs. tensile strength, forged under a pressure of 5,000 tons; it has a hole 6 in. in diameter through its axis, through which a 1½-in. rod passes to connect and hold in position the steel discs covering the ends of the pins in lieu of nuts.

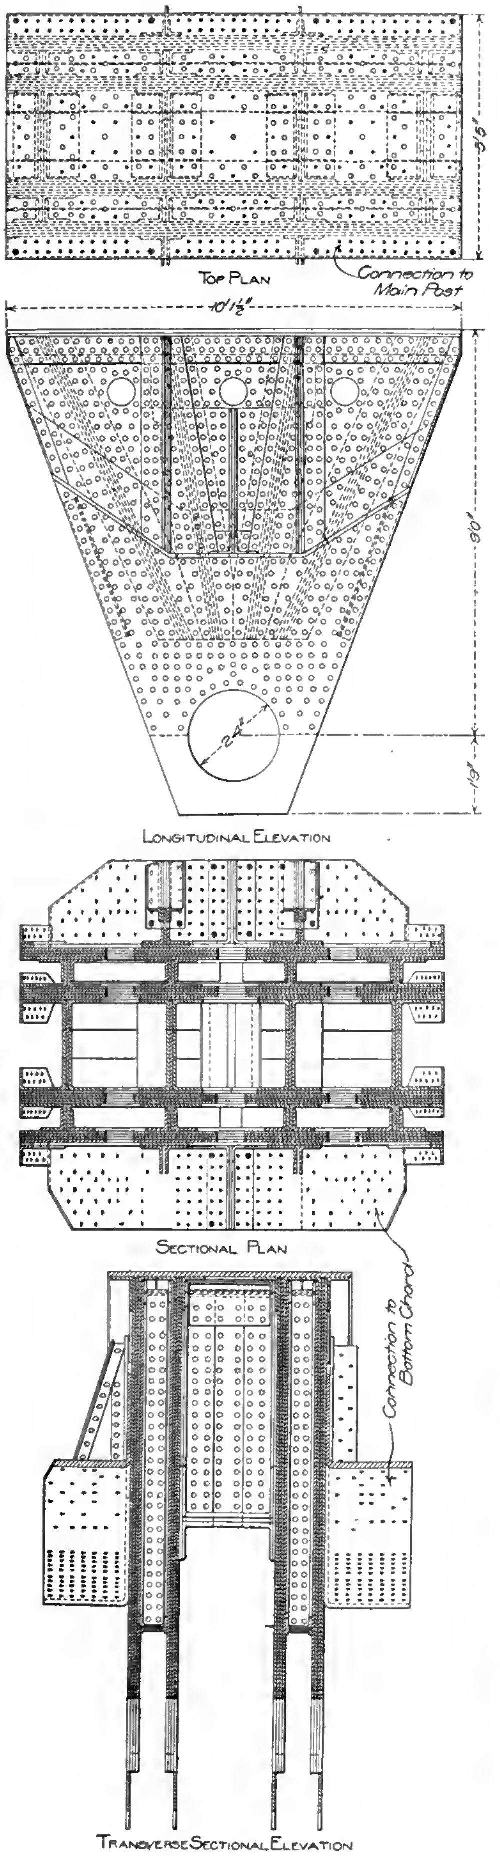
Between the outer webs of the shoe and pedestal it receives the webs of the short end sections of the lower chords which are reinforced to total thicknesses of 6¾ in. These are made with full-hole bearings in V-shaped special sections about 14 ft. long and weigh about 120,000 lbs. each; they were assembled with the shoe and the pedestal, independent of the main sections of the lower chords, which were spliced to them at convenience later. Notwithstanding the mass and rigidity of the members they were designed to fit together with clearances of only 11/16ths in. on the main pin; they were so truly dimensioned and the shop work was so accurately executed, that they were assembled without difficulty in the field. The diagonal members of the truss are theoretically connected to the short pin on which their center lines intersect, but for convenience they are made with separate connections, field riveted to the foot of the lower section of the vertical post.

The accompanying view of the bridge was made from a photograph taken June 12, and is the first picture published which shows the structure from this point, looking upstream, and including the approach span and the complete sub-



View of Approach Span, and of South Anchor and Cantilever Arms.

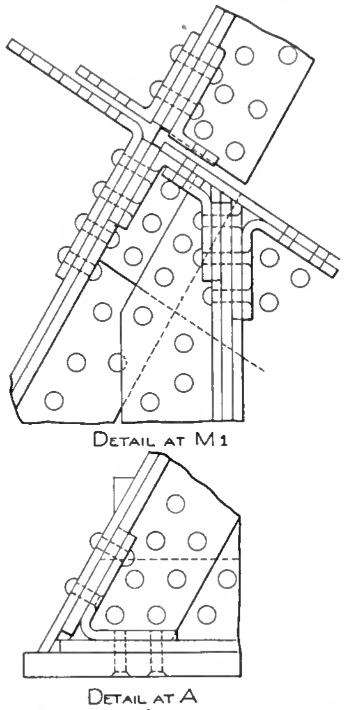
structure on both sides of the river. It shows the completed 600-ft. anchor arm and the 562½-ft. cantilever arm and gives an especially clear view of the south anchor pier and the riveted



Shoe for Main Post.

towers on it enclosing the vertical eyebars extending from the end pins to the anchorage platform enclosed in the base of the pier.

The falsework has all been removed except the bents on the main pier, outside the trusses, and the lower story of the last two bents on shore, and part of it can be faintly seen erected on the opposite shore, half a mile away, while a portion remains piled on the near shore ready for transportation to the other side. The temporary erection girders are still suspended from the extremity of the cantilever and the great traveler supported on them is being dismantled for re-erection on the opposite side of the river. All the principal members are in position in the anchor and cantilever arms and they are completed except for part of the field riveting, which is still in progress from scaffolds, almost imperceptible



Web and Base Plate Connections of Pedestal.

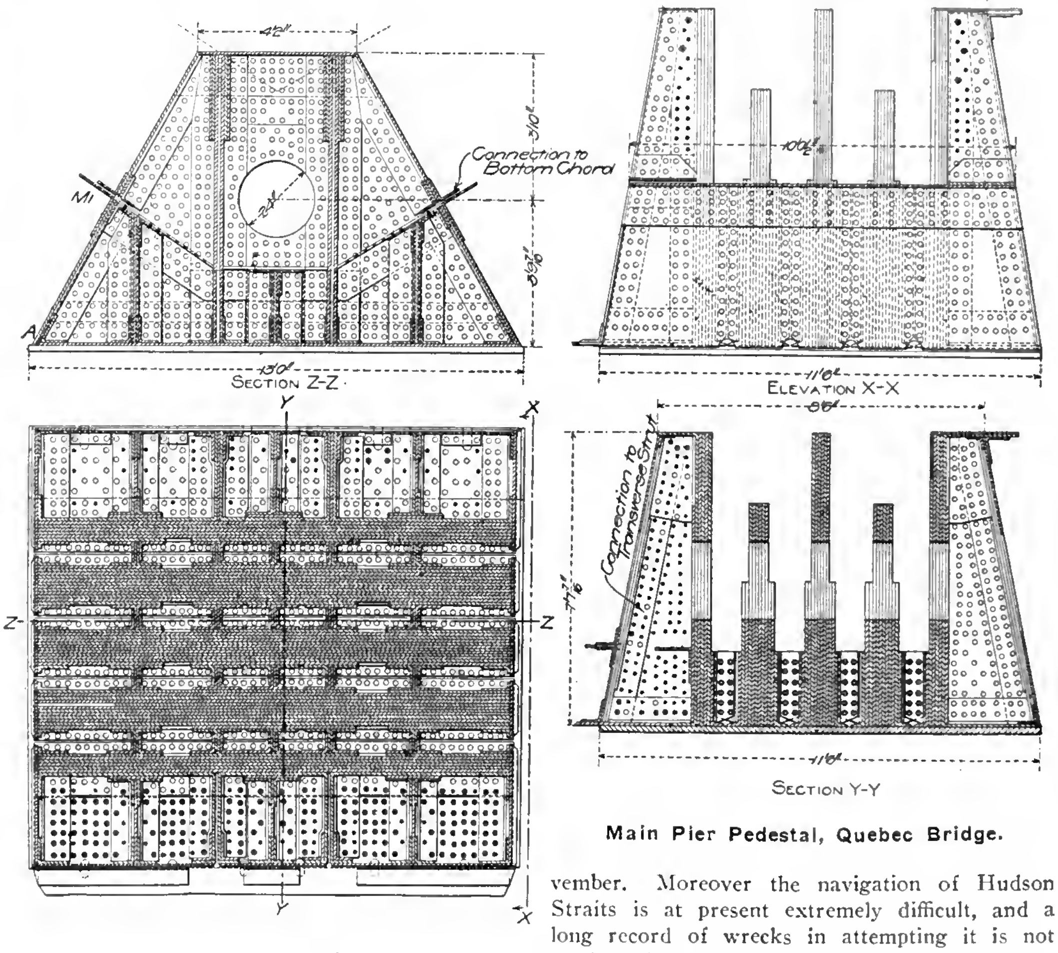
to the scale of the picture, which are suspended from different points of the lower chords and elsewhere.

All of the 3,202 eyebars have been completed, 23,000 tons of steel have been shipped to the site, 12,000 tons more are completed and held in storage at the bridge shops, and only about 3,000 tons more are yet to be riveted in the shops. The steel for the north half of the bridge is being stored in a yard established about 8 miles from the river, at the nearest point now accessible by railroad, where there has been installed an electric traveling crane and service tracks corresponding with those for the south side, described in The Engineering Record of March 4, 1905.

The railroad track is under construction from these yards to the bridge site, and as soon as it is completed the materials will be forwarded to the river and the north anchor arm, north cantilever and north half of the suspended span will be erected in the same manner as previously adopted for the corresponding south portions of the bridge. It is expected that this construction can be commenced early in 1908 and meantime a smaller overhead traveler will be built to run on the top chord and will, this summer, erect as a cantilever the south half of the 675-ft. suspended center span.

Hudson Bay Railway Projects.

Hudson Bay railway projects are now receiving a large amount of attention in the Dominion, and one of the charters for such a road has been secured by Mr. Hill, of the Great Northern system, who formerly ridiculed the project of constructing any line of this character. One of the Hudson Bay roads, the MacKenzie-Mann line, is already about a quarter completed. The great geographical advantage of the route is the shortness of the railroad haul to the ports on the Bay. Unfortunately the season of navigation in Hudson Bay is limited to the short period between the middle of June and the middle of November. Moreover the navigation of Hudson Straits is at present extremely difficult, and a long record of wrecks in attempting it is not particularly encouraging. Nevertheless it seems safe to say that the attention now being paid to the Hudson Bay route is bound to result in a great deal of more definite information concerning its practicability, and possibly before long such a line will be constructed. The Canadian Premier has advocated liberal subsidies to companies undertaking the work.



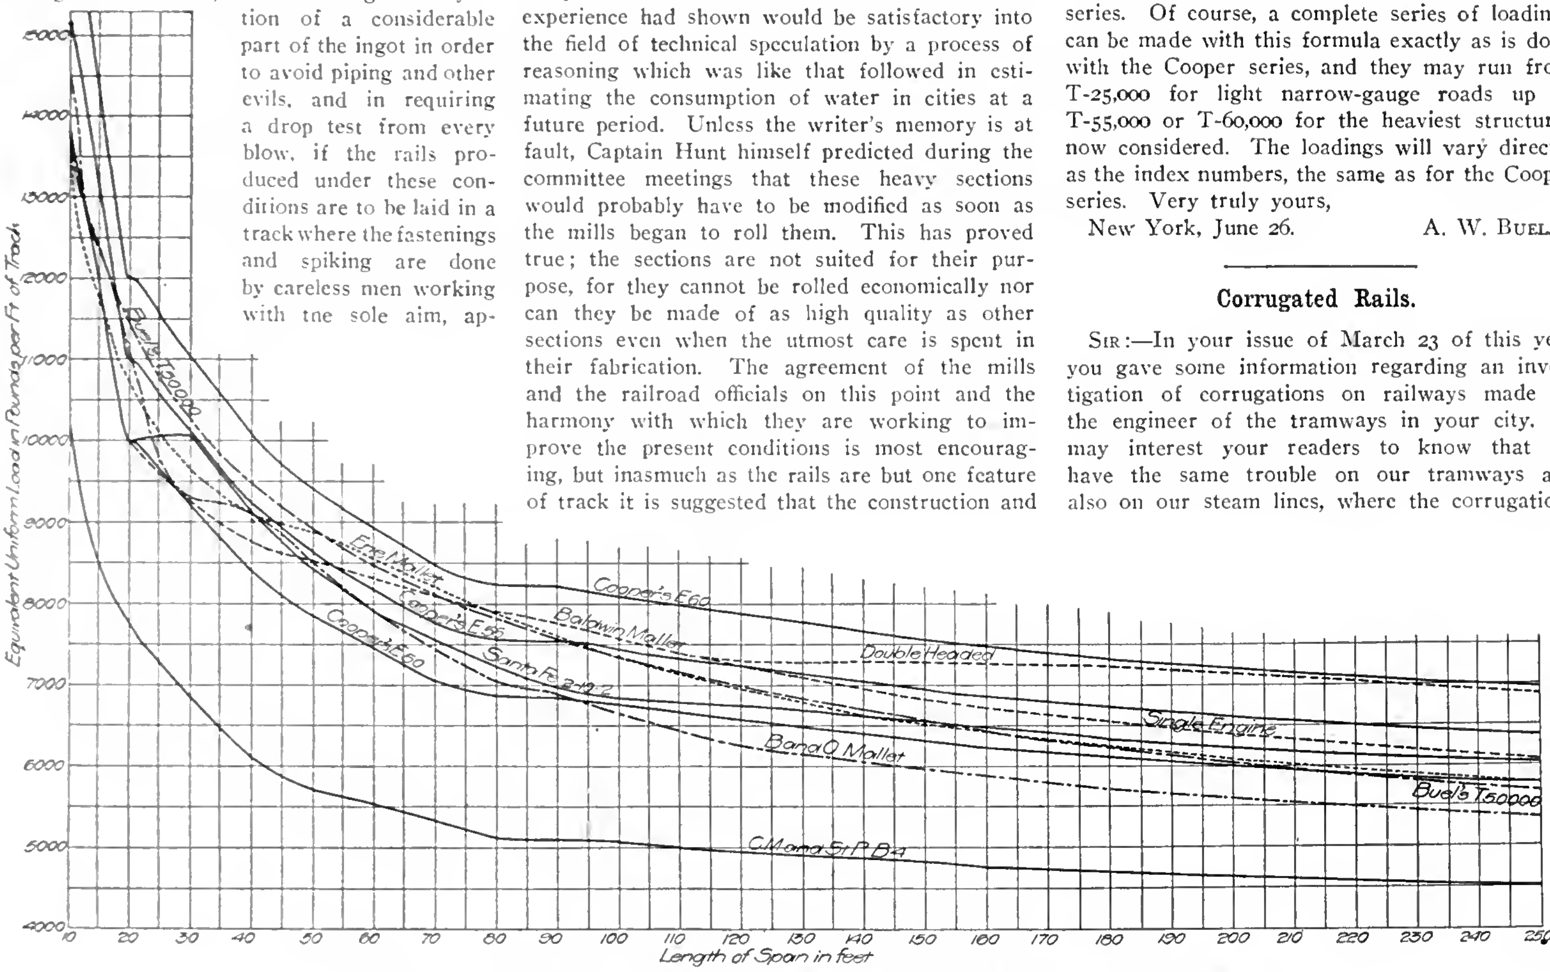
Main Pier Pedestal, Quebec Bridge.

Letters to the Editor.

RAILS AND TRACK.

Sir: Those who have followed the recent discussion concerning the quality of steel rails and at the same time have been in a position to know the manner in which rails are laid in some tracks probably will agree with the writer that the railway officials who are showing so much interest in improving the quality of the rails used on their line would do well to look at the same time into the way in which track construction and maintenance is carried on. Every one must agree that the precautions which seem likely to be taken to secure better rails, even at a considerably higher first cost, are so eminently in the line of an increase in safety as to deserve the heartiest support of stockholders and the traveling public. On the other hand, there seems to be some inconsistency in devising new sections, in demanding the rejection of a considerable part of the ingot in order to avoid piping and other evils, and in requiring a drop test from every blow, if the rails produced under these conditions are to be laid in a track where the fastenings and spiking are done by careless men working with tne sole aim, apparently, of getting the work completed just as fast as possible regardless of character. The brutality of the spiking is sometimes directly preventative of good track conditions. The punishment which rails received when laid improperly can be witnessed by any observant person during a ride of any length. It is generally possible to notice the action of the track under passing freight trains, even in a short ride of a few hours' duration, and after witnessing a few times the pounding of the rails and their vertical vibrations under heavy freight cars and under Pullmans, if one is fortune enough to have an opportunity to witness that, a most illuminating idea of certain track troubles and their cause can be formed. Unquestionably Mr. P. H. Dudley is entirely correct in his statement reported in your issue of last week that the average track on the New York Central lines is much stiffer than it was twenty years ago, owing to the use of heavier rail sections, but there are many lines in this country carrying very heavy trains which are not laid with rails of the New York Central weight and do not keep their roadbed up to such a high standard of maintenance.

These remarks are made without any intention of criticising the present apparent determination of the railway companies to purchase better rails even at an increased cost. There is every reason for improving the quality of rails, as was very well shown at the discussion of the American Society for Testing Materials at its recent convention. Very likely one reason that improvement in the quality of rails has not been more marked during recent years has been the adherence to the Am. Soc. C. E. standard sections for the heavier rails. Those sections were devised, as Captain Hunt pointed out at the convention mentioned, by a committee which had to work absolutely in the dark. Very likely Captain Hunt could have gone farther and stated that the sections were laid down by that committtee with the understanding that they would probably need material modification, and were a compromise or an extension of the sections which experience had shown would be satisfactory into the field of technical speculation by a process of reasoning which was like that followed in estimating the consumption of water in cities at a future period. Unless the writer's memory is at fault, Captain Hunt himself predicted during the committee meetings that these heavy sections would probably have to be modified as soon as the mills began to roll them. This has proved true; the sections are not suited for their purpose, for they cannot be rolled economically nor can they be made of as high quality as other sections even when the utmost care is spent in their fabrication. The agreement of the mills and the railroad officials on this point and the harmony with which they are working to improve the present conditions is most encouraging, but inasmuch as the rails are but one feature of track it is suggested that the construction and maintenance of the track itself might very properly be taken up with the same thoroughness at this time, so that by the time the mills are rolling better rails they will be used in a better manner. At the convention of the American Society for Testing Materials, one railroad officer stated that if the mills could not furnish a better quality of rails, unquestionably they would be subject to some kind of legislation; it is only reasonable to expect that probably the same kind of legislation might be directed at the railroads if they do not improve their track methods. X.



Graphical Comparison of Typical Engines with a Few Recent Heavy Engines.

BRIDGE LOADINGS.

Sir: The article on pages 712 and 713 of The Engineering Record of June 15, "A Comparison of E-50 Loading with Recent Heavy Locomotives," is very interesting and valuable. I have platted on the diagram on page 712, showing the graphical comparison of equivalent uniform loads from typical engines and a few recent heavy engines, another line (see accompanying diagram) showing the equivalent uniform load by my formula, using the index 50,000. This loading I have called T-50,000. The curve of the T-50,000 lies just slightly above all actual loads and above Cooper's E-55 for all spans between 18 ft. and 50 ft. For spans under 16 ft. it is very close to Cooper's E-50 and for spans over 50 ft., up to 250 ft., it crosses the Erie Mallet twice at a span length of about 100 ft., and again at a span length of about 170 ft., but for all spans between 50 ft. and 250 ft. it seems to follow the curve of the Erie Mallet single engine without departing from it more than 2 per cent.

This system of loading was presented at a discussion of the committee report of the American Railway Engineering and Maintenance of Way Association and published in the "Proceedings" of its Seventh Annual Convention, Volume VII, page 211.

I thnk that a mere inspection of the diagram with this line on it is sufficient to show the value of this loading, and that it seems to more nearly meet the actual loadings of to-day than the Cooper series. Of course, a complete series of loadings can be made with this formula exactly as is done with the Cooper series, and they may run from T-25,000 for light narrow-gauge roads up to T-55,000 or T-60,000 for the heaviest structures now considered. The loadings will vary directly as the index numbers, the same as for the Cooper series. Very truly yours,

New York, June 26. A. W. Buel.

Corrugated Rails.

Sir:—In your issue of March 23 of this year you gave some information regarding an investigation of corrugations on railways made by the engineer of the tramways in your city. It may interest your readers to know that we have the same trouble on our tramways and also on our steam lines, where the corrugations produce such a special sound that we call the rails on which they occur "roaring rails." The engineers of our North-Eastern Ry. have been paying considerable attention to the subject, but have been unable to discover the cause of the corrugations. An examination of many corrugated rails failed to show any connection between the corrugations and the composition of the metal or its fabrication, nor did the ballasting, grade and curvature of the track have any apparent influence. A number of rails, some roaring and some quiet, of the same character and from similar locations were subjected to physical tests and microscopic examination. Their hardness was ascertained by the Unwin knife-edge test, which showed that the roaring rails were harder than others, while tension tests showed that the metal at the high points of the roaring rails was stronger as well as harder than that in the low parts. The microscopic and chemical examinations gave no clue to the cause of the corrugations.

Trams.

THE ENGINEERING RECORD

Published Weekly by the

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

114 Liberty Street, New York.

BRANCH OFFICES:

Chicago: Old Colony Building.
Philadelphia: Real Estate Trust Building.
Cleveland: Schofield Building.
San Francisco: Atlas Building.

London Office: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico..........$3.00 a year
Canada ....$4.50 a year
Foreign subscription ....$6.00 a year
25 shillings 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of The Engineering Record on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

Remittances.—Remittances should be made by check, New York draft, or money order, in favor of The Engineering Record.

Changes of Address.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

Back Copies.—No copies of issues prior to July, 1905, are kept on sale, except in bound volumes.

Date on Wrapper indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

Club Rate.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,250 copies are printed. Total circulation for 1907 to date 406,250 copies, an average of 14,509 copies per week.

TABLE OF LEADING ARTICLES.

Ethics, Law and Business Rules.

For a good many years the subject of engineering ethics has been discussed at meetings of technical societies. Until recently nothing came of this discussion, but a year ago the American Institute of Electrical Engineers turned over to a committee consisting of Dr. S. S. Wheeler, chairman; Dr. C. P. Steinmetz and Mr. H. W. Buck, the task of formulating such a code. At the recent convention of the Institute at Niagara Falls the committee reported a set of principles of professional conduct for the guidance of the electrical engineer, which is reprinted elsewhere in this issue. The committee reached the conclusion that it was impracticable at present to formulate an ethical code covering explicitly all the conditions which the electrical engineer may meet in his work, although it believed it to be desirable to record some of the principles which should be a guide, leaving it to him to make specific applications to his own work. The code was discussed at some length at the convention, but on account of constitutional limitations prohibiting any decisive action of a business nature affecting the Institute at a meeting for professional discussions of papers, no final decision regarding the report was reached. As the first attempt by a committee of a national engineering society to establish an ethical standard for its members, the report deserves a great deal of study.

In the first five paragraphs the code discusses certain general principles. It will be noticed, however, that there is no sharp line drawn between professional and business relations in this "general" section, although there is a fundamental distinction between the two. It goes without saying that whether a man be a consulting engineer or an employee on a salary, his relations with those about him may very properly be governed by the Golden Rule. Most people are content to acknowledge that that rule has never been equalled for comprehensive and concise statement; in fact, it was pointed out years ago at a meeting of the American Society of Civil Engineers that better compliance with it would remove the necessity of a code. There is always more or less difference of opinion, however, concerning the application of general rules to specific cases, and it is for this reason that a detailed code of ethics seems to be desired by a considerable number of engineers. In discussing the subject, however, they seem to forget there is such a thing as law in the land, and the legal relations between engineers and their employees or clients will always have to be established by courts and not by the resolutions of technical societies. The courts have many times indirectly drawn a distinction between the rules of conduct which should govern an employee and those which are binding on a professional man. The consulting engineer, like the lawyer, physician and architect, who claims to possess certain specialized knowledge which he places at the disposal of clients for a fee, has to regulate his conduct by legal rules different in some respects from those governing salaried employees. While all these rules are based on the elementary principles of complete justice to everyone, the engineer who works on a salary is essentially a subordinate and not an independent adviser retained for some special purpose. It has accordingly been considered necessary by many who have looked into the subject of professional ethics with considerable care that the first step in formulating any code should be to draw a distinction between professional and salaried men which would recognize the legal obligations of the two classes and thus avoid the pitfall of impracticability. This is shown in the code printed elsewhere in this issue, in the distinction drawn between the property rights of consulting and salaried engineers in their plans and data.

Among the principles enunciated in the code referred to is one that the electrical engineer should incline toward and not away from standards of all kinds. This seems to be rather out of place in a code of ethics, although it might be entirely appropriate in the regulations drawn up by a company for the guidance of its salaried employees. Just what relation exists between ethics and the adherence to or departure from standards it is difficult to understand. The Engineering Record has always held the opinion that an engineer should adopt standard plans and purchase standard machinery when it was to the interest of his employers or clients to do so, and that he should prepare special designs when the standards were not so suitable as special methods or appliances would be. It has been pointed out by many men on many occasions that the innovation of today is the standard of tomorrow, and that progress is only possible by departing from standards. This paragraph is specially referred to because it indicates a feature of the code which seems to be open to a certain amount of criticism, the attempt to include in a code of ethics a number of rules which have no ethical relations. The same criticism might be made of the attempt to incorporate in the code certain legal relations which the courts must settle in any controversies between engineers and their clients or employers. For example, it is stated that the electrical engineer may not accept commissions directly or indirectly from parties dealing with his principals nor be financially interested in inventions and apparatus unless the matter is understood by the principals, statements which are governed by judicial decisions and are discussed in legal text books. Again, it is pointed out that operating engineers should consider themselves responsible for defects in apparatus or dangerous conditions of operation and should bring them to the attention of their employers and urge remedial action. If the causes of the danger are not removed, they should withdraw, according to the code. It might be pointed out that this subject is fully covered in the law of negligence and of master and servant, which are the subjects of many text books.

The portions of the code relating strictly to ethics seem to be confined mainly to paragraphs 22 to 35 inclusive, on the relations of the electrical engineer to the general public and to the engineering fraternity. These paragraphs contain suggestions regarding several relations of the engineer that are not often considered. For example, it is stated that the engineer should not engage in controversies of a technical nature in the daily press with other engineers. As a general proposition this is a good rule to follow, since the specialist who endeavors to conduct a technical controversy in the newspapers is almost certain to suffer in the end from doing so. His audience does not know what he is talking about, most of the time, and he will suffer in comparison with an ignorant man who is able to use English vigorously in the enunciation of ideas which are worthless. But occasions may arise when it is desirable in the interest of the public for an engineer to combat what he knows to be erroneous statements of another engineer in the daily papers. On several occasions in recent years eminent civil egineers have accomplished not a little of good by letters to the newspapers pointing out the defects of plans for public works drawn up by other engineers who were not entirely familiar with the subject, but probably did the best they could. In the opinion of The Engineering Record, therefore, rule 23 of the code of ethics is not wholly advisable. Another rule in the code, No. 32, states that the electrical engineer should not take a position left by another electrical engineer without satisfying himself that the former had left it voluntarily or for proper reasons. This rule seems to be meaningless, for who is to decide what are "proper reasons"? In the case of engineers engaged on a salary to discharge specific duties, it is difficult to see just what ethical rule is involved outside of the customary business relations of employer and employee.

In making these critiicsms on the code, the intention is not to attempt to belittle the excellent work done by the committee. They deserve the thanks of all who are interested in improving the relations of engineers among themselves and with their principals. It is a good thing that such a proposed code has been drawn up by men of the high standing of the committee which prepared this statement, for something definite is presented for discussion. The familiarity of the members of the committee with the difficulties facing engineers connected with manufacturing corporations has doubtless led them to lay more stress on what may be termed ordinary business relations than a committee of civil engineers would be likely to do. This makes the proposed code particularly instructive to civil engineers, for it furnishes a new point of view from which to regard a subject they have long discussed. It is also interesting as an example of an attempt to combine ethical maxims with principles of law and rules of business conduct. In this respect it departs from legal and medical codes which have been suggested from time to time, and opens up a new field of discussion.

Unit Bids in Machine Installations.

In the preparation of quotations to present to a prospective purchaser of machinery, time is usually very valuable in the district office of a manufacturing company. Requests for quotations come in by telephone and telegraph to be later confirmed by letters, and generally the information is wanted at the earliest possible date. Such conditions tend toward the production of blanket rather than detailed unit bids, unless the latter are specifically requested. The advantages of having figures submitted on a unit basis are thus often missed.

Under present-day conditions the completion of engineering and industrial designs requires the use of as much comparative data on similar work as may be available. An installation will be better adapted to its specific service if the data of other comparable work is considered in connection with it, even though the detailed conditions may differ very broadly. If quotations are submitted in an itemized form allowing for a certain range in the size and number of machines selected, these figures will be extremely suggestive and valuable in making future estimates and checks, and will also permit minor modifications to be made in the specific design in hand without delaying the course of events to anything like the extent which obtains if a single blanket bid is required on each set of assumptions.

Thus, in the case of a factory which decides to equip all its important machine tools with individual electric motors, it is of great value to secure the price of each motor as well as the total cost of the installation. Even though the power estimates be made with great care, there often arise modifications of the original plans which necessitate new figures from the manufacturers at short notice. At the last moment the company decides to replace certain machine tools by new outfits of an improved type or to carry the individual drive plan farther than was originally intended. Again, there may be a contraction in the amount of new apparatus decided upon, resulting from an economical turn at a directors' meeting. Accurate estimation of probable cost must be prepared within a few minutes' time in many such instances, and if the quotations are prepared on the unit basis as well as on the basis of a lump sum, it is ordinarily a simple matter to modify the wiring and installation figures in the time available, so that prompt decisions may be reached. When different types of motors are at issue, as in weighing the merits of commutating pole and induction outfits for a given shop, the facility of reaching decisions with the minimum delay depends in no small degree upon the presence of figures for each individual motor in the submitted quotations. Doubtless it takes longer in the first place to secure such individualized prices, and in some instances they are of course not needed from any standpoint, but in the majority of instances where the equipment is at all varied or complex in character, it saves time in the end to secure unit bids. As time passes and machines depreciate and have to be replaced at different times a company never regrets knowing just what the original unit cost was.

The Contracts for the Ashokan Dams.

Bids for the large masonry dam and for the appertinent earth dams and dykes for the Ashokan reservoir have been advertised by the Board of Water Supply of New York to be opened on the sixth of August. These great works are designed to impound about 120 billion gallons in a reservoir twelve miles long, constituting the largest impounding reservoir yet undertaken for a public water supply. It is one of the main features of the additional water supply system for the City of New York, which is estimated to cost, when completed, about $160,000,000. A comparatively small contract has already been awarded for the construction of nine or ten miles of the main aqueduct north of Peekskill, but the award of the contract for these dams will mark an epoch, so to speak, in the progress of construction of this exceptional public work.

The main dam across Esopus Creek, a half mile below Bishop's Falls, is chiefly of masonry and is about 230 feet high above its foundation in the rock, forming the bed of the stream at the dam site. Although it is a masonry structure of unusual magnitude it does not surpass the new Croton dam either in total height, or mass of masonry, or total length, but it possesses certain features which give it a distinct character of its own. There are no serious foundation problems to be met and solved as far as may be judged by the results of the examinations which have been abundantly made, and are available for the information of all bidders.

The features which will impress both engineers and contractors at first sight are the provisions for a series of wells throughout the length of the main masonry structure, placed a few feet from its upstream face, for the purpose of draining away any seepage, and a number of joints through the structure enabling it to be built up in sections and at the same time affording provision for expansion and contraction. It is not the first time that the drainage of seepage water has been introduced in a masonry dam, although this particular method of making the provision has probably never before been introduced in so large a dam. The operation of such features of masonry construction will, doubtless, be observed with great interest after the completion of the work. Although there is not much diversity of opinion among engineers regardng either seepage through masonry or the movement of masonry masses when free to move under changes of temperature, but there probably would be a rather wide range of judgment as to the necessity of severing such masses in the one case, or the introduction of a cellular arrangement in the other. In any event it is at least progressive to anticipate the prevention of certain features of the actual performance as observed in nearly all high masonry dams so far built. The results of such experiences will add substantially to the accumulating sum of engineering knowledge of masonry structures of magnitude.

An examination of the specifications and form of contract shows that they have been prepared with scrupulous care, both as to the city's interest and as to a fair and just attitude toward the contractor. There have been certain features of administration of public works contracts in the City of New York, which redound neither to the credit of the city as a reasonable agent in dealing with its contractors, nor to its efficiency in a business capacity. Progress estimates are often most unreasonably delayed in payment, and final estimates are not infrequently held up for many months after the satisfactory completion of the work. The Engineering Record has commented pointedly upon these features of public works construction, which, by their injustice to experienced and competent contractors, enhance correspondingly contract costs, and tend toward serious delays in the completion of the works affected by them. It is a matter of gratification therefore to find that the initial contracts in the series of greatest public works ever yet undertaken for any city disclose a radical change for the better in these respects, without in any way failing to safeguard with equal efficiency, the interests of the city. Although the aggregate of the bonds required amounts to $1,000,000 in addition to a certified cheque for $250,000 to accompany the bid, the payment of progress estimates is made obligatory within thirty days of date, and the final estimate within forty days of date. This provision is as wise for the city as it is advantageous for the contractor. The prices bid by the latter under such circumstances need cover only the legitimate costs of doing the work. The city puts itself on record as a prompt paymaster, and if there are any delays beyond the periods named, the municipality binds itself to pay four and one-half per cent. interest on the amounts due, and to make those interest payments practically a part of the immediately succeeding progress estimates.

These essential features of the contract for the Ashokan dams are unique in the history of New York City municipal construction. They cannot fail to be attractive to a class of experienced contractors whom it is desirable to secure as constructors of these works. In spite of the fact that the recent attempts to sell bonds for the city have not been successful the credit of the city is excellent, and there is no reason to believe that it will ever be otherwise, at least within any ordinary period of time. It should, therefore, avail itself of its good financial standing and improve every advantage which that condition offers. By prompt payments to contractors who have executed their works in a satisfactory manner, the prices tendered for public works will be reduced to a minimum by relieving the bidders of an interest account which they would otherwise have to carry. The Board of Water Supply has done well in making this fundamental departure from bad precedents and worse practice. It is safe to predict that it will secure highly satsfactory returns in reasonable prices and efficient prosecution of work.

Promoting.

The opportunities which engineers have for discovering water powers, locating new lines of railways and utilizing various natural advantages which they discover in their work are so many that some surprise is occasionally expressed that they rarely take advantage of their chances of this nature. Probably the reason is to be found in their lack of information concerning the manner in which to promote an undertaking of this sort. The word "promoter" has a very bad sound in the ears of many people. It stands for a man who makes glittering promises which are never fulfilled, in their opinion, whereas the real promoter is one of the most useful men a community can have. Through his knowledge of local conditions and insight

into their capabilities he is able to suggest developments that are for the benefit of the district, and an honest promoter accordingly deserves local encouragement. It has been repeatedly noticed, however, that engineers do not seem to possess the faculty of stating their propositions of a new nature in such a form as to make them interesting to capitalists. They wrap the project up in all sorts of technical details which nobody but an engineer cares anything about and leave out the very essential facts which any man of business must have presented to him before he will even stop to consider a proposition. It is essential to have the technical details of any such enterprise worked out fairly well before the financial details can be stated, but it is the financial part of the proposition which is interesting to the capitalists, and unless that can be presented clearly, concisely and convincingly, he will not spend a moment's time in looking into it. These considerations indicate why it is that the successful launching of any enterprise makes a considerable expenditure of money necessary. People sometimes wonder why it is a capitalist takes no interest in the announcement that there is a water power capable of furnishing several thousand horse power within 15 or 20 miles of a large city. As a matter of fact there is no business interest to him in such knowledge. The time and money he would have to spend in investigating this statement can generally be made to yield a larger return if expended on his regular lines of business. Hence a good many people having knowledge of such opportunities for investment, who have presented them in a half-baked condition to capitalists, look upon the latter as extremely unprogressive and miserly men, when the fault really is due to the manner in which the propositions have been presented.

Before any proposition is likely to be of interest to capitalists it must be put on a business basis and this involves a great deal more than a mere rough estimate, made up some evening, of what it is likely can be realized from the resources to be developed if everything goes along happily. Take the case of a water power as an example. The mere existence of such a power is of no financial interest, as a rule. Unless the engineer and his friends have the money necessary to develop the power and construct the transmission lines to the nearest cities, then it is necessary to go to capitalists for financial help. In order to present the matter to them properly it is not only necessary to have a complete and conservative estimate of the cost of building all the works and of the immediate and probable future demand for power, but it is also necessary to have a completely organized company, with franchises, charter and options on all properties. Securing such evidences of good faith, which are necessary to enlist outside capital, involves the expenditure of considerable sums, and these it is absolutely necessary for the promoter and his friends to raise. Moreover, it rarely happens that the people who will underwrite a bond issue are willing to have any portion of the money they advance used for preliminary and prompting expenses. Although such expenditures are entirely legitimate and are to be considered as part of the capital necessarily embarked in the enterprise, it is essential that they should not be represented by anything more than a certain amount of stock in the enterprise. Failure to appreciate this view which is held by bankers and trust companies has been the rock on which a number of enterprises have been wrecked. People looking for help rather than giving it have to accept conditions as they are and cannot undertake to reform a money market condition which does not please them.

Large undertakings nowadays can be best brought to the attention of the public by an engineering promoter through one of the contracting-engineering companies which maintain banking departments. These companies do not undertake small enterprises, however, and the engineer who has a good thing in mind should do his best to interest local people in it before going to the large cities for capital. Moreover, it is necessary for him to arrange matters so that the capital which is advanced for preliminary expenses will be represented by stock, as before stated, for if any attempt is made to dispose of any part of a bond issue in return for money advanced for the purposes mentioned, the sale of the remaining bonds will be rendered practically impossible. Few people care to underwrite an issue of bonds unless the entire issue can be given to them, so that they can completely control the selling price. If this is not done and a few bonds are held by local people, circumstances may arise which will lead the latter to sacrifice some of these bonds for a low sum, thus establishing a price for them which will practically prohibit the underwriters from making any money on the bulk of the issue. It is also very necessary to have a thoroughly responsible lawyer pass upon every step of the proceedings, so that the validity of the bonds and the security of the investment in the undertaking shall be unquestioned. If a proposition has been investigated by engineers who are in good standing among capitalists, its proceedings are legally correct, and the undertaking has the backing of local bankers to the extent of their means, the project may be taken to the larger cities for final financial arrangements with some expectation of success.

Attention has been drawn to all these details because they emphasize the fact, which has been the wreck of a good many ambitions, that by the time all the work of launching a new enterprise has been carried through, the share of the promoter will have dwindled to a small percentage of the stock. This is a condition that must be recognized at the outset, for any promoter who seeks to retain control of an enterprise which he cannot finance is endeavoring to accomplish the impossible. All he can hope to do is to retain a reasonable share of the stock, so that, if his predictions come true under careful management, he will receive a reasonable return on the expenditure of time and money which he and his friends have made. Even this return must be foregone unless the original promoter takes care that all the preliminary steps of expert examination, incorporation, and preliminary organization are thoroughly well done and the local capitalists behind him are friendly and will use their good offices to prevent advantage being taken of him.

Notes and Comments.

THE THIRD-TRACKING of the elevated railways on Second and Third Aves., New York, has luckily been brought up again for discussion, owing to the fact that such matters will be hereafter under the charge of the Public Service Commission, and its policy on such subjects has not yet been determined. The Board of Rapid Transit Railroad Commissioners which went out of office last month was positively opposed to adding a third track on these elevated structures, and for this reason no improvement of transit facilities on the Second and Third Avenue lines was possible. As a matter of fact third tracks have been laid on parts of both of these lines, and are used for storing cars when the traffic is light. The additional trackage to make the complete third lines will not be very great and the need for it seems so strong that a good many people in New York who have to do much traveling during rush hours have felt that the additional tracks ought to be permitted. It is true that an elevated railroad is not a thing of beauty, but it is also true that the addition of a third track at places where it does not already exist would be such a great advantage to a large portion of the public that the slight additional obstruction to light which its presence would cause would be more than outweighed by the benefits to be derived from it. Since the elevated structures are already in position, it seems good public policy to allow them to be utilized to the maximum.

FRANCIS B. THURBER, who recently died in this city, was one of the valued advisers of The Engineering Record in its early days. The paper was established as a journal to spread a knowledge of sound sanitation. This included not only measures to improve plumbing in houses and the sewerage and water supply of cities, but also various important projects to insure purity in food products. His wide acquaintance with men in public life, his personal interest in the affairs of the city, and his knowledge of the measures necessary to prevent the injurious adulteration of food materials, made him a valued counselor, and placed The Engineering Record under obligations to him many times. In fact his willingness to devote a large part of his time to public affairs and to the interests of his friends resulted in his entrusting too much of his business to people unable to carry the responsibilities. The large business he built up was ruined through no fault of his, and at the age of fifty-seven he began life again as a lawyer, being admitted to the bar in 1899. His energy and independence, even when embarking on new work at an advanced age, won him the admiration of many who before had not fully appreciated his sterling qualities.

SEVERAL ROAD IMPROVEMENT projects have been abandoned this year on account of the great objection of the taxpayers to paying money for constructing roads that would attract automobiles. At South Kingstown, R. I., for example, where important improvements were proposed, the opinion of the town, as expressed at a meeting called to consider the matter, was that such good roads would be advisable if the inhabitants of the town could use them with comfort, which was formerly possible but was now out of the question, for the high speed at which automobiles were driven through the town put citizens using the roads in peril of their lives. In view of the strong agitation for highway betterments which is being conducted by motor car enthusiasts, it might be well for them to consider carefully these instances of the determination to postpone road improvements until some laws were passed and enforced which will prevent speeding in towns. It will be recalled that the same revulsion of feeling regarding highway improvements occurred during the last few years of the bicycle craze, when the noisy mobs of cyclists made themselves so obnoxious in many localities that the residents preferred to go without the benefit of better highways than to be overrun on holidays and Sundays with a class of people distinctly undesirable. While The Engineering Record has no sympathy with the attempts of some towns to levy tribute on every owner of a motor car who goes through the streets at a speed above a crawl, it is thoroughly convinced that highway improvements will be more and more retarded unless laws are passed and rigidly enforced which will prevent the fast speeding of cars through streets. The clouds of dust and the odor of gasoline they leave behind them are unpleasant enough without being accompanied by the danger of life and limb to driver and pedestrian. A further evidence of the same feeling is to be seen in the vigorous protest from all parts of the State of New Jersey against permitting the Vanderbilt Cup race to be held there.

THE FORTIETH ST. TRACK ELEVATION OF THE CHICAGO JUNCTION RY.

The Fortieth St. branch of the Chicago Junction Ry., in Chicago, extends from a connection at Forty-second St. and Lake Michigan with the eight tracks of the Illinois Central R. R., north to Fortieth St. and thence west in that street for approximately 2½ miles to the Union Stock Yards. The tracks of this branch cross twenty-six city streets and a number of railroad tracks, over which the trains of eight trunk-line railroads enter the city. The branch provides an entrance to the Union Stock Yards for the following railroads: Illinois Central; Michigan Central; Cleveland, Cincinnati, Chicago & St. Louis; Lake Shore & Michigan Southern; Chicago, Rock Island & Pacific; New York, Chicago & St. Louis; Erie; Wabash; Chicago, Indianapolis & Louisville, and the Pennsylvania. In addition to the heavy traffic carried over the tracks of this branch between the Union Stock Yards and the various railroads with which it connects, a number of industries in the vicinity of the Yards contribute a large volume of traffic to it.

According to the new arrangement of tracks the Chicago Junction Ry. will have one, and the South Side Elevated Ry. two tracks for about ¾ mile from the lake front. The single track of the former rises on a grade from the lake until it is high enough above the street at the crossing of the first street west from the lake to permit that street to pass under the track. The two tracks of the elevated railroad are carried on a steel structure in this distance and thence continue at the same grade as the single track of the steam railroad for nearly three-quarters of a mile to a point where they rise on an incline and connect with the three main-line tracks of the elevated railroad. The steel structure on which these three tracks are carried parallels the steam railroad from this connection for about a quarter of a mile and then turns to the north and crosses over that railroad. From the point where these main-line tracks turn to the north a double-track branch line from the elevated railroad is being built to the stock yards; the two tracks of this tracks of the Chicago Junction Ry. cross at right angles, a six-track elevation carrying the Lake Shore & Michigan Southern and the Chicago, Rock Island & Pacific railroads four city blocks to the west of the point where the main line of the elevated turns to the north. Formerly, the tracks of the Chicago Junction Ry. passed under this elevation; with the new arrangement these tracks cross this elevation on a single-span double-track through Pratt truss bridge. The elevated railroad will be carried over the track elevation on a separate bridge at one side and above the Chicago Junction bridge. The three crossings are thus made at three different grades, the street passing under the original elevation carrying the Lake Shore and the Rock Island tracks, the Chicago Junction tracks on the bridge being above that elevation and the tracks of the elevated railroad still higher, and at one side. In both directions from this crossing of the original track elevation the tracks of the elevated railroad are carried on a steel structure which spans the tracks of the Chicago Junction Ry., between a row of columns along each side of the right of way of the latter.

The tracks of the Western Indiana R. R., a

Construction Work in Congested District.

Section Extending from a Street to an Alley.

This branch of the Chicago Junction Ry. was built at the grade of the streets many years ago when the district through which it passes was an outlying residence district. The area on both sides of the branch for over a mile back from the lake is now one of the most populous of the better residence sections of the south side of the city; to the west from this area the district traversed by the branch is also quite congested, but grades off from the residence section into factories and other industries. Many of the streets which the tracks of the branch cross carry important north and south street railway surface lines and on several of these streets there is a large volume of vehicular traffic.

In order to eliminate the numerous grade crossings of streets and of the various trunk-line railroads the tracks of the Fortieth St. branch are being elevated on a fill carried between heavy concrete retaining walls. The South Side Elevated R. R. is also building a double-track branch line which closely parallels the branch of the Chicago Junction Ry. from Lake Michigan to the Union Stock Yards. The location and erection of the steel structure for this elevated railroad, the narrow right-of-way in which the construction work had to be carried on, the heavy freight traffic that had to be handled over the tracks which were being raised, and the necessity for keeping the streets crossed by the branch open for service at all times, rendered this track eleva-

line are on an elevated steel structure which spans the tracks of the Chicago Junction Ry. for several blocks, and then parallels them at one side to a point near the yards.

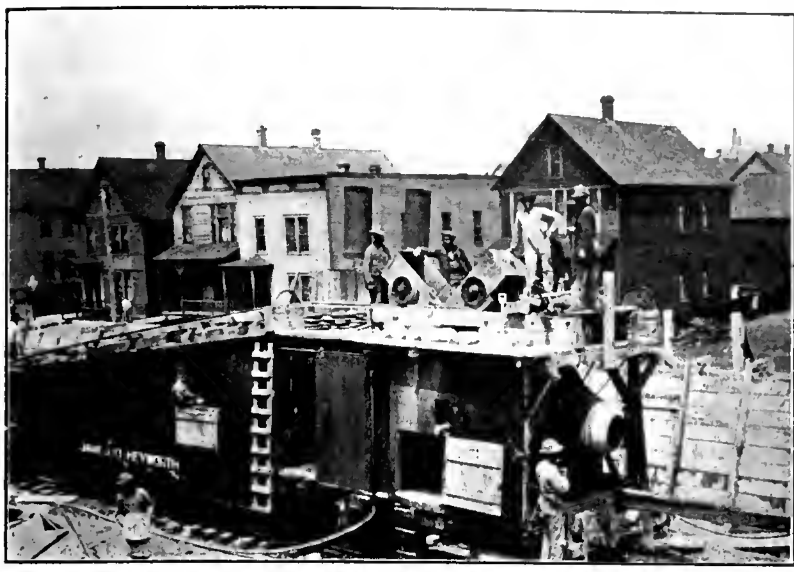
The Chicago Junction Ry. has two tracks for about a mile to the west from the point where the branch of the elevated railroad rises on the incline, and then three and finally several tracks just before entering the yards. In the entire distance from the lake to the yards the tracks are carried on a fill between two parallel gravity-section concrete retaining walls, the street crossings being made on through-plate-girder bridges having solid trough floors filled with concrete. These bridges are carried by concrete abutments and by a row of steel columns at each curb line.

The elevation has a nearly uniform width for three tracks from the lake to within a short distance of the yards, where it widens out to accommodate the extra tracks. From the first street crossing at the lake to the point where the two tracks of the branch of the elevated railroad rise to connect with those of the main line, the track elevation carries the single track of the steam railroad and the two elevated railroad tracl In this distance the city blocks are 400 to 550 ft. long, and as a 20-ft. alleyway is crossed on an overhead bridge between each two street crossings, the concrete retaining walls and the bridge abutments form a series of huge rectangular boxes half a city block in length.

terminal road on which several trunk lines enter the city, is also crossed at right angles by the tracks of the elevated railroad and of the Chicago Junction Ry. a short distance to the west from the crossing of the track elevation just mentioned. The elevation of the tracks of the Western Indiana R. R. to eliminate grade crossings has recently been completed at this point. The elevated railroad structure crosses over this elevation, while the Chicago Junction tracks drop down and pass under it at about street grade. The tracks of the latter rise again beyond this crossing and continue on an elevation into the Yards.

The grade of the tracks of the Chicago Junction Ry. at Halsted St., which is near the end of the present elevation, were formerly separated by carrying the street over the tracks on a three-span bridge with long fill approaches. This bridge has been removed, the 40,000 cu. yd. of material in the approaches to it are being taken out with steam shovels and the street will be carried under the track elevation. The elevation will be carried over this street on a bridge, the street being depressed somewhat to secure the necessary clearances.

The construction of the retaining walls for the track elevation and the placing of the fill between those walls have been carried forward in such order as the heavy traffic would permit.



Dump Car in Partial Dumping Position.

One Type of Concrete Plant for Walls.

before tracks were raised. A track, or tracks as the case might be, were then laid on a temporary pile trestle erected over the completed wall, traffic being diverted over this trestle while the other wall was under construction, and until the fill had been made. The great volume of traffic to be handled, particularly on the tracks west of the crossing of the Lake Shore and the Rock Island elevation, and local conditions necessitated much diversion from this method. In places the fill was carried up under traffic and the retaining walls built later, the sides of the fill being held meanwhile by a cribbing of ties.

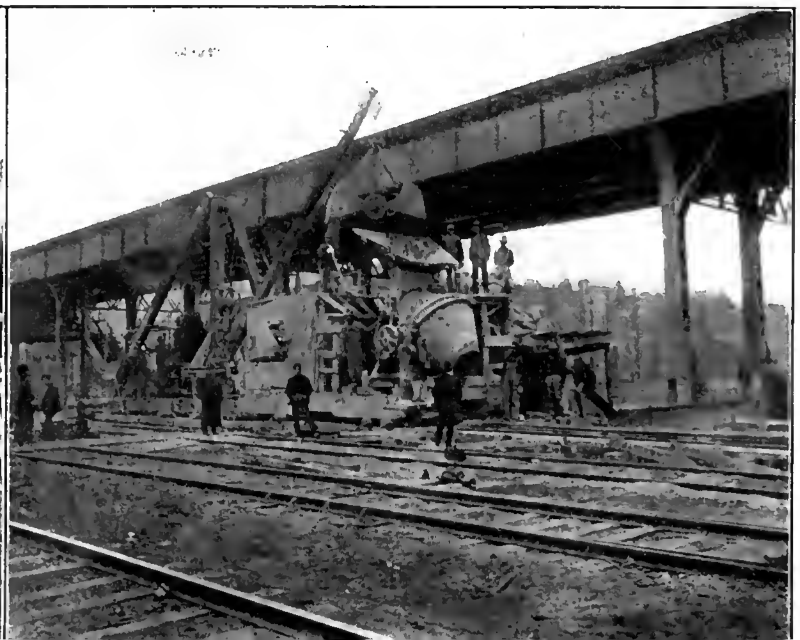
The portion of the elevated railroad structure which carried the three main-line tracks in the short-section where the latter parallel the tracks of the Chicago Junction Ry. had only two tracks and was partly over the site to be occupied by the elevation when operations were started on the latter. This structure was moved several feet to one side, raised 5 ft. and a third track added to it under traffic. A complete description of the manner in which this work was handled was published in The Engineering Record for March 3, 1906.

The excavation for the footings of the retaining walls for the track elevation was for the most part in sand or sandy loam which required the sides of the trenches to be sheeted closely in most of the work. The trenches were nearly all made with a Page scoop-bucket excavator, the sides of the trench being finished by hand. The sheeting was also driven by hand to prevent the loose soil sliding into the trenches.

A portable concrete mixing outfit specially adapted to the work was used in placing the footings. This outfit was mounted on a 12 x 24-ft. platform carried by three pairs of longitudinal 8 x 16-in. stringers. This platform ran on rollers on a runway laid on each side of the trench for the footing. A 30 cu. ft. Smith mixer carrying a charging hopper was mounted on the front end of the platform so concrete could be dumped from it into the footing. The engine driving the mixer was also carried by this platform and storage space for enough cement in sacks to keep the outfit in service was provided at one side of the platform. The concrete for the footings was made in the proportions of 1 part cement to 8 parts pit-run gravel. The latter was delivered from the pit in gondola cars from which it was unloaded directly into the charging hopper of the mixer by a 1-yd. clam-shell bucket handled by a stiff-leg derrick. This derrick and the hoisting engine operating it were mounted on a second portable platform which ran on rollers on the same runways that carried the mixer platform. It was placed immediately in the rear of the latter with which it was moved back and forth along the work. The normal output of this outfit was about 220 cu. yd. of concrete per 10-hr. day, with 22 men, wherever the traffic conditions permitted steady running.

Owing to the limited space available this mixing outfit was generally set up at the intersection of a wall and the street and retained in one position until the footings on that side of the elevation had been completed for a half a city block each way from it. The mixer discharged into 1-yd. dump cars on four-wheel trucks, these cars being operated by hand on a 30-in. gauge track on each side of the trench for the footing. If more space had been available, the outfit could have been made readily portable so it might be moved forward as the work progressed. As it was, the single service track on which gravel was delivered was the only part of the right-of-way occupied by the operations on the footings, and this track was open for traffic when the mixer was not in service.

Two types of concrete mixing outfits were employed in building the retaining walls above the footings. One of these is very similar to those which have been employed on much of the track elevation work in Chicago. In this outfit a Drake mixer was mounted on the front end of a 34-ft. car, and together with its engine was protected by a housing, having a tight roof. A charging hopper surrounded by a working platform was built over the mixer in the roof of this housing. The pit-run gravel used in the wall was delivered in gondola cars, which were placed in a string of three or four immediately back of the mixer car. Plank runways were laid along the top of each side of these cars, leading from the latter up to the charging platform over the mixer. The gravel was hauled to the latter from the cars on these runways in wheelbarrows. The cement was kept in a box car at the far end of the string of gravel cars and was also delivered to the mixer in wheelbarrows. The mixer discharged on a traveling conveyor belt



carried by a 30-ft. boom that could be swung through a radius of 90 deg. and could be raised and lowered at the end through 14 ft. The conveyor discharged the concrete into a bottom-dump hopper bucket attached to the end of the boom, this bucket preventing the gravel from being separated from the remainder of the concrete and also permitting the discharge of the concrete to be directed.

This outfit operated on a single track. It was moved forward or back by a cable attached to an anchor ahead and one in the rear of the string of cars, the cable winding around a drum driven by a set of gears on the deck of the mixer car. The engine driving these gears and the mixer engine were run by one man who also fired the two boilers which supplied steam to these engines.

The other outfit used on the walls, although embodying similar general features of arrangement and operation, was entirely different from this first outfit in several important particulars. This mixing outfit was mounted on a standard-gauge double-truck car, 40 ft. long at the sills. A 3⁄4-yd. Smith mixer and its engine were set at the front end of this car so the mixer could discharge into a bucket on a suspended platform just clearing the ground. A housing with a tight roof was built over the whole mixer car, a charging hopper being placed in this roof directly over the mixer. The gravel for concrete was delivered in gondola cars which were placed in a string of three to five in the rear of the mixer car; the cement was stored in sacks in a box car at the end of this string. A portable 30-in. gauge track was laid along each side of the tops of the gondola cars and extended up on the roof over the mixer car where the two tracks joined in a double-throw switch and were continued as a single track to the charging hopper of the mixer. The gravel and cement were delivered to the latter on these tracks in dump cars of a special type. The mixer discharged into a 3⁄4-yd. bottom-dump bucket in which the concrete was handled to place in the forms by a stiff-leg derrick mounted with its hoisting engine on a second car.

The great drawback to portable concrete mixing outfits of types similar to this one, such as have been employed so extensively on track elevation work in Chicago, has been the difficulty and expense of delivering the concrete materials from the cars to the mixer. The details of the portable tracks used in connection with this particular outfit were so carefully developed, however, and the design of the special dump car used on them was so well adapted to the work, that 8 to 10 men could deliver the cement and gravel to the mixer as fast as the latter could turn out concrete; from 20 to 22 men are generally required in delivering the materials in similar outfits of this kind when wheelbarrows on runways are employed for this purpose, and even with such a force difficulty is experienced in supplying the mixer rapidly enough during hot weather.

The rails of the two 30-in. tracks which were laid the length of the gondola cars in which the gravel was delivered are both attached in pairs toward the ends of 4 x 6-in. tie timbers, 11 ft. long, the timbers being spaced 5 to 6 ft. apart. These timbers are laid transversely on top of the cars so one 30-in. track comes directly over each side of the cars. The rails are attached to the timbers by a special form of fastener, which is clamped to tie plates on timbers by a U-bolt and can be drawn from the plate by pulling a small latch and without loosening any bolts. The tie plates being firmly fixed to the timbers, the latter can be laid on the cars and the rails attached to them at gauge by the fasteners very quickly. The two tracks are rarely dismantled, however, when once set up on a section of work, as they are light and can be lifted readily in sections. When the gravel has been unloaded from a string of gondola cars, the two 30-in. tracks are lifted from them and placed on another string of loaded gondola cars on an adjacent track, or if no other cars are available, or there is no parallel track, they are set on light wooden horses until more cars are brought in.

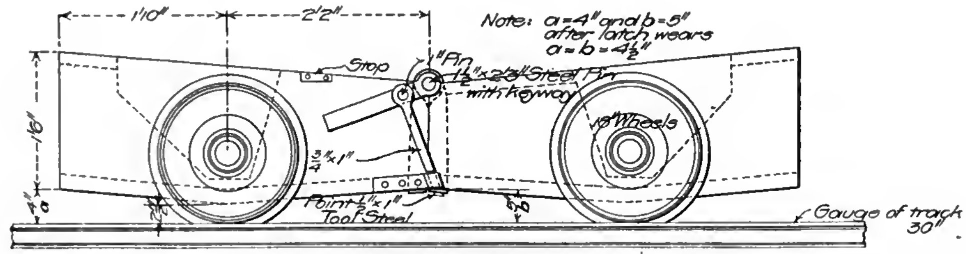
As the gondola cars vary considerably in height, a bracket has been devised to carry the ends of the 4 x 6-in. track timbers, which permits the tracks to be brought to grade over low cars without any difficulty whatever. Each of these brackets is an A-frame built of wooden strips, the legs of the frame being double with the two halves of each leg spaced apart in order that the legs can be placed astride the side of the gondola car. The top of the frame is built to carry one end of a 4 x 8-in. track timber. A row of holes is made in each double leg of the frame, so bolts may be placed in these holes and the frames set at different heights by changing the positions of these bolts, on which the frame rests.

A special dump car used on these tracks was designed and patented by Mr. O. E. Strehlow, the patent being controlled by Mr. James O. Heyworth, the general contractor for this track elevation. The details of this car are shown in an accompanying illustration. The car has a long, low body built of steel plates; this body is divided in half at its transverse center line, the two halves being attached together on each side by a hinge at the top. Each half is carried by a pair of 18-in. flanged wheels with dust-proof bearings which are attached to the side of the body. Each pair of wheels is placed slightly toward the center of the car from the center of gravity of the half which they carry, but when the car is loaded the center of gravity of each half of the body is toward the middle of the car from the wheels. The two halves of the body are held horizontally by a latch on each side of the body, these latches each being attached to the hinge on the side of the body they lock. A lever extending from this hinge carries a 3⁄4 x 1-in. latch strip which passes through a band attached to the lower edge of one half the body and also through a hole in a band on the bottom of the other half of the body.

The latch is loosened by pulling the lever and drawing the latch out of the hole in the band on the bottom. When both latches are unlocked the eccentric position of the wheels causes the center of the body to drop, the two halves of the body turning on the hinges so as to bring the ends of the body quickly together in an elevated horizontal position, thus discharging the contents along the bottoms of the halves, which are brought to a vertical position by the movement. The impact of the two halves coming together loosens the contents of the car and the body of the car is also shaped to facilitate the removal of the contents, the bottom, sides and top of both halves all converging toward the transverse center line. When the car is empty the center of gravity of each half is toward the end from the wheels so the car rights itself after it has dumped.

These cars are not any higher than an ordinary wheelbarrow and as they have a much lower center of gravity and greater wheel base than the latter, gravel can be shoveled into them with no danger of tipping and with greater speed. The cars each hold enough gravel for one charge of the mixer, but may be made any size desired. All parts of them have been made to stand the hard service to which they are subjected, with the result that two of these cars which have been in use for over a year are in practically as good condition as when new.

A double-drum friction hoist was placed on the roof over the mixer, and at the end of the track on which the dump cars were brought to the charging hopper of the latter. The shaft of this hoist was driven by a chain on a sprocket wheel on a shaft of the mixer engine. The cars were each drawn along the track and up to the charging hopper by a cable on one drum of this hoist. Two cars could thus supply materials to the mixer as fast as the latter could produce the concrete. The cement was delivered from the box car at the end of string to the platform around the charging hopper on top of the load of gravel in one of the dump cars.



Special Steel Dump Car.

A 3⁄4-yd. bottom-dump hopper-shape bucket into which the concrete was handled from the mixer to place was also designed specially for this work. The bottom was made in two overlapping halves, each of which was hinged to the sides of the bucket and was arranged on the lever that controlled the two so the amount of opening could be varied. With this bucket concrete could be placed in comparatively narrow wall forms without difficulty.

The entire outfit, including the material cars and the derrick car were moved in either direction along the track by a traction gear on the car carrying the concrete mixer. This gear was driven by a 24-h.-p. duplex marine engine on the car. The shaft of the engine carried a 12 x 22-in. pulley wheel with a 11½-in. paper friction face bearing against a 12 x 32-in. iron rim pulley wheel on a shaft geared to the traction gear. The latter drove a pair of 2-ft. grooved sheave wheels for 1-in. wire cable, these wheels being placed in tandem, 4 ft. 9 in. apart on centers. A 1-in. wire cable was wound six times around the pair of sheave wheels and attached at each end to an anchor in the track; by winding up on one end and paying out on the other end of this cable the entire outfit could be moved in either direction. The sheave wheels were swung below the frame of the car and the cable brought on them at the under side from both ends in order to avoid any downward pull on the car frame.

The design and arrangement of this gear gave the latter enough power to pull the mixer car and five loaded material cars up a 5 per cent. grade. Since much of the track on this elevation work was raised between streets with material from the excavation for the wall footings, it was a succession of humps and grades during the time the concrete work was in progress, so this strong tractive force was of much value in

moving the outfit along the wall as the concrete was carried ahead in horizontal layers. Furthermore, the placing of the gear below the floor and the general arrangement of the interior of the mixer car provided room for a coal storage space 8 ft. wide at one end of the car and ample space for the 42-in. vertical boilers which supplied steam to the two engines on the car.

Mr. J. B. Cox is chief engineer of the Chicago Junction Ry.; Mr. O. F. Cole is assistant engineer in direct charge of the Fortieth St. track elevation. The contract for the excavation, concrete, timber work, pile driving, street depressions and so forth on this track elevation was carried out by Mr. James O. Heyworth, general contractor, of Chicago; Mr. O. E. Strehlow, M. Am. Soc. C. E., associate of Mr. Heyworth, devised and directed the construction and operation of the various special plants which have been described. Mr. Wm. Eesley is general superintendent for Mr. Heyworth. The principal item of the contract was 150,000 cu. yd. of concrete, although the pile-driving, timber construction and street depressions also constituted large quantities of work.

THE COLLAPSE OF A BUILDING into the excavation for a large structure alongside it, which happened in Cincinnati on July 2, calls attention to the necessity of thoroughly shoring all adjoining buildings when a structure is torn down and they are left exposed. The brick building which fell at Cincinnati was four stories high, about 120 ft. deep, and 22 ft. on the street front. It had been shored in the usual manner, according to reports, and its fall was probably due to the weakening of the shores. This may have happened in two ways, judging from the information at hand concerning the condition of the work at the time of the accident. One cause may have been the blasting of a large mass of concrete in the cellar of the building which was being torn down, while the other cause may have been the loosening of the wedges at the feet of the shores by the workmen who were clearing away the débris in the bottom of the excavation, where a large mass of refuse building material had been allowed to collect and was then being removed. It is often seen in the work of demolishing buildings that the class of men employed do not possess sufficient intelligence to appreciate the importance of keeping shores firm.

The Quebec Bridge Superstructure Details.—III.

The Upper Part of the Center Posts.—A maximum stress of nearly 16,000,000 lbs. is transmitted from the top chord of the anchor arm to the top chord of the cantilever arm through the top of each main post. Stresses of about 3,500,000 lbs. are also brought to the same point by each of the two main diagonal members converging there; these forces produce a resulting vertical stress of 9,900,000 lbs. in the upper part of the post which is made separate from the main part of the post and special in order to better provide for the transmission and resolution of stresses. The different members theoretically intersect at a common point where their center lines meet, and where, in ordinary construction, a single pin would receive all the members.

In this case, however, there are thirty 16x2-in. I-bars in each panel of the top chord, making 60 in all besides 12 webs for pin-bearing in the main posts and two webs for the bearings of each of the inclined members, thus making a total of 76 large bearings to be assembled at this point. If these were all grouped on a single pin, it would be impossible to reduce the bending moments enough to avoid makiing the pin of great diameter, and its length would require to be over 20 ft., dimensions which are obviously impracticable. The connection was therefore designed as a special unit to unite the different groups of members at this point and is virtually a complicated multiple link provided with four 12-in. pins, each of which receives only the bearing for a single member and transmits its stress to the link which distributes it among the other members. The heavy reinforced vertical longitudinal plates required for the bearings of the pins are connected rigidly by transverse diaphragms and an elaborate construction is provided to distribute the combined stresses on the four webs of the main section of the post.

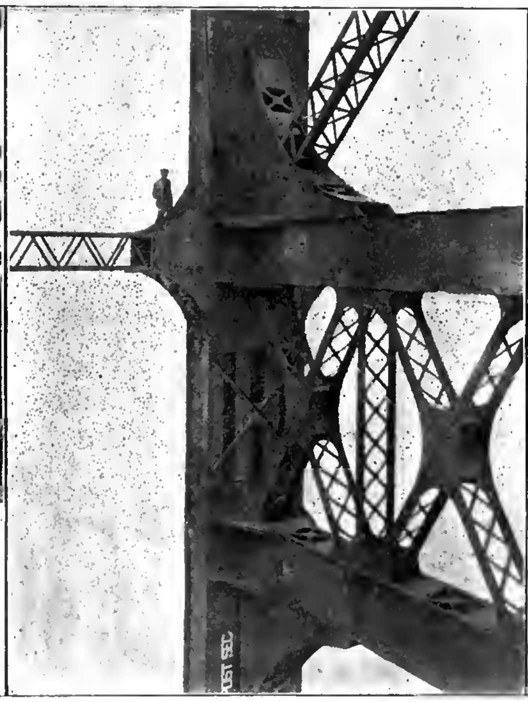
In order to limit the special construction to as small a member as possible, and to facilitate its assembling in the shop and particularly to reduce the dimensions to those conveniently handled in the boring and planing machines, this member was made entirely separate, as a cap, field connected to a horizontal bottom base plate in the top of the upper section of the main post. The cap is 10 ft. long parallel to the bridge axis, 9 ft. 8 in. wide at right angles to it, about 20 ft. high and weighs 230,000 lbs. The shop drawings for it include 19 main elevations and plans, besides several smaller sketches and details and entirely cover a 32-in.x12-ft. tracing which required the entire time of an expert draftsman for many months in its construction.

The cap has 12 longitudinal diaphragms or ribs connected by five vertical transverse diaphragms and, for convenience in manufacture and erection, it was made and shipped in three separate parts, assembled and bolted together on top of the main post. The two center ribs and the corresponding part of the horizontal base plate form one portion and the other two symmetrical portions each consist of five massive vertical longitudinal pin-bearing webs with their connected diaphragms and their base plates. Although nearly symmetrical about its longitudinal and transverse center line there are slight differences on the outer arm and cantilever arm sides which necessitate special construction throughout.

In order to make the pin bearings from 3 in. to 4 7-16 in. in thickness as required, the longitudinal webs of the ribs are made with plates 7/8 in. thick, reinforced on both sides with plates about 3/4 in. thick. Their upper portions serve as short horizontal ribs connected to the eye bars in the outer and cantilever arm and the special reinforcement for ribs which do not receive the outer members are double pairs of 1/2-in. and 9-16-in. plates 10 ft. long. The eye bar pins engage all ribs and the upper ends of the latter are stiffened and connected by transverse diaphragms each side of the pins, four in all. The lower pins, for the diagonal members, although extending completely through the cap, engage only two pairs of webs on each side, the other webs being cut away to give abundant clearance for these pins.

In order to clear the top chord eye-bars, all transverse diaphragms except that on the center line are omitted in the upper part of the cap. Below the eye-bars the webs are connected by four transverse diaphragms, one each side of the lower pin, and additional center diaphragms are provided between the pairs of ribs which afford bearing for the pins in the diagonal members. All diaphragms have I-shaped cross sections made by single web plates from 1/2 in. to 3/4 in. in thickness and four flange angles except the diaphragms on the center line between the outer webs which are made with double sets of vertical

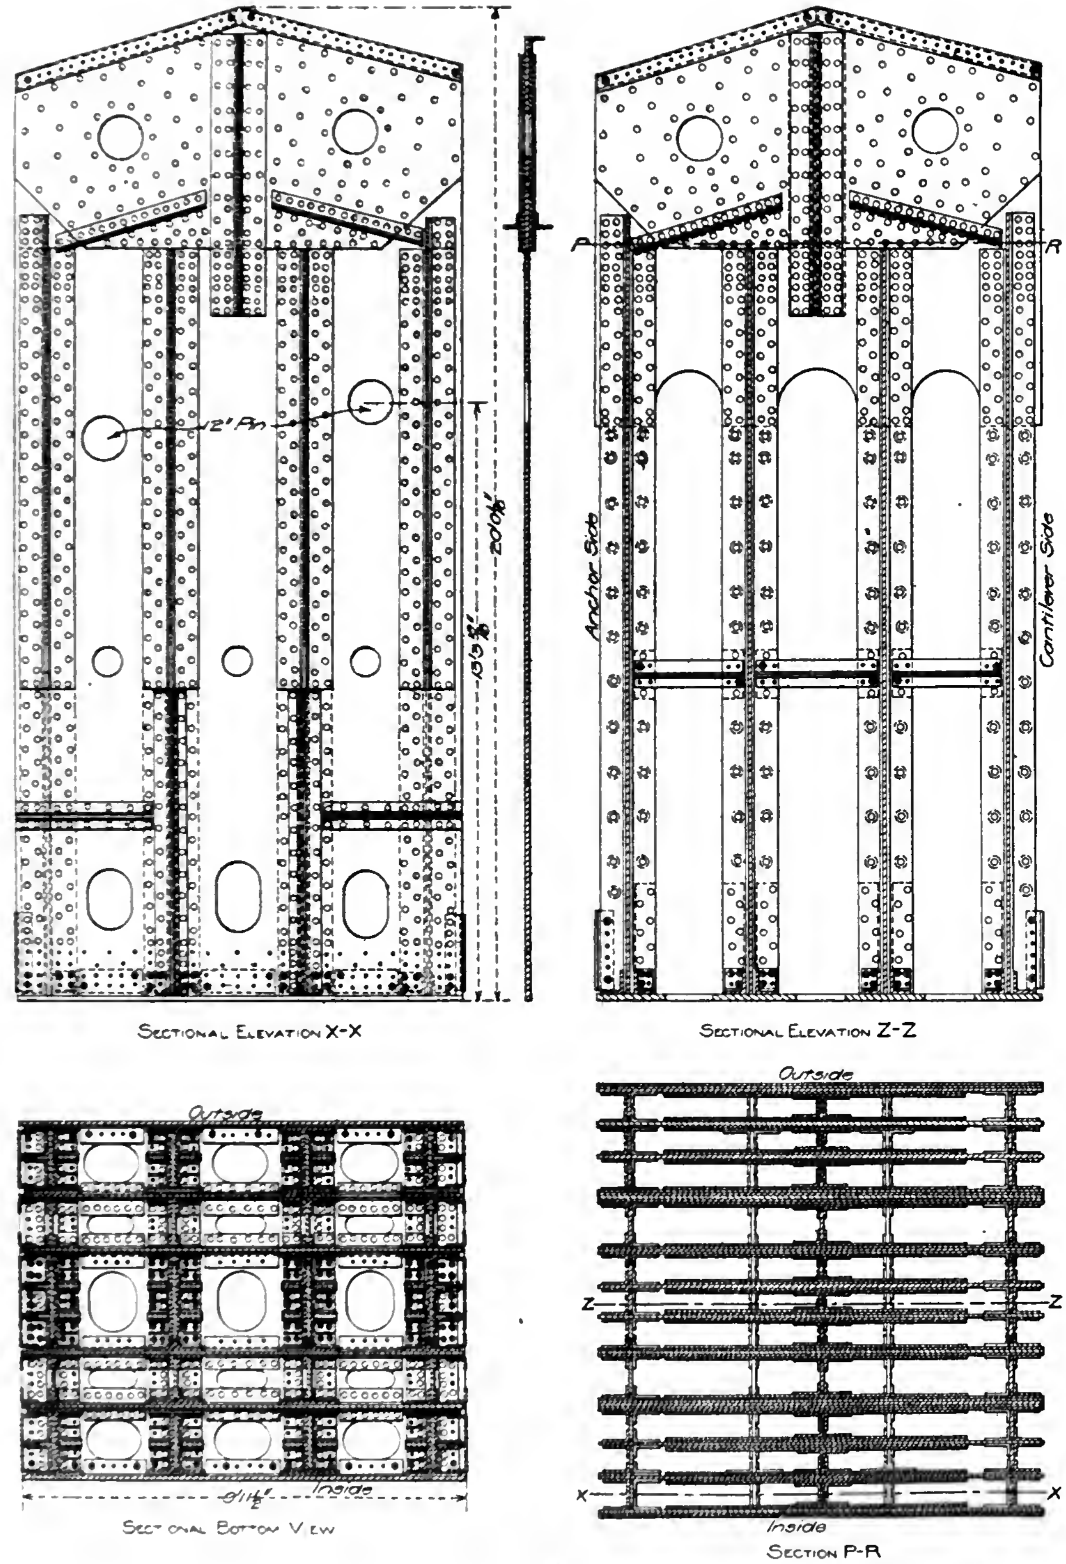
Top Transverse Strut over Pier.

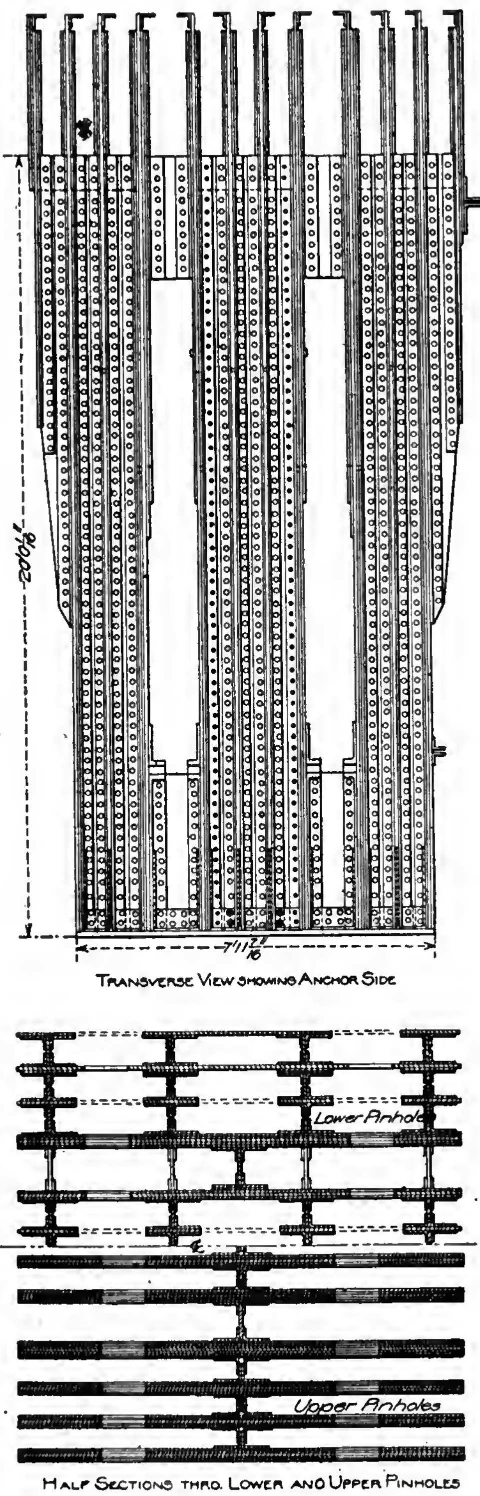


Strut over Roadway at Pier.

Top Connections at Main Post.

angles back to back, forming T-shaped cross sections which engage each other and are riveted together through the outstanding flanges.. Rivets ⅞ in. in diameter are used wherever possible, but where there is not sufficient clearance to drive them and in the connections between the different sections of the cap and between the cap and the top of the post a large number of turned bolts are required and a number of hand holes are left to give access to them.





Details of Cap for Connections at Top of Main Post.

The two outside webs and four interior webs are slotted between transverse diaphragm connections from the bottom to a point nearly 13 ft. higher up and the edges thus left are braced near the center by double pairs of horizontal angles riveted together back to back. As all of the webs on the same side of the center lines differ, many separate elevations were required for the shop drawings and each of these was designated by the number of the rib and by a letter indicating which face of it was shown.

As the adjacent cantilever and anchor arm trusses are not duplicates the pin holes for their connection to the cap are not symmetrically arranged either with regard to each other or with regard to the center lines of the member, but are located at the vertices of a trapezium with sides from about 5 ft. to 6½ ft. in length. One hole was carefully laid out in the top with reference to the longitudinal and transverse axis of the post, and the other holes were located from it by triangulation, their centers being determined by the intersections of arcs struck with trammels from the center of the first pin hole.

The pin holes were first punched in the separate pieces to a diameter of about 10 in. and after assembling were bored and counter-bored in a vertical boring mill to a finished diameter of 12.03 in. for a 12 in. pin. The interior of the cap is closed as much as possible to the weather by means of inclined ¼-in. cover plates field riveted over the top, and by vertical transverse side plates riveted across the edges of the lower end of the longitudinal webs below their points of intersection with the diagonal members.

The main vertical post 315 ft. long on centers has in addition to the special top and bottom sections, five main sections with field riveted butt joints. Their lengths vary from 50 to 76 ft. and their maximum weight is over 100 tons. The total combined maximum stresses amount to 11,928,000 lbs., for which a cross sectional area of 526 sq. in. is provided by four webs which with their flanges and cover plates build up the 4x10-ft. rectangular section. The 48-in. web plates and the 8x6-in. flange angles are separately riveted together to form the I-beam elements of the posts and are connected by very long and thick batten plates, amounting almost to cover plates, on the flanges and by 6x3½x7-16-in. angles riveted transversely across the flanges to divide them into panels about 7 ft. long, each of which is X-braced by a pair of angles of the same dimensions, one of which is continuous and the other is cut to clear and spliced across the intersection with an 18x⅝-in. connection plate. Care is taken to fit the cut ends of the angle to close bearing against the flanges of the continuous X-brace angle.

The lower section of the post, 51 ft. 9½ in. long over all, is typical of the other sections and varies from them chiefly in the minor details of connections with the transverse bracing and with the top and bottom portions of the posts. The splice which is typical of the other splices in the same member has about 1,000 field driven rivets and is made with single cover plates on the flanges and with double cover plates on each side of each of the four ends. All of the splice plates are shop riveted to the lower section of the post and project beyond it, forming jaws to receive the field riveted lower ends of the webs of the section above. At the lower end of the post the 119½x¾-in. cover plates are about 18½ ft. long and have in the outer edges about 500 field driven rivets for the connection with the main inclined post. The lower ends of the webs are united both by their cover plates or battens and by two lines of vertical longitudinal shop riveted diaphragms which strengthen it and tend to distribute the load uniformly and stiffen the 65x1⅝-in. base plate 10 ft. long to which it is connected by horizontal flange angles. Very great care is taken to fit the lower edges of the main webs and diaphragms to accurate bearing on the base plate which is planed on both upper and lower surfaces and is connected to the horizontal upper plate of the pedestal by a large number of field driven rivets. Just above the base the cross section is divided into nine rectangles by the webs and diaphragms and just below the splice it is stiffened by angle frame horizontal X-braces.

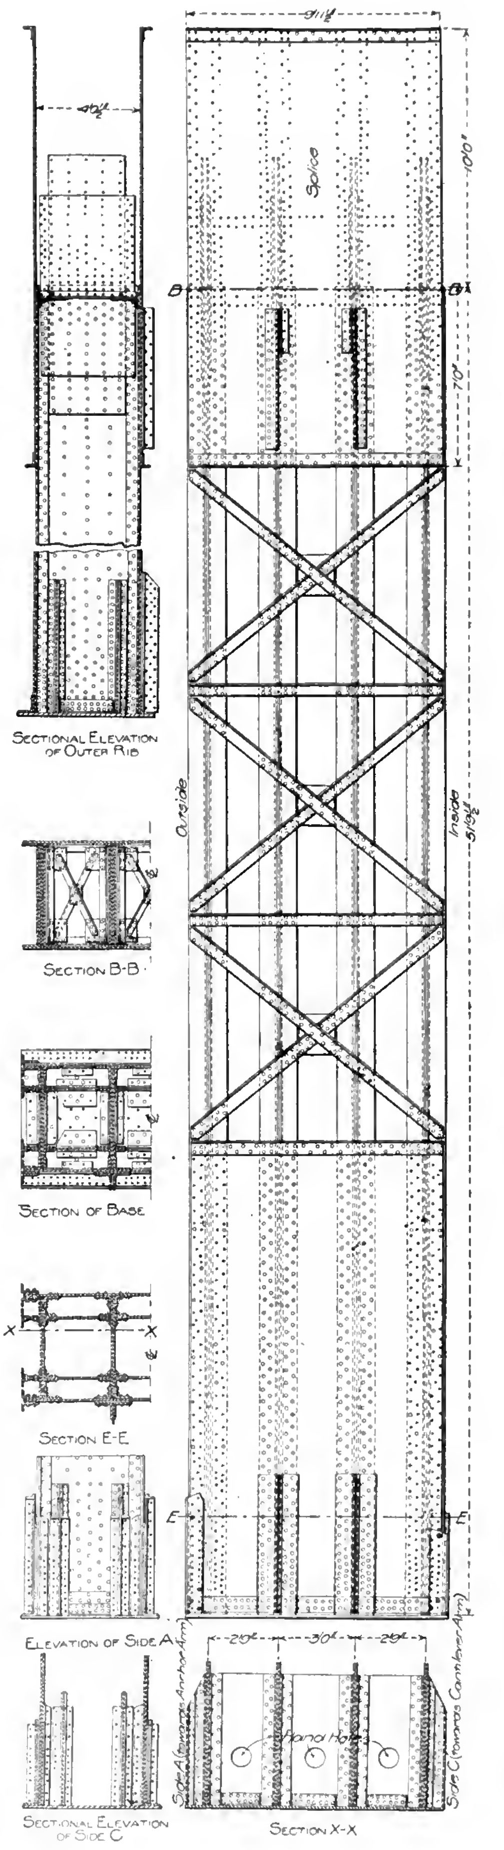
(To be Continued.)

A Gravity Water Supply at Montrose, Colo.

The town of Montrose in the western central part of Colorado formerly obtained its supply of water from the Umcompahgre River. During the summer months this stream is practically diverted for irrigation purposes before the waters reach Montrose, with the result that the only supply available from it in the late summer is that which returns to the river in the form of seepage. This seepage is highly impregnated with alkali and contains a large amount of organic matter. The water is consequently almost impossible to use for laundry or manufacturing purposes on account of the hardness, and during the time it was the source of the domestic supply several epidemics of typhoid fever occurred in Montrose.

The only other available supply that could be obtained was from the Cimarron River, which is 30 miles or more from Montrose, a high divide separating the latter from it. This river had been tapped, however, by an irrigation company, which operates a ditch carrying about 100 cu. ft. per second across the divide into the valley of the Uncompahgre River. At the top of the divide, known as Cerro Summit, a reservoir site covering about 19 acres was obtainable by the construction of a dam about 480 ft. long and 35 ft. in height. This site is at an elevation of approximately 7,800 ft. above sea level, the elevation at Montrose being 5,800 ft. The quality of the water delivered to the reservoir by the irrigating ditch is fairly good, but from the reservoir to Montrose the soil contains a large amount of salts, making it impossible to carry the water from the reservoir to the town through an open channel. The high rate of evaporation in the dry climate and at the high altitude also made an open ditch undesirable. As the distance from the reservoir to the town is about 14 miles, the method of conveying the water became a very serious one. On the basis of an estimate prepared, it seemed probable that the town could not raise sufficient funds to construct an iron pipe line. The nearby town of Delta had experimented under somewhat similar circumstances, with glazed tile pipe, with seriously disappointing results. Consequently, a wooden stave pipe conduit was adopted.

The contract for the construction of the dam,



Lower Section of Main Post.

a 10-in. wooden stave conduit, slightly over 14 miles in length, and about 10 miles of cast-iron distribution mains in Montrose was awarded to the American Water & Light Co. in the spring of 1905. These works have since been completed and the whole system is in satisfactory operation.

An earth fill dam having a puddle core wall was built to develop the reservoir site. This dam is 10 ft. wide and 480 ft. in length at the crest, 35 ft. in height, has a 1 on 3 slope on the upstream side and 1 on 2 slope on the downstream side. A low dam 320 ft. long at the crest and with the same slopes as the larger dam was also built across a saddle near one end of the latter. Both dams have their upstream slopes paved with 6 in. of gravel to the top, although an overflow prevents the water reaching a depth of over 30 ft. at the dam.

The puddle core wall of each dam was built in a trench carried 5 ft. below the natural surface. The core wall of the main dam is 10 ft. wide from the bottom of this trench to the natural ground surface, above which it has a batter of about 1 in. to the foot to its top, 32 ft. above the ground level. The ground rises from the center of the dam toward both ends. This rise was overcome in the core wall by cutting steps having 1-ft. risers and 5-ft. treads in the bottom of the core wall trench.

The outlet from the reservoir is a 4ft. circular screen chamber, 32 ft. high, built in the dam. The water may be drawn from the bottom of the reservoir, or from a point 11 ft. above the latter into this chamber, the outlet from which is an 8-in. cast-iron pipe laid in concrete to the downstream toe of the dam, where it connects with the wooden stave conduit.

As the reservoir is 2,000 ft. above the town, the pressure had to be reduced at intervals along the conduit. This reduction is obtained at each point by a special reducing valve placed in a small valve chamber. Whenever the difference in elevation reached 200 ft., one of these valves was inserted and the pressure reduced to that of the atmosphere so no section of the pipe stands under a greater hydraulic head than 200 ft. Ten of these valves and valve chambers were, therefore, installed. These chambers are 6x8 ft. in plan and have concrete bottoms and side walls 6 in. thick. A gate valve is placed on the conduit immediately inside the chamber and just beyond this valve is the one in which the pressure is reduced. The outlet from the chamber is through a 10-in. strainer on a free end of the conduit.

The pipe was all laid with a cover of at least 4 ft. in the trench. The latter was largely all made with a Buckeye traction ditching machine. For the first 6 miles from the reservoir the trench was blasted out of the rock in the side hills to a considerable extent. Most of the remaining 8 miles of the trench had to be made through cementing gravel, which could only be moved with a pick when taken out by hand. The ditching machine was very successfully and economically employed in all of the trench over this 8 miles, working over the rough places in the line without any difficulty. It was also used with good results in making the trenches for the distribution mains.

Some trouble was experienced at first in making the wooden stave conduit tight, owing chiefly to the fact that the wood had not been properly seasoned before it was delivered. The leaks were caulked after the line had been in use for some time, and at present the conduit is in good serviceable condition.

A HEAVY-CAPACITY CAR of unusual proportions has recently been built for the Bethlehem Steel Co. by the Philadelphia & Reading Ry. for the transportation of castings weighing 125 tons. This load is distributed on 32 wheels, grouped in four eight-wheel trucks. The load is carried in a "well," formed between two 6-ft. plate girders 67 ft. in length, which taper at the ends, and rest on center-plate frames of 26-in. plate girders, 20 ft. long, that are supported by two of the 8-wheel trucks. The "well" accommodates castings 5x24 ft. in size by 12 ft. 10 in. high, and the load is distributed over a total wheel base of 94¼ ft., of which but 12¾ ft. is rigid.

An Official Examination of the Battery Tunnel, New York.

Owing to numerous statements in the daily papers concerning the condition of the Battery tunnel between Manhattan and Brooklyn, Mayor McClellan instructed Mr. Nelson P. Lewis, chief engineer of the Board of Estimate and Apportionment, to make an examination of the work. This has been done in a thorough manner, everybody connected with the undertaking placing all information in their possession at the disposal of Mr. Lewis. As a result of his inspection of the tunnel and examination of the records of the engineers and contractors, he submitted last week an instructive report, from which the following notes have been taken:

Both cast-iron tubes have been completed for their entire distance. In the north tube the concrete lining and the ducts are practically complete from the Manhattan end to the lowest point, which is near the middle of the East River, where the tube leaves solid rock, while the bottom lining has been carried about to the point where the tube enters the reef of rock about 600 feet further east. There is nothing but the cast-iron shell from this reef to the Furman St. shaft, while from this shaft to the Brooklyn end of the tube the greater part of the concrete lining and some of the ducts are in place. The concrete track invert has been placed for the short distance between the Manhattan end and the Battery Park Shaft.

In the south tube the concrete lining, ducts and track invert are practically complete between the end of the tube and the cross tunnel at the lowest point, and the cross-ties are in position for the greater part of the distance. From here to the Furman St. shaft there is nothing but the cast-iron tube, while from Furman St. to the Brooklyn end of the tube the lining and ducts have been completed.

The portions of the tubes which have been built in rock are in excellent condition, and the work is so far advanced that tracks could be laid and this part of the tunnel made ready for operation in a very short time. Where soft material was encountered great difficulties were presented, and there were variations from grade and section which had to be corrected.

Variations from Theoretical Grade.—North Tube: Beginning at the Brooklyn end the bottom of the tube is about 4 inches below the theoretical grade, this variation decreasing toward the west to a point just east of Garden Place, where the tube suddenly rose to 9 in. above grade, then gradually approached true grade, crossed it about 100 ft. east of Hicks St., and 100 ft. west of Hicks St. dropped to 28 in. below grade, this being the greatest departure. Up to this point the tunnel is wholly or in part above water level. The true grade was recovered in the next one hundred feet, and from there to the bulkhead line the tube bottom was mostly above grade, the maximum distance being about 10½ in., while at one point it fell 9 in. below the grade. After crossing the bulkhead line the tube continued above the theoretical grade for over 500 ft., the maximum variation being seventeen inches. It then ran very closely to the true grade for about 500 ft., and within the next 100 ft. it reached a maximum of 18 in. below grade. For the remaining 200 ft. before the rock reef was reached, the grade line was somewhat irregular.

South Tube: The grade of this tube from its easterly end shows slight variations from the true grade, with a maximum of about 5 in. above and below, but after passing Hicks St. there is, as in the case of the north tube, a more noticeable departure, dropping to about 23 in. below the true grade, which, however, was quickly recovered and was closely followed to the bulkhead line, the maximum variations in this distance, which is about 900 ft., being 3 in. above and somewhat less below the true grade. In both tubes the maximum departure from grade occurred just west of Hicks St., or at the point where the tubes became wholly submerged. Work was in progress on both tubes at this point at the same time, namely, in May, 1904, so that in both cases was presented simultaneously the problem of passing from material which was dry or partly in water to a position wholly below the water level. Work on the north tube was continued, with the results as to grade already outlined, but in the south tube operations were suspended until November, 1904, and it is a significant fact that in the south tube the variations from grade and the deformation are much less noticeable, the maximum east of the bulkhead line being 3 in., and under the river section 6 in. As the material through which both tubes passed is precisely alike, the inference is that the contractors had gained a valuable experience in their work on the north tube which was used to good advantage on the other.

Settlement After Building.—From the Brooklyn end to points about 500 ft. west of the bulkhead line, both tubes rest upon coarse sand of excellent supporting power. From this point to the rock reef and between the reef and the rock through which the west end of the tunnel is driven they rest upon a very fine sand and river silt. The parts of the tubes resting upon this soft material have settled somewhat since they were put in position. Statements as to the time and causes of this settlement are conflicting It has been claimed that this settlement may have occurred gradually during some months after the tunnel was driven. The engineers of the Rapid Transit Railroad Commission and of the Rapid Transit Subway Construction Co. assured Mr. Lewis that the settlement, which reached a maximum of 12 in. in the north tube and 9 in. in the south tube, occurred when air pressure was reduced before the joints had been calked and the fine material coming into the tubes left spaces into which they settled. That this was what actually occurred appears probable from the fact that the contractors made an attempt to adjust the grades by opening the bottom of the tubes at high points in order that material might flow into them, thus causing them to settle to a uniform grade line, and it is said that in this they were partially successful. So far as Mr. Lewis could learn there has been no perceptible settlement during the past year.

Supporting Piles.—In order that further settlement may not occur either through inherent lack of supporting power of the soft material above referred to, or through any change in the character of the material may possibly be caused by the vibrations due to train movement, supporting piles are now being placed under those portions of both tubes which rest in this material. [This work has been described in detail in this journal.] In the space west of the rock reef these piles are being driven about every 35 ft. East of the reef and until the tubes reach coarse sand, the piles are placed about 50 ft. apart. These piles are in pairs, 7 ft. apart between centers, each pile consisting of a steel tube 20 in. in diameter filled with concrete and reinforced with steel rods and hoops. Each pair of piles supports a cradle made of concrete strongly reinforced with steel, this cradle being 11 ft. long and 5½ ft. wide, equivalent to three rings of the tunnel tube.

Under the north tube all of the supporting piles have been put in place east of the reef, and all but seven west of the reef. Under the south reef five pairs remain to be driven to the east and eight pairs to the west of the reef. There will be 63 pairs of these supporting piles, all of which will go to rock or hard pan, their length varying from 4 ft. to about 75 ft. This work is being done very rapidly, and will be completed in about three weeks.

Deformation of Tubes.—Flattening occurred in both tubes and was most noticeable where there were sharp changes in the grade lines. If a ring of the tunnel were to be tightly bolted together and placed in a vertical position, there would undoubtedly be a certain amount of flattening, which would be increased by any loosening of the bolts. This flattening or deformation is most noticeable in the land section, reaching its maximum as in the grade variation about where the tubes became entirely submerged where it was about 10 in. in the north and about 7 in. in the south tube. Between this point and the bulkhead the south tube, which followed the grade more closely, showed a maximum flattening of less than 4 in., and still less under the river.

Correction of Grade and Section.—Where the departure from grade and section has been sufficient to interfere with passage of trains or to endanger the integrity of the tubes, the plates have been removed and concrete, and in one case brick masonry, has been substituted, in some places for the roof, and in other places for the bottom above the water line, while under water new plates giving an elliptical section with the longer diameter vertical have been put in place of the old ones. This was a very difficult undertaking, but it has been successfully done by the use of novel and very ingenious methods. [These have been described in detail in this journal.]

Cracked and Broken Plates.—Much has been said about cracked and broken plates. By far the greatest number occurred on the Brooklyn land section of both tubes, where the material was coarse sand and gravel and where the tubes were wholly or in part above water, and, as in the case of the flattening, they are most noticeable where there are sharp changes from the true grade line. This would appear to indicate that the cracking of plates was not due to the inability of the tubes to retain their shape or to perform their proper functions after they were in position, but to the stresses to which they were subjected by the irregular course of the shield when it departed from the proper grade and the efforts to bring it back to grade after such departure. There are few cracked plates in the river section, especially in the south tube, and Mr. Lewis was informed that nearly if not quite all of the cracking occurred immediately behind the shield during the progress of the work. None of the cracked plates appear to be lacking in that part of the tubes east of the Furman St. shaft, although for about 600 ft. the tubes are entirely below mean high tide. In the portions which are still under air pressure Mr. Lewis could see no leaks either at the joints or from cracked plates, but some may develop when the air pressure is again removed. They can, however, be stopped as have been those east of Furman St.

The inability of the tubes to retain their shape and carry moving trains without leaks, settling and deformation, depends upon the character of the material in which they lie. This material, except for about 800 ft. east and about 600 ft. west of the rock reef, has ample supporting power. As to the very fine sand and river silt on both sides of the reef, there is a difference of opinion. Mr. Lewis examined a number of samples, most of which were taken from under the tubes when plates were removed for the purpose of sinking the supporting piles. Some of these samples are in water, while others are dry. The former appear to be nearly all very fine sand, while the latter have the appearance of a putty-like mud, although all contain a large amount of exceedingly fine sand. While some of the engineers who have this work in charge seem confident that the fine material on each side of the reef is capable of supporting the completed tubes with the moving trains, it is realized that the problem is a novel and difficult one; that tunnels are now being built beneath both the

Hudson and the East Rivers under conditions which have not been found elsewhere; that the tubes, if not otherwise supported, will settle if the underlying material flows into them; that in one of the Hudson River tunnels the original plans called for supporting piles, and that it is, therefore, prudent to insure against settlement by the supports now being put in place.

That the most unfavorable material encountered has considerable supporting power, there can be no doubt. Should this prove to be even less than was believed when it was decided to introduce the supporting piles, the number of these supports can be increased at any time.

Difficult Cofferdam Work on Decomposed Rocks.

A discussion of recent improvements in steel sheet piling elicited some reminiscences of difficult cofferdam work accomplished with heavy wooden sheet piles where troublesome conditions of an unusual character were overcome by simple expedients that are suggestive for similar work under other circumstances.

Several years ago a massive sea wall about 40 ft. high and 114 ft. long was built by the Department of Docks at the foot of East 116th St., on the Harlem River, New York City. The bank and river bed were of mud and miscellaneous fill and peat down to the surface of the characteristic gneiss rock which had an irregular surface sloping from about 15 to 34 ft. below high water level. The footings at both ends of the wall were close to those of buildings which it was dangerous to disturb, and the space at the south end was occupied by an old timber and stone filled crib which made excavations especially difficult. A sewer also crossed the site of the wall and was supported only on the earth and fill. A portion of the bottom at the south end had been badly broken up by dredging and the conditions were such that it was not considered practicable to build the wall with the standard large cast concrete blocks usually adopted by the Department of Docks in New York City. It was therefore decided to enclose the wall by a cofferdam and build it with concrete placed in moulds in open excavation.

A cofferdam about 114 ft. long and from 20 to 25 ft. wide inside, was therefore constructed with some difficulty with 6-in. splined wooden sheet piles driven to the surface of the rock which they penetrated about 1 in. When exposed it was found that the surface of the rock, apparently sound and hard, had been badly decomposed to a considerable depth, perhaps by the action of the peat, and that although firm and quite hard, it could be easily cut by a pick or shovel and when removed in small pieces could be crumbled to fine sand.

When the sheet piles were first driven it was sufficiently solid to afford bearing for them and exclude a large part of the water, but as the interior of the cofferdam was pumped out and the unbalanced pressure on the outside became large, the surface of the rock was rapidly cut out and water entered under the bottoms of the piles in very large quantities so that it soon became impossible to pump it all out and it was necessary to keep up an almost continual redriving of the piles, going around and around the cofferdam and forcing them down as fast as they were undermined.

In this way they were gradually sunk to sounder rock 1 or 2 ft. below the original surface and at the same time a large amount of good puddle clay was dumped around the outside of the cofferdam and protected the feet of the piles so that eventually the leaks ceased and the dam was made good everywhere except at the upper end where the surface of the rock was only about 10 ft. below low water level. Here a large boulder intersected the end of the cofferdam and stopped the sheet piles which brought up hard on top of it with their upper ends forming a curved line extending above the tops of adjacent piles and corresponding exactly with the profile of the boulder. The boulder was lodged in a fissure in the rock bottom, under which the water entered the cofferdam in a great volume.

Efforts were made to close the fissure with cement, concrete and sand, but it was very difficult to place them and it proved impossible to close it entirely, although the leak through it was somewhat diminished so that finally it could be controlled by the operation of one 8-in. and one 6-in. centrifugal pump and one 6-in. and one 3-in. pulsometer. When all of these were working to their full capacity the cofferdam could be emptied, but if any one of them was out of service for a short time the remainder could not control the leak and the cofferdam would be flooded.

Finally, an interior cofferdam of sand bags was built to partly enclose the end of the boulder, where it projected inside the cofferdam, and divert the leak at that point to the opposite side of the main cofferdam. Behind this protection a curved concrete wall about 3 ft. high was built forming a quadrant with one end abutting against the end wall of the cofferdam. In it there were placed two or three large drainage pipes and after the wall was completed the pipes were opened, allowing the flow from the leak to pass through them into the bottom of the main cofferdams while the temporary sand-bag cofferdam was removed and rebuilt on the other side of the boulder, diverting the flow from that portion of the cofferdam where it had previously been. Under its protection, an additional section of curved concrete wall was built connecting with the first quadrant and with it making a semi-circular curb 9 ft. in diameter, with both ends abutting against the end wall of the main cofferdams and entirely enclosing the boulder, fissure and leak. Six-inch outlet pipes were also built into the bottom of this part of the curb wall but were temporarily closed while the water from the leak flowed through those at the other side and was conducted to a large deep sump in the body of the wall in the middle of the cofferdam, which was maintained until the concrete covering the face of the rock was built up to its level when another sump was formed on the opposite side of the cofferdam.

The ends of the pipes leading to the first one were closed with wooden plugs and the sump itself filled up. The second sump received the flow from the leak through the other set of pipes and enabled the bottom to be kept sufficiently dry to permit concreting on the opposite side until the level of this sump was reached when the same operations were repeated, building successive sumps on both sides until finally the general level of the concrete was brought up to, the top of the curb enclosing the boulder and a wall was continued up to low water level after which, of course, it was easy to fill in with concrete over the boulder at low tide, thus completing the foundations. The work was done in successive halves on both sides of the cofferdam while the water was flowing violently over the opposite half. The sumps were large enough to maintain a constant body of water for the pump suction and enable the action of the centrifugal pumps to be graduated exactly to the required service, a requirement which could not have been filled had it been attempted to use the curb enclosing the boulder directly for a suction sump.

The work was completed and the wall finished in about 7 months under the direction of Mr. A. McC. Parker, assistant engineer.

The Big Cottonwood Conduit of the Salt Lake City Water Supply.

The water supply of Salt Lake City is secured from Utah Lake and a number of creeks in the mountains near the city. The flow of the creeks is conserved in reservoirs from which the water is fed to the city mains by large pipes and conduits. The latest extension, the Big Cottonwood conduit, leads the water from the creek of the same name to a reservoir previously built in Parley's Canyon. The construction of the conduit was started in September, 1905, completed during the latter part of last year, and put into service on Feb. 5, 1907. It is a reinforced concrete structure 38,167 ft., or about 7¼ miles long, and has a capacity of 32,000,000 gal. in 24 hr.

Two different sections have been used for the conduit, the one first adopted being rectangular and the second, which was substituted about 5 months after the work had started, has an arched instead of a flat roof. Both sections are 3½ ft. wide. The rectangular section is 4 ft. high with a depression of 2 in. at the center of the floor, the thickness of the latter being 8 in. at the side and 6 in. in the center. The side walls are 6 in. thick, and the flat roof from 4 to 6 in. according to the depth of cut in which the conduit was constructed. In the arched section the floor is the same as in the rectangular type, except that the corners were rounded to prevent the lodgment of impurities, but the side walls were increased to 8 in. in thickness and the roof to 6 in. at the center. The rise of the arch roof is 10.3 in. Of the total length of the conduit, about 27,000 ft. have the section last described.

The reinforcement consists of ⅜ and ½-in. twisted steel bars imbedded in the concrete in planes at right angles to the axis of the tunnel and spaced 6 to 9 in. on centers. In a number of places the conduit is built on piers above the level of the ground, and in such cases additional reinforcement is provided by rods laid longitudinally.

The inside of the conduit is plastered with a coat of cement grout composed of equal parts of cement and sand, and all exposed stretches of the conduit are covered with at least 2 ft. of earth. Blow-off valves with mud drums are provided at three convenient points along the line so as to allow the conduit to be drained for cleaning or in case of emergency.

In building the conduit, as soon as a sufficient length of line to be served economically by one concrete mixer had been graded, the forms for the bottom and walls were erected, and on them, supported by the bracing across the top, was laid a narrow-gauge track on which were operated the steel cars carrying the concrete. The mixing plants were located at suitable intervals in places which could be conveniently reached for delivering the materials and were installed immediately alongside of or over the line of the conduit so as to be able to discharge by gravity into the steel cars. Wooden forms were used exclusively on the work, the lagging for the inside of the conduit being of dressed and matched lumber.

The head of the conduit in Big Cottonwood Creek is in the concrete diversion dam which has been thrown across the canyon so as to create a storage reservoir. From this point it follows the side hills along the hydraulic gradient, through a rough country where considerable rock excavation was necessary, and finally empties into Parley's Canyon reservoir.

The cost of the conduit was $376,600 and about $23,000 more was expended on the dam and headworks and on the improvements to the Parley's Canyon reservoir. The work was done by contract by Mr. P. J. Moran under the supervision of Mr. Lewis C. Kelsey, city engineer.

Heavy Columns in the Metropolitan Tower, New York.

The great tower now under construction in this city for the home office building of the Metropolitan Life Insurance Company will be, as noted in recent articles in The Engineering Record, a 75x85-ft. rectangular steel cage structure with the unprecedented height of 608 ft. above the sidewalk and over 690 ft. above its foundation on the side lot. The exterior walls are of white marble lined with brick, and the floors are of concrete construction. As the lateral dimensions on the tower are equal to those of many tall office buildings and its height is fully three times as great, the static load alone is enormous, and when augmented by the loads from a wind pressure assumed at 30 lb. per square foot of the exposed surface of the tower, the combination results in stresses so large as to be almost or quite unprecedented in this class of construction and to require very special and interesting treatment in the design of the cross-section, details and connections of the principal columns.

The columns are arranged, as illustrated in The Engineering Record of February 9, in four transverse rows about 20 and 25 ft. apart. All of the 12-wall columns are connected by massive rigid sections of deep double girders and knee-braces forming a framework which substantially corresponds to heavy vertical trusses on each of the four faces of the tower, reaching from the foundation to the 38th floor where the roof commences. The corner columns thus receive double increments of wind loads, which give them, in the lower stories, maximum stresses of 7,500,000 lb. each.

The allowed unit stress reduced by the proper formula to nearly 14,000 lb. per square inch requires for these columns a cross-sectional area of 544 sq. in., which is provided as shown in the accompanying detail by twelve 8x8x1-in. flange angles and twenty 1-in. full length plates, two of them 44 in. wide; two, 38 in.; two 20-in.; eight, 14-in.; and six, 8-in. wide. The plates are so arranged as to form continuous webs projecting beyond the flange angles on two sides of the columns to provide connections for the wall girders and knee-braces and receive the wind stresses and distribute them throughout the columns without the use of detached plates, thus very much simplifying the column details and insuring direct and efficient transmission of stresses. A considerable economy is also effected by the almost entire absence of gussets, angles, etc., reducing the estimated weight of the columns to about 1,980 lb. per lin. ft., an amount scarcely in excess of that due to the effective cross-section. It is sufficient, however, to bring up the weight of a single one-story section to the very respectable amount of 26 tons.

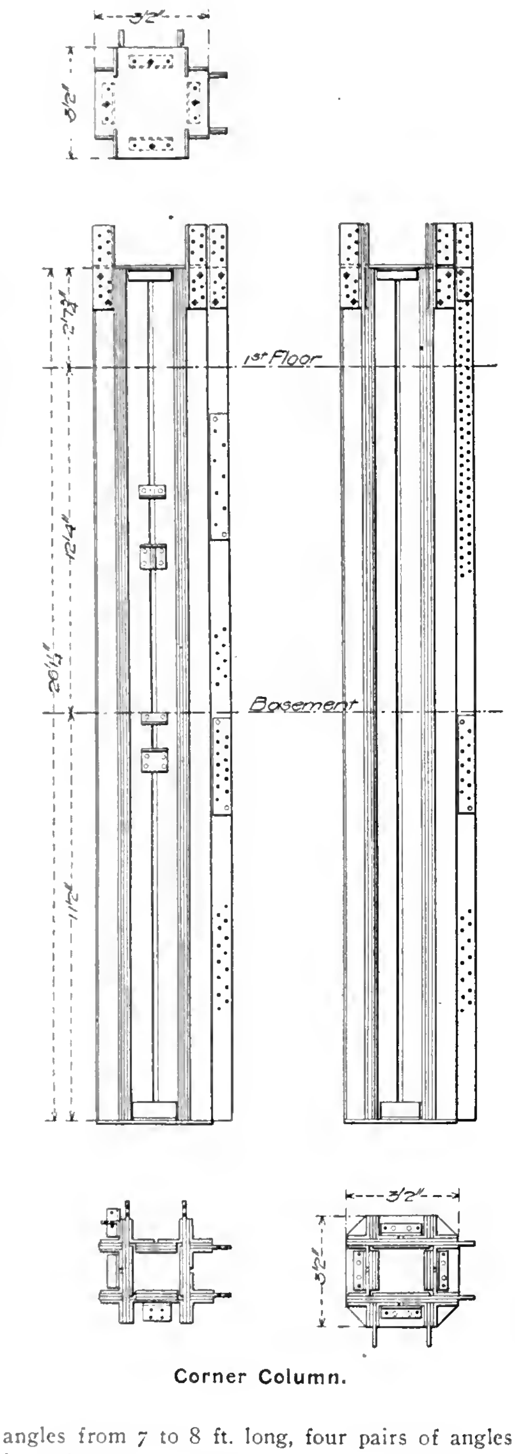
Each column has a 38x38-in. base plate 1-in. thick seated on a cast steel pedestal, 7 ft. sq. and 3 ft. high, which weighs about 11 tons and distributes the load through an I-beam grillage embedded in concrete on the solid rock. The upper end of the column has a horizontal cap plate 1¼ in. thick and receives the foot of the second-story column which is connected to it with eight ½-in. splice plates 5½ in. and 6½ in. in width which are field riveted to both members and serve only to maintain them in accurate alignment until they receive a portion of the dead load, which is, of course, entirely transmitted to the carefully milled butt joints.

The intermediate wall columns although receiving somewhat lighter wind loads carry heavier floor loads and thus require cross-sections only a little inferior to those of the corner columns. Columns 7 and 14 in the first and second stories are 38 ft. 3¼ in. long, have a cross-sectional area of 416 sq. in. and a total estimated weight of 57,493 lb., equal to about 1,500 lb. per lin. ft. They have an ordinary rectangular closed cross-section made with three webs and two cover plates, all of them heavily reinforced and built up with eight 6x4x1-in. flange angles, eight 22x1-in. web plates and six 28x1-in. cover plates, all full length. The connections for wall girders and knee braces are on opposite sides and instead of being formed by extensions of the continuous pieces forming the column sections are made with pairs of 8x6x½-in. angles and 6x6x½-in. angles from 7 to 8 ft. long, four pairs of angles in each set.

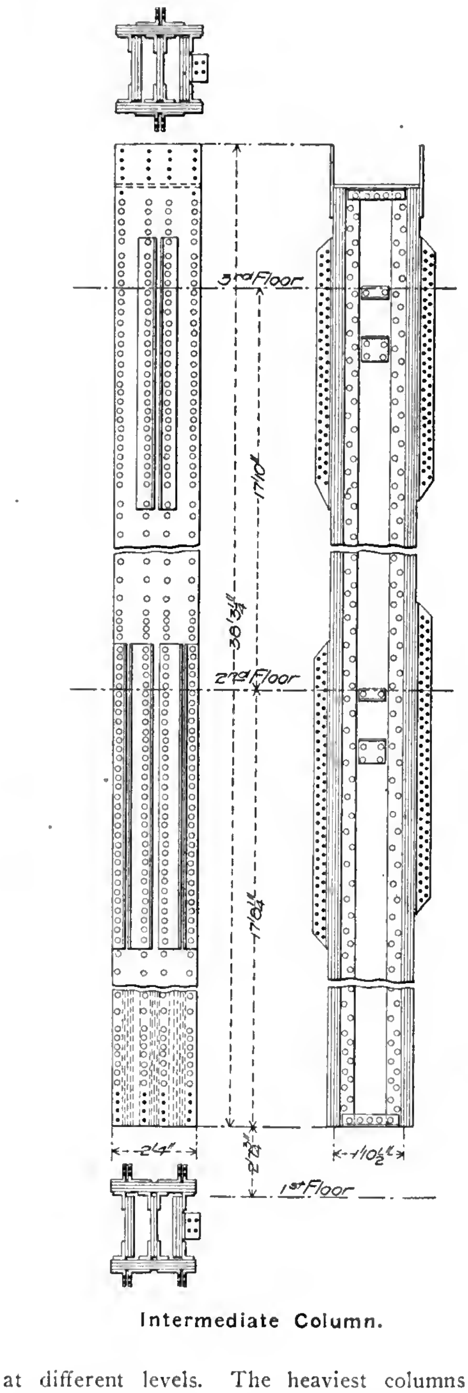
The columns have horizontal cap plates at the upper end and the splices are very simply made with pairs of short cover plates shop riveted to the upper ends of the lower sections of the columns and field riveted to the lower ends of the upper sections. The connections for each of the twin wall girders in the lower story are made with fifty-two 1-in. rivets in double shear. Sub-punching and reaming is permitted only in material less than ¾ in. thick, and as all of the principal parts of these columns are made from thicker materials the rivet holes are drilled from the solid metal, thus making an unusually large amount of shop work, but insuring very perfect work.

In the upper part of the tower the dimensions of the columns diminish to 42x42-in. at the fifth floor, 38x38-in. at the 12th floor, 36x36 in. at the 18th floor, 32x32 in. at the 20th floor, 19x29 in. at the 25th floor, 18x28 in. at the 28th floor, 20x24 in. at the 33rd floor, and 12 in. at the 37th floor. Most of them are shop riveted in two sections with an average length of 24 ft. above the 12th floor, below which the stories have heights of 13 to 20 ft.

The weights of even the lighter columns are therefore considerable, as is indicated on the special weight diagram provided for the erectors and showing the maximum loads to be hoisted



Corner Column.



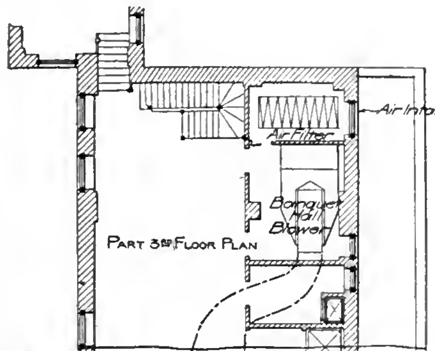
Intermediate Column.

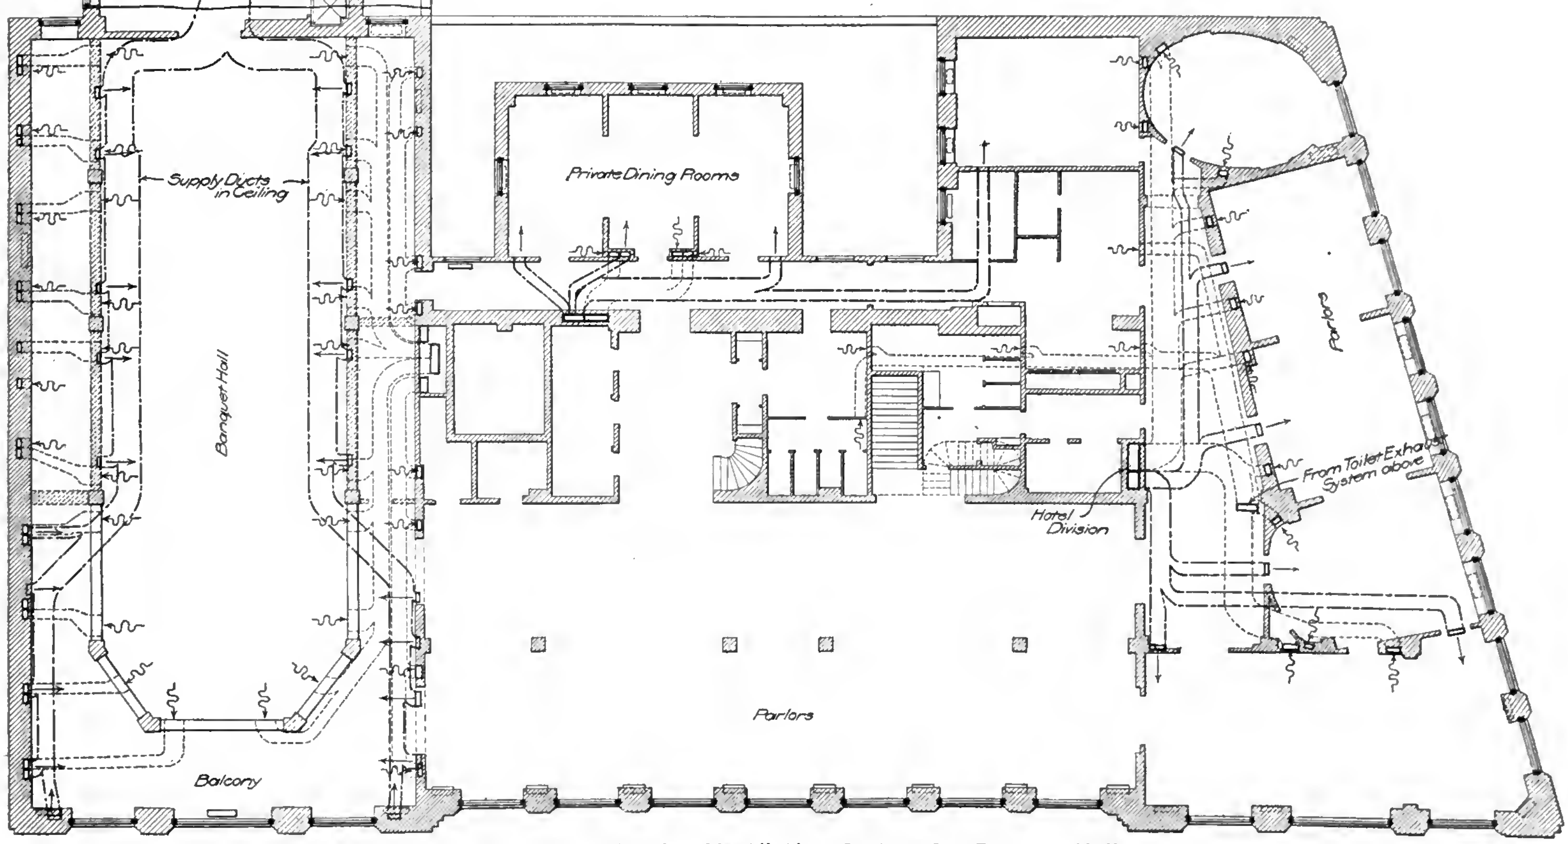
at different levels. The heaviest columns are at the 3rd floor and are 39 ft. long and weigh 29 tons each. At the first floor there are 25-ft. 25-ton columns; at the 12th floor, 151 ft. above the sidewalk, 29-ft. 19-ton columns; at the 19th floor, 14-ton columns, and 33rd floor, 48-ft. columns weighing 8 tons each, which have to be hoisted over 400 ft. above the sidewalk. There are besides a number of heavy girders including 48 plate girders 78 ft. long, weighing 11 tons each at a height of 441 ft. above the sidewalk and shorter 4½-ton girders 491 ft. high; the highest heavy pieces are the 24-in. I-beams 13 ft. long over 600 ft. above the sidewalk.

Mr. N. LeBrun & Sons are the architects, Purdy & Henderson the consulting engineers, and Post & McCord, the contractors for the fabrication and erection of the steel work.

Heating and Ventilating the Hotel Knickerbocker, New York City.

The Hotel Knickerbocker, which was opened to the public early in 1907, is the most recent and one of the finest appointed of the transient hotels in New York City. It is a 12-story fireproof structure occupying an irregular corner plot, fronting 110 ft. on Broadway, 180 ft. on 42d St., and extending through the block at the rear corner to 41st St., with 50 ft. frontage on the latter street. It has, on the main floor, the hotel lobby, cafe and dining room, on the second floor parlors, private dining rooms and a banquet hall, and guest rooms from the third to the eleventh floors inclusive, with employees' dormitories on the 12th floor and ventilating apparatus in pent houses on the roof. The basement is devoted to kitchen and serving rooms, and a grill room, while all mechanical apparatus is accommodated in a spacious sub-basement, which also contains storage rooms and the laundry. Both the basement and sub-basement extend under the sidewalk, except where this is prevented on the 42d St. side by the underground structure of the New York Subway.





Second Floor Plan Showing Ventilating System for Banquet Hall.

The mechanical equipment of this hotel is unuslly complete, embracing an extensive power plant with the usual service auxiliaries, and a very complete installation for the ventilation of the lower and sub-surface floors as well as all toilets and baths on upper floors. The particularly open location of the hotel facing directly on Times Square, with window exposure on practically all four sides, obviated the necessity of ventilation in the guests' rooms on the upper floors. All of the bath rooms that have not exterior windows are, however, fitted for exhaust ventilation, air being admitted to such rooms through louvres in the doors. On the second floor, however, there is a large banquet room, which, together with a number of smaller private dining rooms, are amply fitted for ventilation, both fresh air supply and exhaust, and similarly all the public rooms on the lower floors are well ventilated. The purpose of the ventilating equipment has been to provide ample changes of air throughout, for maximum conditions of occupancy in all of the public portions, while in the kitchen and heated machinery section, cool fresh air is supplied for the sole purpose of relieving the high temperatures that would otherwise render these departments uncomfortable. The ventilation in this building is made entirely independent of heating throughout, heating being accomplished by direct radiation operated with low pressure steam from the power plant.

The ventilation of this building is laid out in seven divisions, four of which are for the lower floors and the remaining three for the ventilation of the baths on the guest-room floors and auxiliary rooms. The four lower divisions include what is known as the hotel system, covering the grill room in the basement, the entire first floor and the parlors on the second floor; the banquet hall system; the kitchen and laundry system, and the engine room system. It was found advisable to separate the banquet hall system from that first mentioned, called the hotel system, owing to the fact that the banquet hall is used at infrequent intervals only, and when in use requires a comparatively large ventilating capacity. The kitchen and laundry and engine room systems are operated separately owing to the fact that in the former a considerable amount of air tempering is required under winter weather conditions while in the latter cold fresh air only is supplied at all times, there being no need for warming in the heated machinery section of the sub-basement. The fans for all of the systems for the four lower divisions are located in the sub-basement, with the exception of the supply fan for the banquet hall system which, for convenience of air intake and distribution connections, was located on the third floor. The toilet exhaust systems have disc exhaust fans located in the usual arrangement on the roof of the building and draw through vent flues which connect in the various sections of the building with the bath rooms and toilets to be ventilated.

The ventilation is generally applied in the public portions on the downward system, the fresh air being supplied through outlets near the ceiling in all cases, with exhaust through registers near the floor. The floor exhaust registers are, however, duplicated throughout by registers from the same flues at the ceiling line, to permit ceiling exhaust in warm weather or in special cases where it is desired to remove cigar smoke. In the hotel division the wall supply outlets are distributed at frequent intervals in the upper sidewalls in the main dining room, the cafe, the bar and the grille room. The exhaust registers, which are of the same size, are given corresponding locations to render the circulation positive. The lobby on the main floor and the large parlor on the second floor are, however, without ventilation connections, the entrances from out-of-doors and the numerous connections with the corridors and other adjacent rooms providing sufficient ventilation for all practical purposes. An extension of this system is made in portions of the second floor to a number of smaller parlors, private dining rooms and special rooms, to each of which there are individual supply and exhaust connections, as shown on the accompanying second floor plan; these connections are, it should be stated, independent of the toilet and locker room exhaust systems which are also shown on this plan, the latter being operated by a flue connection from one of the roof exhaust fans. The private dining rooms consist of a group of three connecting 11x20-ft. rooms fitted with independent supply and exhaust connections on the above arrangement, by which uniform rates of ventilation are insured in each under all conditions. The capacities of air supply and the exhaust apparatus which are provided for this hotel division are almost exactly

Fan Equipment in the Hotel Knickerbocker.

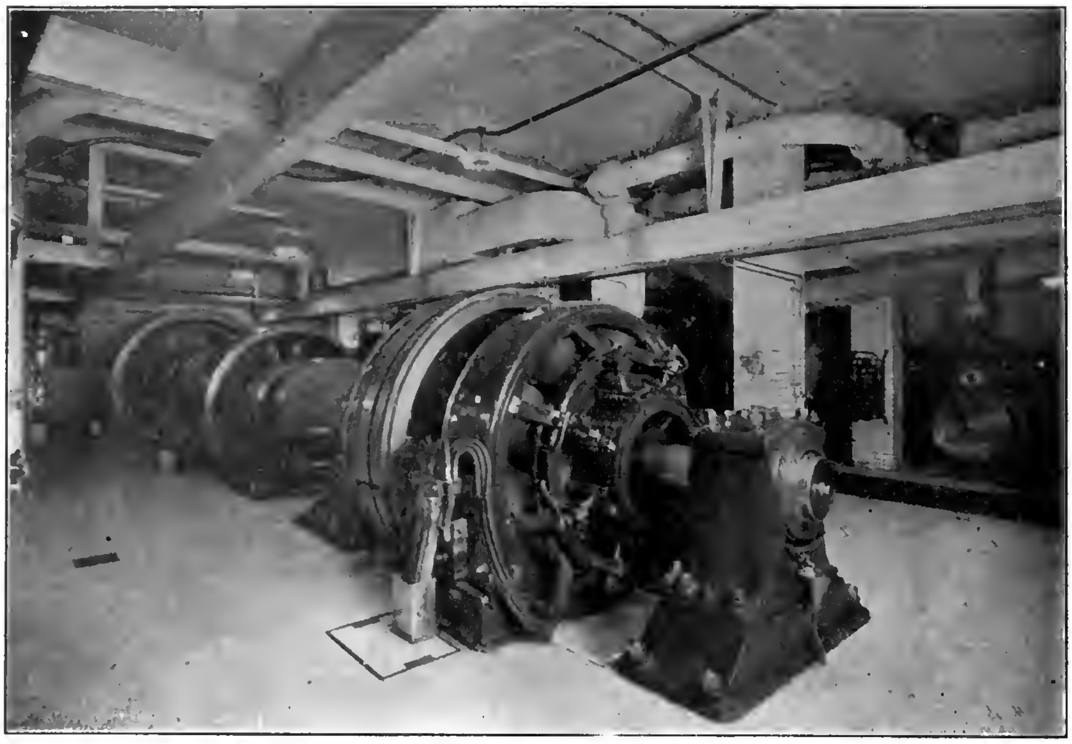
		Size of Fan.	Wheel Width.	Speed.	Capacity per Min.	Size of Motor, H.P.
Hotel division	Supply	9 ft.	5 ft.	130 r.p.m.	44,900 cu. ft.	18
	Exhaust	9 "	4½ "	130 "	40,400 "	15
Banquet hall division	Supply	5½ "	3 "	150 "	11,450 "	4
	Exhaust	7 "	4 "	150 "	26,000 "	8
Kitchen and laundry division	Supply	6½ "	3½ "	220 "	27,980 "	15
	Exhaust	9½ "	6 "	123 "	56,000 "	25
Engine room division	Supply	5½ "	3 "	213 "	16,200 "	7
	Exhaust	8 "	4 "	147 "	31,800 "	12
Bath room division	Exhaust	2—60 in.	....	300 "	48,000 "	4½
Annex	Exhaust	1—42 "	....	450 "	13,000 "	3

equal, the supply being a trifle in excess of that for exhaust.

The banquet hall is a room 47x93 ft. in plan, occupying the entire easterly end of the second and third floors. It has a balcony on the third floor level at the forward end, narrowing at the rear on this level to a width of 29 ft. for a distance of 57 ft. The arrangement of ventilation in this division consists of fresh air supply from 10 registers near the third floor ceiling line which are arranged as shown in the accompanying plan and exhaust connections at the edge of the gallery on the third floor level and also under the gallery in the sidewalls near the second floor level. The arrangements of registers were carefully studied for proper distribution of ventilation under extreme conditions of occupancy in the hall, it being made possible to remove air in large volumes at the balcony level and thus prevent the disagreeable accumulation of cigar smoke. The distributing ducts for the ceiling fresh air supply outlets are arranged above the main ceiling of the hall, connecting at the rear to the supply fan which is located on the third floor level. The exhaust registers are operated by independent duct connections to the sub-basement, where dampers are provided to enable either the top or bottom registers to be operated independently or together as required by conditions in the hall. For this hall, comparatively great ventilating capacity has been provided to permit of ample ventilation in times of extreme occupancy. The capacity of exhaust is also made considerably in excess of that for supply, the purpose being to cause a state of plenum inward and thus prevent the communication of cigar smoke or odors to the hall or corridors of the hotel.

The kitchen and laundry system involves the simple arrangement of supply and exhaust fans in the sub-basement with short direct connections to the kitchen directly above, and the laundry at the forward end of the sub-basement. The arrangements of supply and exhaust outlets in the kitchen follow the usual arrangement, consisting of numerous vent openings over the ranges, stock boilers, and other cooking utensils and cool fresh air outlets at the rear of the positions occupied by the cooks, to permit of a blast of cool air from the rear when at work. The bakery, pastry and dish-washing departments are also similarly equipped with ample ventilating connections, and owing to the heated condition of these departments all exhaust registers are located at the ceiling line. The ventilating connections in the laundry follow also this latter arrangement, the arrangement of connections differing principally in this department in that large gathering hoods are located over some of the mangles and other washing apparatus from which large volumes of steam are emitted; this tends to keep the laundry atmosphere clear and prevents the communication of steam to the corridors of the building. In this division the exhaust capacity is, of course, made considerably in excess of that for fresh air supply, for the purpose of creating a strong plenum inward, and thus preventing the communication of odors from either department into other portions of the building. Similar to this system in all its details is the engine room ventilating division, which involves fresh air supply and exhaust in all portions of the heated machinery section. The fresh air is supplied without tempering and the capacity of exhaust is also considerably greater than that for the fresh air supply for the same reason as in the case of the preceding division.

For exhaust ventilation from the baths and toilets on the guest floors there are two vent risers, each with groups of gathering ducts from the various rooms, which are located at the front and rear corners of the building on the 42d St. side. These systems are installed solely for the ventilation of baths and toilets which have no opening to outside air; such bath rooms as have outside windows are not thus equipped. The general arrangement is shown in the accompanying second floor plan, that in the front corner exhausting in general from nine bath rooms on each of the floors and that at the rear similarly from eight baths; the smaller flue shown in the central portion serves to exhaust from groups of two inside baths on each of the floors, as far down as the fourth floor, being connected at the top to the rear corner riser. These two larger vent flues are operated by 60-in. Howard & Morse disc fans which are located in pent houses on the roof and discharge directly to the atmosphere. These fans are vertically arranged for economy of space, and are each driven by a 4½-h.-p. round type vertical shaft Sprague electric motor. The third exhaust system consists of a 42-in. disc fan of similar make, direct driven by a 3-h.-p. round type Sprague vertical motor, which is located on the roof of the annex and exhausts from the servants' dining rooms and a number of auxiliary rooms in the annex.



Electrical Generating Units in Engine Room.

The fans operating the four ventilating divisions in the lower portion of the building, of which there are seven in the fan room in the basement and one on the third floor at the rear of the banquet hall, are all Sturtevant steel-plate centrifugal fans, which have been installed in the following sizes (see appended table for list of dimensions and capacities.) These fans have intake through a filter chamber with 8 x 10-ft. shaft connecting to a ventilation court on the 2nd floor level, the filters being of the usual zig-zag cheese cloth type, designed for low filtering velocities. The motors operating these fans are all of the type D Sprague direct-current motors which are equipped with variable speed starting boxes by means of which considerable changes of speed may be obtained. The motors are operated at 110 volts, each on separate power circuits from the switchboard. The duct connections are all of rectangular iron construction and are well arranged in the sub-basement for the complexity of equipment involved. They are heavily covered with asbestos air-cell coverings, protected with canvas sewed on.

The building is heated throughout by direct radiation, utilizing low pressure exhaust steam from the steam using machinery of the power plant with the Paul system of returns. Automatic temperature regulation is provided upon radiation in practically all of the public portions of the buildings, but that in the guests' rooms is fitted for hand control. The distribution of radiation follows the usual plan of units underneath window-sills in varying capacities to correspond with the amount of glass exposure to be counteracted and in all public and guest rooms, radiators are enclosed in recessed spaces with ornamental grilled fronts. Steam is supplied to the radiation on the one-pipe system through risers located in chases in the sidewall construction, which are fed by a distributing main on the sub-basement ceiling. The distributing main consists of a 12-in. line connecting with the muffler tank of the exhaust steam system of the power plant which extends to the front of the building reducing to 7 and 6 in. to supply the risers, and full size to the rear, supplying both risers and tempering coils of the fresh air supply fan systems in the fan room at the rear corner of the basement.

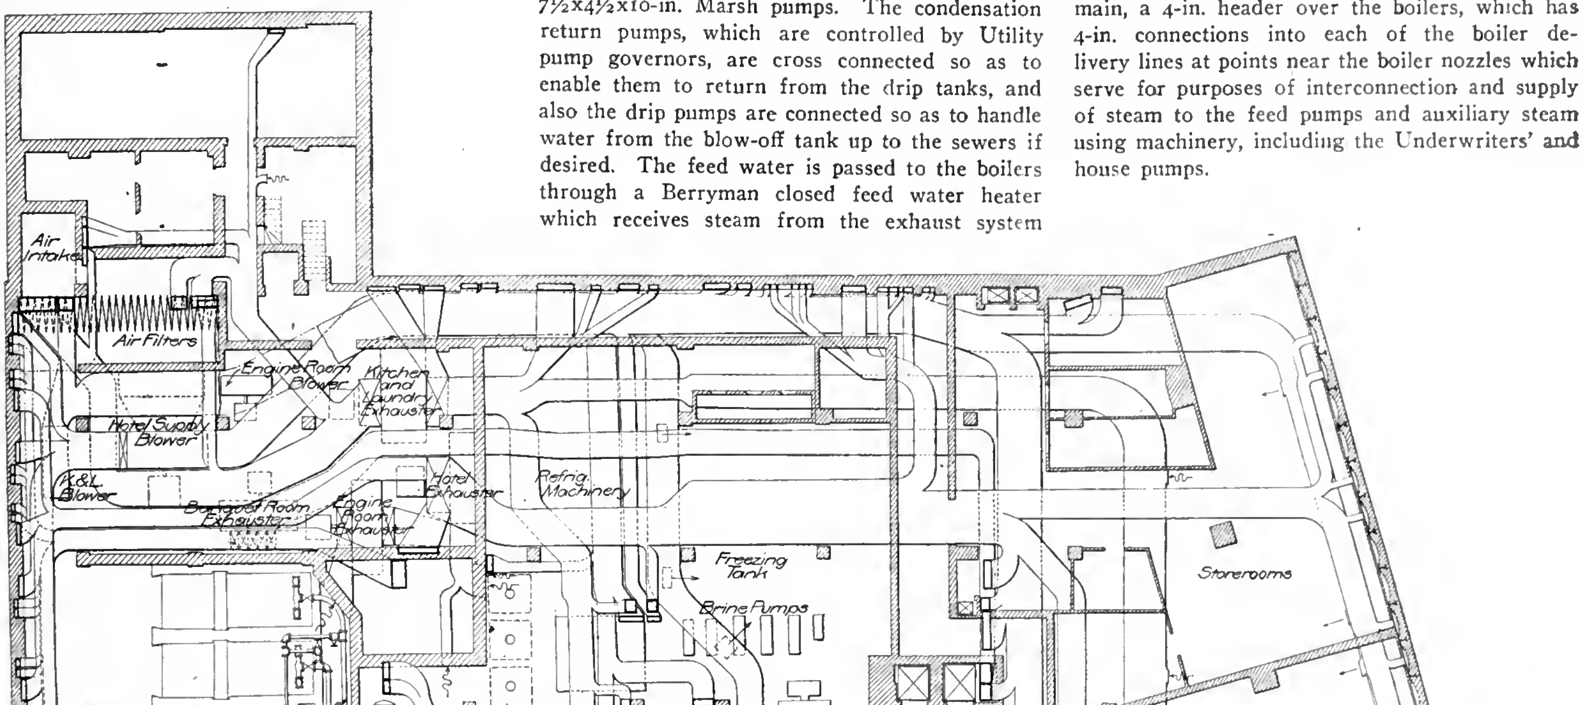
The power plant and mechanical equipment of the hotel occupies about two-thirds of the sub-basement space, the remaining third of the sub-basement at the Broadway end being devoted to a 60x70-ft. laundry and a number of store rooms for hotel supplies. The power plant section consists of a 43x60-ft. boiler room at the rear on the 42nd St. side with 12-ft. coal bunker extension under the sidewalk, a 40x60-ft. fan room

and in the central portion, the main engine and machinery room, which is 75 ft. in width and extends entirely across the building, a distance of 120 ft. Ample head-room is provided in practically all sections of the sub-basement for overhead piping and duct connections, that in the engine room permitting a traveling crane runway over the electric generating machinery for handling of parts. A feature of this mechanical plant installation is the care that has been given to the appearance of the interior, the floors being finished in tile throughout the machinery and laundry section, all piping and duct work being conveniently and orderly arranged and the interior attractively finished throughout.

trolley, installed by the Northern Engineering Co., of Detroit, Mich., the buckets having a capacity of 500 lb. each. The ashes are handled by the same trolley system, being delivered to a small ash hoist near the coal-bunker which raises the ashes in cans to the street level.

Boiler feeding is provided for by an equipment of eight pumps, flexibly arranged in four groups of duplicated units, four of which return condensation from the heating system, two of the remainder handling water from the high or low pressure drip tank and the two others for the make-up water from the city water supply. The condensation return pumps are 10x6x12-in. Marsh duplex steam pumps, while the other four are 7½x4½x10-in. Marsh pumps. The condensation return pumps, which are controlled by Utility pump governors, are cross connected so as to enable them to return from the drip tanks, and also the drip pumps are connected so as to handle water from the blow-off tank up to the sewers if desired. The feed water is passed to the boilers through a Berryman closed feed water heater which receives steam from the exhaust system

tion having a gate valve at the drum and a Bedford non-return stop valve at the boiler nozzle. The main delivery connections consist of a 9 and a 12-in. line to the engine room, the former supplying a 150-kw. and a 200-kw. generating unit and the latter a 250-kw. and a 300-kw. generating unit, all through Cochrane steam separators; an 8-in. line delivers steam to the elevator pumps, the refrigerating compressors, brine pumps, etc., a 3-in. line through a pressure reducing valve to the laundry and kitchens, and a 6-in. delivery line through a 6x12-in. reducing valve to the heating supply mains for make-up to supplement the exhaust steam in case of deficiency. There is in addition an auxiliary main, a 4-in. header over the boilers, which has 4-in. connections into each of the boiler delivery lines at points near the boiler nozzles which serve for purposes of interconnection and supply of steam to the feed pumps and auxiliary steam using machinery, including the Underwriters' and house pumps.



Details of Ventilating Equipment in Sub-Basement.

Steam is generated in an equipment of four Babcock & Wilcox water-tube boilers which have an aggregate capacity of 1,400 h.-p. These consist of two small units set in a single battery and two larger units each in single settings, the smaller units having 120 and the larger units 210 four-in. tubes 18 ft. in length. They each have 42-in. steam drums, 18 ft. in length for the smaller units and 14 ft. for the larger ones, and are designed for a working pressure of 125 lb. The settings are equipped with Thompson shaking grates for hand firing, the coal consumption under ordinary conditions of operation being about 28 tons per day. Coal is stored in a 200-ton bunker, under the sidewalk at the 42nd St. end of the boiler room, into which it is dumped directly from the street. The coal is handled to the furnaces by a bucket and chain industrial

of the plant and preheats the feed water to about 200° Fahr. The blow-off system involves a 4x8-ft. steel plate tank in the machinery room at the rear of the boiler fittings, to which 2-in. blow-off connections are made from the boilers. A Utility pump governor connected to this tank controls the blow-off pump to keep the tank half filled, discharging the blow-off from the boilers to the sewers as it accumulates.

The steam piping of the power plant embraces an unusual arrangement of individual connections from the boiler nozzles to a large steel plate drum or header on the engine room side of the division wall, from which drum the high pressure delivery connections are made. The drum is 30 in. in diameter by 15½ ft. long and has 6-in. connections to the smaller boiler units and 8-in. connections to the larger ones, each connec-

The electrical generating equipment consists of four Sprague multipolar engine-type generators direct-connected to Fleming four-valve engines. These units have been installed in a novel arrangement of sizes, their capacities being 150, 200, 250 and 300 kw. respectively, in order to permit of adjusting the generating capacity as close as possible to the current consumption in the hotel at all times. The units are located in an engine room of more than usual beauty, each being guarded by a 2-in. polished brass railing and the flywheel shrouded by a Russia iron casing. The room is spanned by a 10-ton hand-operated traveling crane supplied by the Northern Engineering Co. The engineer's office is located in a mezzanine gallery at the westerly side, from which position a clear view is had of the entire engine and machinery rooms.

The generators deliver current at 110 volts, direct current, the hotel being wired on the 2-wire system. The circuits are controlled on a large switchboard in front of the generators, which is divided into two sections for power and lighting service. All motors are operated on individual circuits from the power sections and on the lighting section, there are 42 feeders of capacity from 100 to 800 amperes. The average running load carried by the generating machinery is 3,000 amperes.

The elevator equipment of the hotel consists of 11 passenger elevators installed by the Standard Plunger Elevator Co., of New York, which are operated by three 18 and 28x13x24-in. American compound single cylinder pumps of the outside center packed plunger type. These units have each a capacity of 650 gal. of water per min. against a pressure of 160 lb., being installed in the three-unit layout to permit of one pump carrying the load when the service is light, and not requiring over two pumps under any circumstances, so that one unit is always held in reserve. There are three pressure tanks, consisting of 6x22-in. steel plate tanks suspended on the ceiling over the pumps, in which air space is maintained by a 10x8 and 4x12-in. two-stage Marsh air compressor. The elevator discharge tank has a capacity of 15,000 gal.

The refrigerating plant consists of two 45-ton and one 3-ton machines of the ammonia compressor type which were built by the York Mfg. Co. Either one of the 45-ton machines will handle the entire refrigeration duty in the hotel and the 3-ton machine is for very low temperatures for making ice-cream, etc. About 9 tons of ice is manufactured daily, and the total refrigerating duty averages about 45 tons per day. All cooling service in the hotel is operated by brine circulation, for which there are two services, one for the upper portion of the building and the other for the lower. The upper or high pressure circulation is operated by 7½x4½x10-in. single cylinder Marsh pump in duplicate while the low pressure service is operated by three 10x8x12-in. American pumps. A separate system is used for ice manufacturing, a 4x6x8-in. Marsh pump circulating the brine to the ice tank. Other auxiliary services operated include extensive vacuum sweeping and pneumatic tube systems, and an electrically operated printing establishment in the annex, in addition to which large amounts of live steam are used in the laundry and kitchen apparatus.

The mechanical plant of the hotel was designed by G. A. Suter & Co., New York, in consultation with Mr. Alfred R. Wolff, consulting engineer, New York. The steam generating, heating and ventilating equipment were installed by G. A. Suter & Co., the generating machinery by G. E. & A. L. Pennock, and the wiring by the Lord Electric Co., New York. The architects of the building were Trowbridge & Livingston.

Automatic Coaling Barges of the American elevator type have recently been introduced on the Mersey in England, five such barges of 1,300 tons capacity each being operated there. They are fitted with elevated bins, which are filled from the barge below by continuous bucket conveyors, on the principle of the floating grain elevators, and thence discharged through adjustable chutes into the coal bunkers of the steamers. The coal delivered is automatically weighed and each barge can deliver at the rate of 180 tons per hour. In a recent test 904 tons of coal were placed on board of one of the English war vessels in 4¾ hr. by two of these barges, although if a sufficient number of workmen had been available for trimming the coal in the bunkers, this could, it is said, have been accomplished in 3½ hr.

A Novel Moist Closet.

Read at the annual meeting of American Society for Testing Materials on June 22 by Mr. E. B. McCready, of the Lehigh Valley Testing Laboratory at Allentown, Pa.

A brief description of a moist closet—fully equal to a slate or soapstone closet—which may be made in any laboratory with a minimum of cost considering its character, may be of interest to some of the members of this society. The closet illustrated was made of "waste cement" left from a testing—all brands mixed—and several samples of natural sand from the same source. The cement was thoroughly mixed, as were the sand samples, so as to insure uniformity in color.

The mortar was mixed 1 to 2 and wet enough to be filled readily into and tamped down in a ⅝-in. space. The walls are 1¼ in. thick, except the center panels of the doors, which are only ½ in. thick. The walls are reinforced with ½-in. mesh galvanized wire netting.

The hinges in this closet were specially designed to be imbedded in the walls and doors. Of course, if desired, ordinary strap hinges can be used, except that they should not be of iron, and may be bolted to the doors and walls. The hinge shown is a little more expensive, but makes a better appearance.

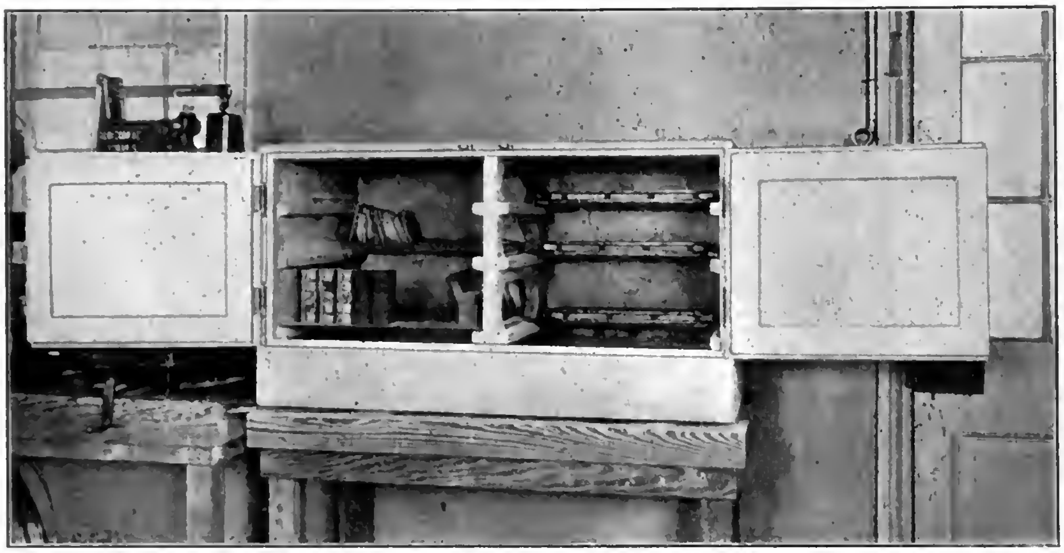
The dimensions of this closet are practically the same as those of the soapstone closet described by Mr. R. L. Humphrey and illustrated by Taylor & Thompson and others, but shape and size may be varied to suit the space to be occupied or the size of molds used. The necessary forms can readily be made by any carpenter and consist of an outside form or box, without top or bottom, and two inside forms or cores, which are simply boxes with tops, but no bottoms. As the closet is cast face or front down, the top of the forms means the back of the closet. When the forms are in position, there must be 1¼-in. clearance all around each core, top, bottom and sides.

The doors are cast first by filling in a frame of the proper dimensions, laid on a pane of glass or other flat surface which has been oiled. The hinges are placed by marks on the frame and secured to it by small brads before the mortar is filled in. The same form answers for the two doors by simply reversing the position of the hinges. If made like those illustrated, the hinges must be "right" and "left."

When hard enough to stand handling, the two doors are placed, in their proper relation, face down, on a flat surface and the outer box-form placed around them. The edges of the doors are covered with several thicknesses of oiled paper and the cement mortar filled in around them level with the doors, making the layer of mortar just 1¼ in. thick. The inside forms are immediately placed in position, open end down, and are supported by the doors, which are sufficiently hard. If correctly made, they will reach to withiin 1¼ in. of the top of the outer form and there will be an open space of 1¼ in. all around each core. The mortar is then filled in around and over these cores and smoothed off even with the top edge of the outer form; this top layer forming the back of the closet.

Of course, the placing of the reinforcement adds slightly to the detail of these operations. The doors and the back are filled in two layers with the wire placed between. The wire for the sides, in one piece, is placed in position and kept in the middle by strips of half-inch board which are moved along or taken out as the mortar is filled in.

The doors may be panelled and their weight reduced by placing in the frame, before and after filling a piece of plate glass, slate or even wood of the desired shape and thickness. These are removed after the mortar has hardened.



Interior of Moist Chamber of Reinforced Concrete.

The forms must be thoroughly shellaced and oiled before use. The cores must be put together with screws, entirely from the inside and exposed ends and edges slightly bevelled so that they may be removed after the cement has set.

The shelf cleats are provided for by longitudinal strips on the ends of the core boxes, in width equal to the distance desired between the cleats. The space between, when filled with mortar, makes the cleat.

The appearance of the closet may be enhanced by thoroughly moistening the green surface after the removal of the forces and sifting some neat cement lightly and evenly over the whole from a 50 or 80 mesh sieve.

This closet has been in use a little over a year and has given great satisfaction. It is water-tight and requires no felt lining to maintain a uniform degree of humidity. By actual repeated tests, we have found the percentage of saturation on the top shelf to be as high and often a little higher,—owing, perhaps, to a slight difference in temperature,—than at the surface of the water.

The Pavements of Berlin have a total area of 7,499,600 sq. yd., of which 4,521,000 sq. yd. are stone, 2,857,300 sq. yd. are asphalt and 120,-900 sq. yd. are wood, the remainder being slag, macadam and concrete. The stone blocks rest on an 8-in. bed of crushed stone and the asphalt on 8 in. of concrete. Natural asphalt 2 in. thick after compression is used.

The Hydro-Electric Plant of the Vancouver Power Co.

The Vancouver Power Co., Ltd., has for some years been operating a hydro-electric plant supplying current for electric lighting, street railways and commercial purposes in Vancouver, B. C., and the surrounding towns. The plant, which originally had a capacity of 9,000 h.-p., will eventually have a capacity of 30,000 to 40,000, the supply of water being ample for such a development. Measurements of the flow of three streams had been made for a number of years, but owing to the high cost of the first installation the work was not started for 10 years after the feasability of the project was determined. Construction was finally started in August, 1902, and current was first generated in December, 1903, though the plant was not completed until a year and a half later.

Early in 1902 a very careful examination was made of the water supplies which had been under observation, and as a result of the report rendered the plans which have since been executed were adopted. The scheme has been to build a dam across the outlet of Coquitlam Lake and bore a tunnel to Trout Lake, a distance of 12,775 ft., using the former lake for storage, and the latter as a balancing reservoir. The outlet of Trout Lake will likewise be closed with a dam, from which the pipe lines will lead to the power house, situated on an arm of the sea just above high tide.

The main source of supply, Coquitlam Lake, is a glacial lake having an area of 2,300 acres, situated 432 ft. above sea level. The drainage area is approximately 100 square miles, and the annual precipitation over it about 150 in. The smallest flow from the lake in thirteen years was 300 cu. ft. per second, and this continued for about fifteen days. Trout Lake is separated from Coquitlam by a mountain range, about 2½ miles across, rising 4,000 ft. above the lakes. The former lake is located 400 ft. above sea level, close to the north arm of Burrard Inlet, and 32 ft. lower than Coquitlam Lake. Its area is approximately 500 acres, and the storage capacity which can be drawn upon amounts to a depth of 16 ft. over this area. The attainment of very high peak loads is therefore possible without danger of a failure of the water supply.

The dam at the outlet of Coquitlam Lake is a rock-filled timber crib structure 113 ft. long, 14 ft. high, 12 ft. wide at the top and 50 ft. at the base. Below the dam is a very heavy timber apron, and on each side of the river below are two smaller aprons for protecting the abutments. This extensive protection was required because in flood periods large logs up to 6 and 8 ft. in diameter are brought down by the river. All the timbers are 12 in. square, drift-bolted together. The foundation of the dam rests on glacial hard pan over which was a stratum containing large boulders. A trench was dug in the hard pan along the upstream face of the dam and a double row of timber sheeting driven in the trench and spiked to the heavy timbers of the dam, the trench being then refilled and the material well rammed. The sheeting covering the dam consists of one thickness of 4-in. plank, over which is laid one thickness of 2-in. plank.

The tunnel connecting the two lakes is 12,775 ft. long, and has a normal section 9 x 9 ft., with rounded corners. The grade falls at the rate of 1 per cent. for the first 875 ft. from the Coquitlam portal, and from this point, where a drainage sump and pumping plant were located during construction, rises on a 0.02 per cent. grade for 5,600 ft. The last 6,300 ft. reaching to the Trout Lake portal is a down grade of 0.14 per cent. The tunnel intake in Coquitlam Lake consists of three submerged openings each 8 ft. square driven in the solid rock, and leading to a cross heading 30 ft. back from the lake, where the 9x9-ft. section starts. This cross heading is 10 ft. square and about 36 ft. long normal to the tunnel axis. The three openings are protected from driftwood and debris by two lines of rock-filled timber cribs, supporting screens, the tops of which are at the level of extreme high water. Sixty feet back from the tunnel portals are two gates for controlling the flow of water. Each gate is 9 ft. high by 4½ ft. wide, built of structural steel shapes, and carries brass rollers, which run on I-beams forming part of the framework of the water tight bulkhead. The gates are operated by screw stems and hand wheels, and are worked from an operating tunnel above the main tunnel. The mountain is syenite or quartz syenite with occasional dykes of diorite, the latter being particularly hard and tough. No timbering was required.

The dam across the outlet of Trout Lake is a solid concrete structure, 361 ft. long, 54 ft. high above the base, with a top width of 7 ft. and a width on the base of 35 ft. It contains 10,000 cu. yd. of material, putting stones and 1:2½:5½ concrete, the stone in the latter being crushed granite. The mixture on the face for 18 in. is somewhat richer in order to secure water tightness. The foundation for the dam is a very sound syenite.

The openings of the pipe lines leading to the power house are steel pipes built into the dam, the tops of the pipes being 22 ft. below the crest. There are ten 54-in. and two 24-in. pipes, each fitted with a special brass-roller gate-valve at the face of the dam with a separate screen for each pipe. The intake gate-valves work in guides bolted to the face of the dam, and are fitted with brass rollers, on which the thrust due to the water pressure comes. A circular ridge on the back of the gate is machined to make the seat and a corresponding seat is made on the gate frame, to which the pipes are riveted. The gear for operating the gate is a simple screw stem and hand wheel, and the gates though quite tight can be operated with ease by one man at all stages of the water.

The total length of the pipe line is 1,800 ft., of which the upper 800 ft. are of wooden-stave construction, 54 in. in diameter, and the remainder of riveted steel varying in thickness from 9/32 to 17/32 in. and in diameter from 48 to 42 in. The exciter pipes are of steel throughout their entire length, and are 24 in. in diameter at the upper end and 18 in. at the lower end. Each pipe is fitted with air valves at three different points, a relief valve at the lower end, and a stand pipe just below the dam. The pipes are laid in a trench and covered with the excavated material, the top layer being of fine material in which clover was sown. At the lower end where curves occur the pipes are anchored to concrete piers from 12 to 16 ft. apart.

The power house, 40 ft. wide and 160 ft. long, is situated on an arm of Burrard Inlet, just above high tide. The main units, of which three were installed when the plant was constructed, have a capacity of 3,000 h.-p. each, and consist of a 2,300-volt Westinghouse generator, with two Pelton water wheels, one on each side of the generator. The water for each unit will be supplied by a separate pipe, a Y being inserted near the unit to conduct the water to the two wheels of each set. The head of water is about 400 ft.

The current is transmitted to Vancouver, a distance of 16 miles, at 23,000 volts. At Barnet the transmission lines cross a navigable arm of the harbor, the distance between supports being 2,750 ft. and the height of the conductors above high tide 150 ft. For the crossing twelve 7-strand 9/16-in. plow-steel cables are used as conductors.

The surveying and construction of the plant were quite interesting. Owing to the steep, rocky slopes and perpendicular cliffs of the mountains separating the two lakes, it was found impracticable to carry the levels over the range, and four lines of levels were therefore run from one proposed tunnel portal to the other, around the end of the range, a distance of 25 miles, the results having a maximum variation of 0.23 ft. A Buff transit having a large, high-power telescope was used for the alignment. Four transit stations were established, of which two were on the mountain 3,200 ft. apart, one on the further shore of Coquitlam Lake, and one on the further shore of Trout Lake. These latter stations were placed across the lakes from the tunnel portals because the latter could not be seen from the points on the mountain.

The tunnel was driven simultaneously from both ends, and hand drilling was used for the first 4 months when the installation of compressor and haulage plants was completed. The construction plants were furnished by the power company, but the work was done by contract on the percentage basis, the contractor's profits being increased in proportion to the decrease in the cost per foot from bidders' prices, and an independent bonus being offered for speedy completion. A 36-in. gauge railway was run from tide water to the Trout Lake portal, the first section having a length of 1,800 ft. and a rise of 400 ft. This portion was operated by a Lidgerwood hoist having a pull of 2,000 lb. The rest of the road is level, and the hauling is done by an electric locomotive. The plants at the portals consisted of a boiler supplying steam to an Armington & Simms high-speed engine, a 60-kw. d. c. 550-volt generator, supplying current for lights, ventilating motors and locomotives, and a Leyner two-stage air compressor, having a capacity of 400 cu. ft. of free air per minute. For the transportation to the Coquitlam portal it was necessary to build 2 miles of new road through dense forest and swamp, and to rebuild 7 miles of old road and bridges.

The full section of the tunnel was blasted out without driving an advance heading or drift. As soon after a blast as possible drilling was commenced for the next shot, the miners standing on the muck of the last blast and putting in the upper holes first. The muckers meanwhile removed the debris and then covered the floor of the tunnel for 30 ft. back from the face with ¼-in. iron plates about 4 ft. square. The iron plates afforded a suitable shoveling surface and greatly facilitated the speed of mucking.

The air for the drills was carried from the receiver, which had a capacity of 100 cu. ft., through a 4-in. pipe for half a mile from the portal, and through a 3-in. pipe the remainder of the distance. The temporary connections to the drills were made with 2-in. pipe. To overcome the trouble due to wet air, short drops were placed in the air line at half-mile intervals, and drip cocks on the pockets were left "cracked" to expel the condensed moisture. Flanged unions were provided at 500-ft. intervals to facilitate repairs and all joints were made up with oil and graphite. A number of different types of drills were used on the work, all operating at a pressure of 100 lb. per square inch. Four drills were constantly on hand at each end, two being in use and the other two in reserve.

The spoil cars were of special design, 30 in. high above the rails, with a capacity of 2 cu. yd. The bodies are of steel and swing on a centre king-bolt, dumping out of one end and on either side of the track. Each car weighs 1,500 lb., and cost $130. A General Electric locomotive with two 10-h.-p., 500-volt motors having a draw-bar pull of 1,200 lb. was used at each end. Each locomotive readily handled two loaded cars on a 6 per cent. grade. They were worked at a speed of 4 to 6 miles per hour.

Ventilation of the headings was provided through a 12-in. galvanized iron pipe of No. 24

gauge. Forty-inch Sturtevant fans driven by 5-h.-p. motors were placed at intervals of 2,000 ft., working in series, each fan forcing the air to the next one in the line. The speed of the fans was between 1,300 and 1,400 r.p.m. and cleared the tunnel of smoke and gas in 45 min. after a blast. In addition to this provision a stream of compressed air was blown into the heading through a quarter-inch orifice. Several methods of lighting the tunnel were tried, but were abandoned in favor af candles, which best fulfilled the miners' requirements. Temperature readings showed a rise of 2° Fahr. for each 1,000-ft. advance, the maximum temperature of 60° being found near the middle of the tunnel, and 3,500 ft. below the surface.

The work was begun at the Coquitlam portal by driving a working tunnel 5 ft. above the elevation of high water in the lake so as to guard against flooding the heading. This tunnel sloped downward on a 6 per cent. grade to meet the main tunnel. Thirty feet from the portal a shaft was sunk in the floor of the working tunnel to a depth of 18 ft., the bottom of the finished tunnel. From this shaft a cross heading was run at right angles to the tunnel axis, and from it three 8x8-ft. headings were driven backward toward the lake. During construction about 10 ft. of rock was left in place in the three headings to guard against flooding.

In building the Trout Lake dam a temporary cofferdam was built about 100 ft. upstream, and from it a flume 600 ft. long carried the flow of the creek past the site of the permanent structure. The earth excavated from the site was hoisted in skips by a derrick, dumped into the flume, and sluiced away, 20,000 cu. yd. being removed in this manner. The bedrock on which the dam rests was prepared for a good bond with the concrete by drilling it with 6-in. holes, 3 ft. apart, which were loaded and fired, thus producing a rough surface. The sand used for the concrete in the dam was dredged from the sea bottom near the mouth of Fraser River, pumped into scows, and after being towed to the landing was dumped into cars and hauled to the site. The sand, though not coarse, was very clean and sharp. Four brands of Portland cement were used on the work, White Bros., Hercules, Condor and Alsen.

In building the pipe lines a narrow gauge track was installed in the pipe trench for its whole length and operated by a steam hoist, all the materials for the pipes being brought to their proper place by means of it.

The wooden stave pipes were built by the Excelsior Wooden Pipe Co., San Francisco, at a cost of about $4 per lineal foot. The steel pipes cost approximately $14.50 per lineal foot, for the pipe alone. The cost of the grading for the pipe lines, including trench excavation, and back filling was $25,400.

The contractors were Ironside, Rannie & Campbell for the tunnel; Pelton Water Wheel Co., water wheels; Vancouver Engineering Works, steel pipe lines and head gates; Canadian Rand Drill Co., drills; and the Westinghouse Electric & Manufacturing Co., electrical equipment. Mr. Wynn Meredith was the consulting engineer, and Mr. E. B. Hermon, from whose article in the Transactions of the Engineering Society, University of Toronto, these notes have been taken, and Mr. H. M. Burwell, engineers in charge of construction.

The New Custom House in New York is not only one of the best examples of architecture in the city but it also seems likely to become famous for being completed considerably under the appropriations, which were $4,965,000 in all. While it is not yet completed, it is believed that when all bills are settled it will have cost under $4,900,000.

Sinking a Shaft Through Quicksand by the Pneumatic Process.

A mine shaft which presented unusual difficulties in its construction has recently been sunk by the pneumatic method on the Mesaba Range, near Biwabik, Minn., for the Syracuse Mining Co., to open up a rich deposit of iron ore. The ore body is adjacent to and extends under a lake of considerable size and immediately on top of the deposit is 45 ft. of quicksand. Owing to the proximity of the lake the ground is saturated with water. The mining company, realizing that the sinking would be difficult, arranged to use a patented method of sinking open shafts through water-bearing material and work was begun in December, 1904. The method adopted involved the driving of a series of cofferdams inside each other, the size decreasing with the depth.

Wooden sheet piles 18 ft. long were driven down around two sets of walling timbers, and the excavation was started. Very slow progress was made, owing to the heavy inflow of water and sand. The second set of piles was started, but a bed of large bowlders was encountered and piles could not be forced down. By this time four No. 10 Cameron pumps could not handle the inflow of sand and water. After a four months' trial the mining company decided to stop all operations at this point and shift the location of the shaft about 200 ft. south, where the overburden is perhaps 50 ft. greater, but the chance of encountering bowlders was considered much less.

The permanent mining plant which had already been installed was accordingly moved at considerable expense up a steep hill to the new site. Here the company sunk a large timber shaft with its own force to the quicksand, about 50 ft., by the method commonly employed on the Mesaba Range. Rings of timber are suspended from the surface about 3 ft. apart. As the excavation proceeds 2x10-in. plank, 4 ft. long, are slipped in back of these timbers, forming a comparatively tight wall to keep out the soil. Each course of waling timbers, or "set", as it is locally called, is suspended from the set immediately above it by 1¼-in. bolts, the uppermost set being connected in a like manner to large round bearing timbers on the surface, spanning the excavation and carrying the weight of the shaft lining until the bottom is reached. As it was intended to drive steel sheet piling to the ledge through the quicksand, the shaft was accordingly made large enough to accommodate a steel sheet pile cofferdam at the bottom of and inside the timber lining.

Driving the steel sheet piling was begun in November, 1905, and continued until the following spring. The piles were driven by an ordinary derrick pile driver which rested on the timbers at the surface, a specially designed follower being used. A 3,000-lb. hammer was used and at one period of the work a water jet was also employed. The piles were very heavy in section and were driven very hard.

After the pile cofferdam was completed, a No. 10 Cameron pump was installed and the excavation started inside the steel piling, waling pieces and struts being introduced about every 3 ft. as the work progressed, to keep the piles in place. The excavating was accomplished without much difficulty to a point about 20 ft. below the top of the piles, but below this point it proceeded very slowly. After a few feet of material had been taken out the quicksand would suddenly begin to boil up from the bottom, a corresponding movement of the material on the outside of the shaft occurring at the same time. This badly distorted and cracked the shaft timbers.

It became evident that there was a bad leak or break in the steel sheet piling. Accordingly a crib of 10x10-in. timbers, 3 ft. high, was built at the bottom of the excavation inside the shaft, the intention being to load this crib and force it down till it overlapped the leak or break in the piling. It was hoped that the inflow could thus be checked. After the crib was forced down a few feet it stuck and very little was gained by the scheme. In the meantime each period of excavation was followed by an upward boiling of the quicksand at the bottom. The material around the outside of the shaft settled away, leaving the upper part of the lining exposed. Hay and straw were placed outside the shaft in the hope that at each settlement of the sand, this material would be carried down outside the steel piling and ultimately stop the leak.

At this stage it became necessary to support the timber shaft, which had broken away from the bearing timbers at the surface and was settling down and telescoping the steel cofferdam. This was accomplished by placing steel rails and timbers across the top of the cofferdam and under one of the sets of the timber shaft lining, allowing the latter to take a bearing on them. Pumping was then resumed, and pieces of sheet iron were forced down alongside the sheet piles in an effort to locate and stop the holes where the quicksand was entering the shaft. As a last resort grout was pumped down to the ledge through a 2-in. pipe, it being withdrawn and moved frequently. This was allowed time to harden and the excavation was resumed. After an advance of a few feet had been made, the sand and water broke in from the bottom and boiled up as usual. In August the mining company decided that the shaft could not be sunk by ordinary methods, and called on The Foundation Co., of New York City, who devised plans and contracted to put the shaft down to and far enough into the ledge to make a watertight joint with the rock.

Operations were resumed early in October, 1906. The new plan involved lining the upper or timber part of the old shaft with reinforced concrete, leaving a shaft 13 ft. 6 in. by 6 ft. 1 in. having two 4-ft. 6-in. by 6-ft. 1-in. hoisting compartments at each end, and one 6-ft. 1-in. by 3-ft. 6-in. compartment in the center for pipes and ladders. An air-tight concrete diaphragm fitted with an air shaft and lock was then to be built on the upper ends of the steel sheet piling so that the excavation and timbering below could be done under air pressure. Provision was to be made to suspend the entire weight of the timber lining from the diaphragm until a bearing was secured on the ledge. It was decided to pump out the shaft as low as it had been excavated, about 18 ft. below the tops of the steel sheet piles, and timber from that point up to where the concrete diaphragm was to be; then to construct the diaphragm and line the old timber shaft above with concrete up to the surface of the ground, at the same time replacing the timber bracing with two 6-in. concrete transverse partition walls, reinforced with horizontal ⅝-in. square rods in each side on 6-in. centers.

On account of the dangerous condition of the timber shaft and because it had been strengthened from time to time with cross braces, which left very little working room, this order of operations was found to be impracticable and it was decided that the old timber shaft must be made secure and safe first. Accordingly the weight of the shaft was transferred from the tops of the sheet piles to the surface of the ground by putting in some extra heavy 60-ft. bearing timbers across the top of the shaft at the surface and connecting the timber lining to them by twelve 1¼-in. bolts. The cross timbers and rails on which the lining formerly rested were then cut out, leaving the lining again suspended from the surface.

A 2-ft. space was then cleared of bracing and broken struts at the bottom of the timber shaft, and forms were started preparatory to placing the lining and division wall concrete. Great care had to be taken in cutting out and shifting the struts and braces to make room for the concrete, which was deposited in sections about 2 ft. thick. The timber in the shaft was cracking and moving a good deal of the time while this work was being done, and it was difficult to persuade men to stay in the shaft. A few of the crossbrace ends were embedded in concrete and after the concrete had set the braces were cut and the ends dug out, the resulting space being filled with concrete. Horizontal reinforcing rods 5/8-in. square were placed in the concrete lining on 12-in. centers. A 6x18-in. recess was left 1 ft. from the bottom of the side and end walls to engage the edges of the diaphragm. This work necessarily proceeded very slowly, temporary braces and jacks being used continually. The scarcity and poor quality of the labor available also tended to make the work go slowly. On Nov. 9, the concrete lining had reached a point 10 ft. from the top of the shaft and it was then considered to be in a perfectly safe condition.

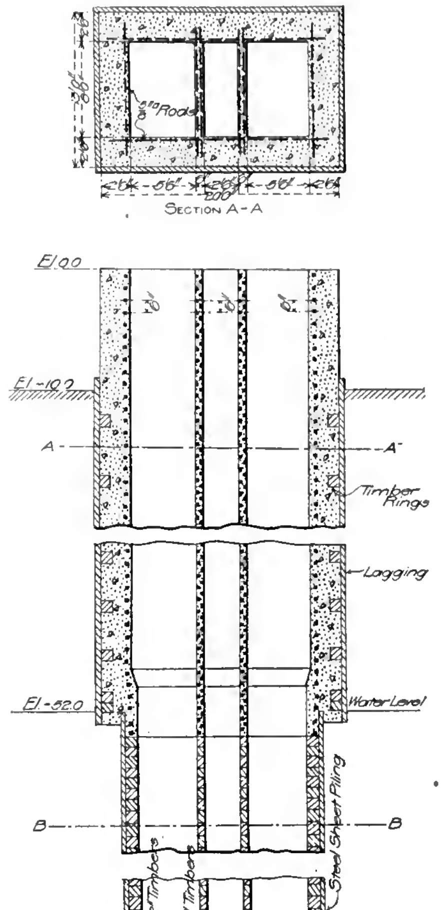
The shaft was then pumped out to the sand, about 18 ft. below the bottom of the proposed concrete diaphragm, and the work of lining the shaft from this point to the diaphragm with rings of 10x12-in. timbers was commenced. This was a difficult piece of work, for the bracing then in the shaft at this point had to be removed and solid timbering substituted. Each ring of timbers rested immediately on the one below it, the joints between the successive rings being well calked with oakum.

The rings were braced transversely by two solid walls of 6x12-in. timbers, each placed 1 ft. 9 in. from the center of the shaft, as shown in an accompanying illustration. These also served to divide the shaft into three compartments, a skidway at each end and a pipeway and ladderway in the center. In each of the four corners of the shaft a 3½x3½x½-in. angle was bolted to each set. These secured and braced the ends of the timbers in a very satisfactory manner.

The centering for the diaphragm was suspended by twelve 1¼-in. bolts from 12x12-in. timbers extending across the finished concrete walls of the shaft. The diaphragm was a 5-in. slab of concrete and was built into the keyway left when the concrete lining was built, as before mentioned. The slab was heavily reinforced both transversely and longitudinally with 1¼-in. steel bars placed on about 6-in. centers. Eight 1¼-in. steel bolts were built into the slab and after the concrete had set sufficiently, the weight of the timbering below the diaphragm, which was built on the sand bottom, was transferred to these bolts so the sand could be excavated below the timbers without danger of settlement. A section of 48-in. air shaft had also been built into the roof, and when the concrete had set this shaft was continued up in one of the hoisting compartments to a point 30 ft. above the diaphragm. A Moran air lock was then connected to the top of the air shaft and air was turned on Dec. 18, 1906.

The work of excavating the shaft and placing the timber lining inside the steel sheeting was carried on rapidly for 12 ft., though the old 3-ft. crib previously mentioned had to be cut out and sent to the surface. All the timber lining was lowered through the air lock and shaft from the surface, where it had previously been framed. As each stick was put in place it was suspended from the timber above it by 2¼x¾-in. iron straps 24 in. long fastened to each timber by two 7x¾-in. lag screws. After ten courses were suspended in this manner, an iron strap of the same dimensions, but long enough to engage ten sticks of timber instead of one, was fastened to the wall in the same manner and attached to the roof bolt, as an additional precaution.

Between the outside of the finished shaft and the steel sheet piling for the first 23 ft. there was a space of 3 to 6 in., which was filled with rich concrete. This had to be suspended from the diaphragm like the timbers, and had to be put in from the bottom instead of the top. However, the general line of the steel piling slanted toward the center of the shaft, and it was not long before the space enclosed by the piling was not any too large to receive the timber lining.



Sections of Mine Shaft.

Twelve feet down it was discovered that four of the sheet-piles had been deflected from their course by a boulder and, being driven further, had curled up inside the shaft in almost true circles, 4 to 6 ft. in diameter. These were cut off with pneumatic tools and sinking was resumed. On account of the large space left open for the escape of air, caused by cutting out these four piles, and the peculiar nature of the ground, great difficulty was experienced from this point down to the ledge. In a good many cases it was possible to put in place a set of timbers only by the aid of jacks and an air jet, owing to the difficulty in keeping down the water level.

As sinking progressed more steel sheet piles were encountered that had broken away from the general line of the piling and been forced into the shaft area. Some of them had to be cut several times as the excavating and timbering proceeded. In all 143 cuts were made in the steel sheet piles. This was slow work, as a good many of them had to be cut 14 in. below the surface of the sand and water to allow for placing the timbers. The work was further retarded by a fire caused by the flame of a miner's candle, and at another time by the breaking down of an air compressor, and it was not until March 12, 1907, that the ledge was reached.

It was the intention of the contractor to stop the shaft at the ore ledge and, after making a tight joint, turn it over to the mining company, but the ledge was found to be so badly broken up and seamy that it was finally decided to carry the excavation under air into the ledge. After going into the ledge 12 ft., it was thought best to stop further sinking under air pressure and finish the shaft in the open. Accordingly a tight joint was made with the ledge and air was taken off on May 10. The walls of the shaft were found to be tight and in good condition. Very little water came in, and that only in the center of the ledge.

The Syracuse Mining Co. was represented by Mr. C. H. Munger, general manager, and the work was done under the direction of Mr. F. W. Adgate, superintendent for The Foundation Company.

The Demolition of Masonry Arches.

The demolition of masonry arches over the double-track railway between St. Denis and Survilliers on the Northern Ry. of France, to permit four-tracking was recently done by an ingenuous method without interfering with traffic. The bridges were segmental arches with skewbacks below the track level thus giving a wide lateral clearance with a small vertical headway on each side of the tracks. In this space a timber falsework tower, triangular in transverse vertical elevation, was built on each side of the track with its upper surface closely fitted to the intrados of the arch. Slight cantilever projections adjacent to the tracks at the tops of these falseworks provided seats for a thin steel shield, put in position during the short intervals between trains and fitted closely to the masonry. This method was equivalent to reducing the span to a minimum and then closing it with a light steel arch which proved strong enough to sustain the masonry of the bridge above after the arch action ceased. The shield was only about 7 ft. wide and as the bridges were about 16 ft. wide it was necessary to move it twice for each bridge. The towers were accordingly seated on oak skids and first used to take down one end of the arch, then moved to the opposite and, after removing it, were replaced in the center and completed the demolition. The thickness of the steel shield was only about 2 in., leaving a clearance of scarcely more than 1 in. below it.

AN EXTRA ADHESION RAILWAY for mountain climbing has been built at Clermont-Ferrand, in France, which makes use of a double-headed rail mounted horizontally between the running rails, upon which horizontal flanged traction wheels underneath the cars bear for propulsion or braking. On the locomotives the horizontal wheels are geared to the main driving axles and adhesion is obtained by a pneumatically operated mechanism which forces them against the double-headed rail with a powerful toggle action. The locomotives weigh 33 tons and the pressure on the horizontal wheels may be caused to reach the equivalent of 50 tons, so that three coaches are hauled up grades ranging from 6 to 12 per cent. without difficulty. The line rises 3,566 ft. in its length of 46½ miles.

The Engineer as a Professional Man.

Extracts from the Annual Presidential Address before the American Society of Civil Engineers, Mexico Convention, July 8. By George H. Benzenberg.

The Constitution of our Society provides that the President shall deliver at the Annual Convention an address, presumably consisting of a general résumé of the most important work in progress and of whatever advance has been made in the engineering art during the past year. Such a statement, however, would be but a repetition of what is being currently presented by the various publications devoting their columns to engineering subjects. Through the perusal of these ably edited and carefully compiled periodicals, we are sufficiently enabled to keep fully abreast of the times, in a statistical and instructive way. It may not be inappropriate, however, to call your attention to the fact, that during no similar period in the history of engineering in this country have so many works of such gigantic magnitude, requiring the expenditure of such vast sums of money, been undertaken or entered upon as during the past year. Among these, the principal works, probably not over nine or ten in number, are all devoted to improving or enlarging present facilities for navigation, travel and commerce, or to providing new channels and new terminals for the accommodation of such, and involve the expenditure of nearly seven hundred millions of dollars, while nearly as large a sum is to be spent from public funds for the development or improvement of water supplies, the betterment of sanitary conditions, the reclamation of arid lands, and the construction or reconstruction of highways, bridges, and other public works for the health, relief, and convenience of man.

It is, however, not only the constantly increasing needs of commerce and transportation, and the comfort and welfare of the public at large, that engage the talent of the engineer. The prevailing tendency to acquire profit and benefit by the introduction of more economical processes of construction and manufacture, as well as by the reduction of wastes, makes it imperative to enlist his analytical and inventive skill and his trained and experienced judgment in almost every branch of human activity, and to secure his advice or approval in every important enterprise. Hence, everywhere, immense interests and ever-increasing responsibilities are being entrusted to the engineer by private as well as corporate organizations. So thoroughly has he been able to meet every expectation, to fulfill every obligation, and to demonstrate his ability to meet every emergency successfully, that his counsel is not only invariably sought in the line of design and construction, but very frequently also as to the possibility or probability of any undertaking becoming a profitable venture. It is in keeping with the world's practical grasping at every opportunity to profit by the knowledge of the highest and best exponents before entering upon or engaging in any great or important venture. These exponents, therefore, should not only be well informed, accomplished, and gifted in their calling, but they must also be the representative of the very best and highest type of that which is implied by American citizenship. Besides being designers and constructors of works for the upbuilding of commerce and every other industry, they should also, to come up to the standard of the profession, become foremost and eminent among their fellow men. The marked position of trust, influence, and eminence which the profession has attained so signally in the industrial world is undoubtedly due to the fact that engineering has become a science of the highest standard.

This progress has been particularly along the line which constitutes the very essence of engineering, and consists in establishing and advancing a thorough knowledge and understanding of the various properties of material, of the forces and latent energies of Nature, and of their economic and intelligent application to the needs and benefit of man. This present knowledge has been acquired by faithful and patient study, by close and careful investigation, by thorough and systematic experiments and tests, and by compiling and communicating the results by reports and publications, in order that the profession might have the full benefit of such research and continue the same for the information and benefit of its members.

Furthermore, the various engineering colleges and technical schools of to-day contain libraries whose shelves are stocked with treatises containing specific and valuable instruction in engineering, as well as with official reports on engineering work. They also possess complete laboratories, thus enabling the student in every branch of the profession to become at least somewhat familiar with the practical end of his study and to train his mind in the proper method of investigating and diagnosing the engineering problems which may present themselves. Moreover, every engineer of to-day, besides his collection of books of reference, keeps himself supplied with all the current literature and with every report and article published pertaining at least to that branch of engineering in which he is especially engaged, in order to remain well informed and abreast with the current conception, practice, and experience of the craft.

To promote and foster this service further, and to maintain the high standard of the profession among its members, as well as in the estimation of mankind, the profession in our country organized this Society, as well as many kindred associations relating to the different branches of professional work, for the advancement of the individual engineer.

To the younger generation of engineers a membership in this and kindred societies is of inestimable value, for it affords them the opportunity not only of participating in practical discussions, but also of having access to valuable documents, papers, drawings, and publications, containing a great mass of information which otherwise is not to be had, and which the earlier engineers did not possess. The present very rapid and remarkable growth in the membership of this Society demonstrates that this fact is now fully understood and appreciated.

It may be properly stated, therefore, that the present-day engineer largely owes whatever success he may have achieved, or reputable position he may occupy, primarily to the advantage which the profession has accorded him, through the close study and diligent research of others who have preceded him and have given the benefit of their learning and experience to the craft, and to which he in turn has likewise added his share for the benefit and welfare of others who may follow.

If this be true, and the engineer, because of this service and also the eminence of his profession, occupies to-day a higher position in the world and enjoys a standing and reputation which compares most favorably with that of any other profession, then the question very properly arises, what duty does he in return owe to the profession; what should be his attitude toward it and his brother engineer, and what position must he ever maintain before the community at large, in order to receive always the full confidence to which he and it should and must always be entitled? The query is a pertinent one, which no engineer should disregard or hesitate to answer.

With the prevailing and ever-increasing tendency of the present day to acquire wealth rapidly, many temptations are thrown in the way of the engineer. Individuals or corporations engaged in monopolizing natural or artificial advantages for selfish purposes, to the detriment of others, do not hesitate to seek the aid of the engineer in furthering their objects. They tempt him to close his eyes to questionable and reprehensible practices. The engineer who is the head of, or is employed in, a municipal or other government department, or who has charge of work executed under contract, is nearly always exposed to such temptation. Every kind of influence is brought to bear upon him to exercise the duties of his office for the benefit of some individual, party, or combination. It assumes every conceivable guise, and is frequently used in such an insidious manner that the unsuspicious mind is not aroused. How often has not the engineer on municipal work been importuned to place the inspection of such work in the hands of someone whose sole qualification consisted in nothing better than the possession of political influence, and who was expected to be not overscrupulous in carrying out the instructions of the engineer?

The element of loyalty to duty, of absolute faithfulness to every honorable engagement, which is not infrequently ignored in many professional and business enterprises, must ever be a distinguishing characteristic of every member of this profession. No matter what may be thought, said, or done in any other walk of life, that much, at least, the engineer owes to his calling, which through its combined achievements reflects credit and reputation upon the individual. The world must know that the engineer does not lend himself, his ingenuity, his skill, or his experience to aught but what is right, and that, having the privilege of declining, his acceptance of a commission means that he is not, knowingly, lending himself to any questionable undertaking, and that his sense of probity, his pride in his work, and his devotion to his profession rise above every other influence or consideration.

To his brother engineer he should always be fair minded and honorable. His sense of justice and equity will never allow him for one instant to forget that he himself is not infallible, that there is often more than one way of solving a problem, and that the work of the "other" may be capable of as good results, with as high economy, as his own solution; nor will he forget that his fellow engineer has the absolute and unqualified right to receive the same consideration he would himself expect. He will, with the innate spirit of a gentleman, honor and respect the opinion and judgment of his fellow engineer, if given in good faith, to the same extent that he values his own; for the argument and reasoning of the one may be as sincere and logical as that of the other, and may possibly be founded on as good or even better experience, the relative merits of which can only be determined by unbiased consideration. He should also recognize that the reputation of the individual is inseparably linked with that of the profession, that the honor and glory of one reflects upon the other, and that, therefore, by maintaining the standing and reputation of its members, he is but maintaining his own.

The respect and esteem which a community entertains toward any profession or its members is always in proportion to that which the members of such profession entertain toward one another.

Unfortunately, there are those who do not hesitate to presume upon the general confidence accorded by the community to any profession, and to exploit it or its reputation for purely personal profit and gain. In the other professions the law has been invoked to provide protection against the unauthorized acts and unpro-

fessional practices of members or individuals whose dealings and transactions tend to reflect discredit upon their several occupations. Happily, there has been no necessity for the enactment of any special statute to protect a community against imposition from the engineer or from one who claims to be a member of our profession, probably because his deeds and works speak for him, while his misdeeds advertise themselves with surprising rapidity.

The engineer is not infallible; he may make mistakes, and it would be remarkable indeed if he did not at some time err in his judgment; but, so long as he is conscientious, exercises every care, and exhausts all his resources in the performance of his obligations, it cannot be said that he is culpable or negligent in his duty. It is necessary, therefore, that he should always be circumspect and vigilant. That the engineer has recognized these obligations toward his profession is evidenced by his standing in the community to-day, and by the trust and confidence with which every material development has been committed into his hands.

Strength of Red and Yellow Douglas Fir Bridge Stringers.

The terms red and yellow fir are not thoroughly defined. By some, only close-grained, bright yellow sticks are designated yellow fir and all other sticks called red fir; while others call only close-grained sticks of a pronounced red color red fir and all other material yellow fir. Both red and yellow fir are secured from the same species, Douglas fir, and often from the same tree.

STRENGTH OF RED AND YELLOW DOUGLAS FIR BRIDGE STRINGERS.
(Yellow fir expressed in percentages of red fir.)

Kind of Fir.	Grade.	Number of Tests.	Rings per Inch.	Per Cent. Moisture.	Weight per cu. ft. As Tested.	Weight per cu. ft. Oven Dry.	Unit Fiber Stress at Elastic Limit.	Modulus of Rupture.	Modulus of Elasticity.
Red	Select	48	10.3	29.6	38.2 lb.	29.5 lb.	4,427 lb.	6,974 lb.	1,645,000
Yellow	Select	45*	17.5*	87.0	94.0	97.0	101	96	100,000
Red	Merch.	71	9.0	29.7	35.9	27.7	4,056	6,019	1,534,000
Yellow	Merch.	38*	16.4*	90.0	97.0	99.0	101	102	97,000
Red	Seconds	43	7.5	27.4	35.7	28.0	3,674	4,923	1,319,000
Yellow	Seconds	11*	14.5*	98.0	104.0	105.0	99	106	98,000

* Not expressed in per cent.

An analysis of the strength tests made by the Forest Service on Douglas fir bridge stringers is shown in the attached table. These stringers were graded according to the export grading rules of the Pacific Coast Lumber Manufacturers' Association, and in the table are grouped by grades. In classifying the stringers according to color all timbers of a reddish tinge were called red fir, and all of a yellowish tinge were called yellow fir. The rings per inch shown in the table indicate that yellow fir is of slower growth than red fir. It also ranges higher in grade. Of the 94 yellow fir stringers tested 47.8 per cent. were selects, 40.4 per cent. were merchantables, and 11.8 per cent. seconds. Of the 162 red fir stringers tested 29.8 per cent. were selects, 43.8 per cent. were merchantables, and 26.6 per cent. seconds, but, grade for grade, these tests show that there is practically no difference in the strength and stiffness of red and yellow fir in bridge sizes.

A CO_2 RECORDER has been constructed for furnace gas investigations by the Cambridge Scientific Instrument Co., which depends on the variation in pressures of waste gases when confined in a vessel with porous walls. Under such conditions the outside air diffuses into the vessel more rapidly than the furnace gas diffuses outward, and the pressure rises within the vessel. The rise depends upon the difference in specific gravity of the gas and the air, which enables the proportion of CO_2 to be measured.

Proposed Code of Ethics for Electrical Engineers.

Submitted by a special committee of the American Institute of Electrical Engineers at the Niagara Convention.

General Principles.—1. In both his professional and his business relations the electrical engineer should follow strictly the same ethical principles that are recognized in the social relations of every-day life. He should consider himself personally responsible for the character of the enterprises and the persons with which he is associated professionally.

2. Before entering into professional relations, it is therefore the duty of the electrical engineer to satisfy himself that the enterprises with which he connects himself are of a legitimate character. If, after becoming associated he finds them to be of a questionable nature he should sever his connection as soon as possible. It should not be considered an excuse that his connection extends only to legitimate engineering work.

3. An electrical engineer permitting the use of his name in any enterprise or exploitation becomes morally responsible for the character of the latter. He should therefore not allow the use of his name in connection with anything upon which he is not qualified by training and experience to exercise competent judgment.

4. The electrical engineer should take care that credit for engineering work is attributed to those who, as far as his knowledge of the matter goes, are the real authors of such work.

5. The electrical engineer should incline toward and not away from standards of all kinds, since standardization is peculiarly essential to the general progress of the profession. This applies to construction, measurement and expression, or nomenclature, as well as to conduct, or ethics. Even the tendency to give individuality by providing special construction may sometimes be avoided with advantage.

Relations of the Electrical Engineer to His Employer, Customer, or Client.—7. The electrical engineer should consider the protection of his client's interests as his first obligation, and therefore should avoid every act that would be contrary to this duty; if any other consideration such as professional obligations or restrictions interfere with his so acting, in accordance with the expectation of his client, he should inform him of the situation.

8. He can honorably accept compensation, financially or otherwise, from one side or party only, interested in the same matter. The electrical engineer, whether consulting, designing, or operating, may therefore not accept commissions, either directly or indirectly, from other parties dealing with his principals.

9. Electrical engineers in a position to decide on the use of inventions, apparatus, etc., should not be financially interested in their use, as by receiving a royalty, etc., unless the matter is clearly understood by the client.

10. Electrical engineers should not accept employment while financially interested in a rival concern except upon the express permission of both parties. An electrical engineer may be employed by more than one party, as in the case of a consulting engineer, when the interests of the parties do not conflict and it is understood, as is usual in such cases, that he is not expected to devote his entire time to the work of one party but is free to enter into other engagements. A consulting engineer permanently retained by a party should notify other prospective employers of this affiliation before entering into relations with them. A consulting engineer when not exclusively retained by one side may advise rival concerns, with the full knowledge of all of them and upon taking care that the interests of the parties do not conflict in the particular matter handled.

11. Operating engineers should consider themselves responsible for defects in apparatus or dangerous conditions of operation, should bring the same to the attention of their employers and urge remedial action. If the causes of the danger are not removed they should withdraw.

12. An electrical engineer should in general be considered directly responsible to his employer or client for the successful fulfilment of the work upon which he has been engaged and for its satisfactory performance as a whole. It should therefore be clearly understood at the outset just what the extent or the limitations of responsibility of the engineer are to be. Whether he has been employed merely as designer or whether he is retained to design and to superintend construction; whether to design only the chief features, or to pass as well upon all details of the apparatus that is to be installed. Attention should be directed to the fact that defects in the manufacture of material or apparatus is a matter distinct from the matters of design or installation. An engineer should not be held responsible for the unsatisfactory performance of a plant resulting from defective aparatus furnished, unless he has undertaken to include this subject.

Relations of the Electrical Engineer to the Ownership of the Records of His Work.—15. The following general principles should be recognized:

If in executing his work, the electrical engineer uses data or information which are not common and public property, but which he receives, directly or indirectly from his employer, or if the problem solved by the engineer is met in the pursuit of his work for his employer, and is not of such character that his attention would have been directed to it regardless of his relations to his employer, the products of his work, in the form of inventions, plans, designs, etc., are not his private property, but the property of his employer, though the engineer may be entitled to special remuneration for such inventions, etc.

16. If in the execution of the work the engineer uses only his own knowledge or data or information which are public property by prior publication, etc., and receives no engineering data from his employer or customer, except performance specifications, the results of the work, such as inventions, plans, designs, etc., are the private property of the engineer, and his employer or cusomer is entitled to their use only in the specified case.

17. All the work done by the engineer in the form of inventions, plans, designs, etc., which are outside of the field of engineering for which his employer has retained him, are the engineer's private property.

18. When an engineer or manufacturer builds apparatus from engineering designs supplied to him by his customer, the designs remain the property of the customer and should not be duplicated for other customers without express permission. When the engineer or manufacturer and his customer are jointly to work out designs and plans or develop inventions, a clear understanding should be arrived at before the beginning of the work regarding the proportionate

rights of the ownership in any inventions, designs, etc., that may result, since in such case both parties should be considered to have rights therein.

19. Any engineering data or information which an electrical engineer obtains, directly or indirectly, from his employer or customer, or which he creates as a result of such information, must be considered by the engineer as confidential; and while the engineer is justified in using such data or experience in his own practice as going towards his education, the publication thereof without express permission is improper, as is also its use in producing for other parties, work that is characteristic of the original customer or employer.

20. Designs, data, records and notes made during his engagement by an engineer employed under permanent engagement, and referring to his work, are his employer's property. The same matter in the case of a consulting electrical engineer are the property of the consulting engineer.

21. A customer, in buying apparatus, does not acquire any right in its design beyond the use in the apparatus purchased. A customer of a consulting engineer does not acquire any right to the plans made by the consulting engineer except for the specific case for which the apparatus was built or the plans made.

Relations of the Electrical Engineer to the General Public.—22. The electrical engineer should endeavor to assist the public to a fair and correct general understanding of engineering matters, spread the general knowledge of electrical engineering, and discourage wrong or exaggerated statements on engineering subjects published in the press or otherwise, especially if these statements are made for the purpose of, or may lead to inducing the public to participate in unworthy schemes.

23. Controversies on engineering questions, however, should never be carried on in the public press, but should be confined to the technical press and the engineering societies.

24. First publication of inventions or other engineering advances should not be made through the public press but rather through the technical press and the engineering societies.

25. The publications which an electrical engineer is justified in making through the public press should therefore be of a historical, educational, instructive or similar character and should not relate to controversies between engineers or on engineering questions, to new inventions, etc., nor contain technical criticisms of fellow engineers, and it should be considered unprofessional to give opinions without being fully informed on all the facts relating to the question, and on the purpose for which the opinion is asked, with a full statement of the conditions under which the opinion applies.

26. In giving expert testimony before judicial bodies, the electrical engineer should confine himself to brief and clear statements on engineering or historical facts. He should not give personal opinions without so expressly stating, and should avoid pleading on one side or the other.

Relations of the Electrical Engineer to the Engineering Fraternity.—30. The electrical engineer should take interest in and show due regard for the electrical engineering societies and the technical press.

31. He should assist his fellow engineers by exchange of general information, experience, instruction, etc.

32. He should not take a position left by another electrical engineer without satisfying himself that the former has left it voluntarily, or for proper reasons.

33. Where engineering work is in charge of an electrical engineer, no other electrical engineer should undertake the work except on request of or in co-operation with the electrical engineer who had charge of the work before, unless the latter's connection with it has already terminated.

34. An electrical engineer in responsible charge of work should not permit other engineers or non-technical persons to over-rule his electrical engineering decisions. If this is done and persisted in, he should as soon as is practicable withdraw.

35. In engineering work in charge of a board of engineers, the respective limitations of the authority of each should be decided at the outset, and each electrical engineer should give full and complete information on his part to the other engineers and insist on this being reciprocated.

Relations of the Electrical Engineer to the Standards of His Profession.—40. The title "electrician" should be applied to those having practical training sufficient to enable them to carry on intelligently certain classes of electrical work, such as the installation of electric lights, signaling systems, and the operation of small electric plants.

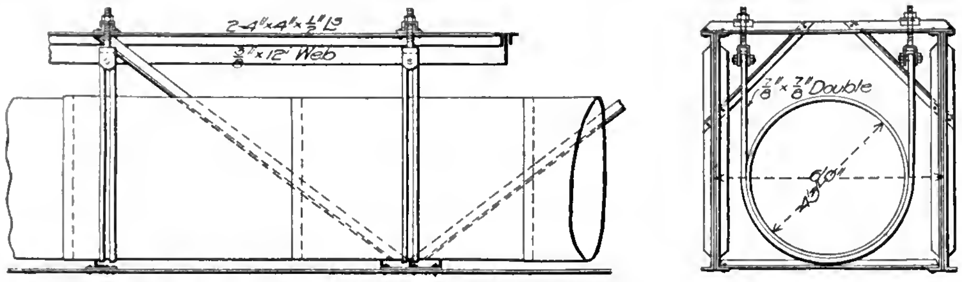
41. The title "electrical engineer" should be applied only to graduates from the electrical engineering school of universities of recognized standing, and such men as possess an equivalent knowledge of electrical engineering.

42. The title "consulting electrical engineer" should be applied only to those electrical engineers who possess such knowledge and experience in electrical engineering as would qualify them to full membership in the American Institute of Electrical Engineers.

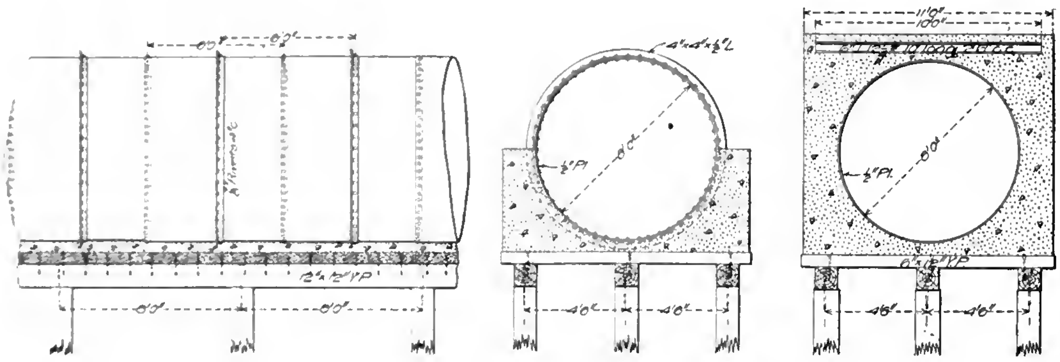
Large Riveted-Steel Sewers in Jersey City, N. J.

An 8-ft. riveted-steel storm-water sewer is now being built in 12th St., Jersey City, N. J., to serve a high 600-acre tract of thickly settled property known as the Hudson City section. The sewer has its origin in the Horseshoe Meadows below the Hudson City section and will extend eastward about 5,200 ft. to its outlet in the Hudson River. At the origin the invert is at El. 65 and at the outlet it is at El. 2, or 4.5 ft. below mean sea level. The average elevation of Hudson City is about 125. This district is at present drained by a 5½-ft. riveted-steel sewer, which is entirely inadequate to carry the storm flow.

Formerly during every severe rain storm cellars in Hudson City were flooded. This has been remedied by constructing a 5-ft. brick sewer through the section and connecting it with the steel pipe at El. 65. This has transferred the water from the residential section to the head of the steel pipe, where it is placed under pressure. The new sewer will also receive at its upper end the flow from cast-iron and steel pipe extensions of the old sewers, and is designed to operate under a maximum head of about 65 ft. It will receive no water from the meadows or neighboring low land.



Side and Sectional View of Pipe Bridge, Jersey City Sewers.



Concrete Reinforcement of Jersey City Riveted-Steel Sewers.

The pipe is made of ½-in. plates, 6 ft. 3 in. wide, and is delivered and laid in 18-ft. sections. All the seams are single-riveted, with 3-in. laps and ⅞-in. rivets 4 in. between centers. Around the pipe, midway between the successive circumferential seams, 4x4x½-in. stiffener angles are attached with ⅞-in. rivets on 6-in. centers. Each 18-ft. section is coated with refined asphaltum in the usual manner. The field riveting is done by hand.

Near the upper end of the new sewer it crosses the lands of the Erie R. R., passing under several tracks. Here and in the soft meadow land special support is secured by three lines of piles, spaced 5 ft. center to center longitudinally and 4 ft. 6 in. transversely. These carry three lines of 12x12-in. yellow pine stringers, spiked to the pile tops, and on these is laid a floor of 6x12-in. pine plank. Under the railroad tracks the angle stiffeners are omitted and the pipe is encased in concrete, as shown in an accompanying illustration, 6-in. 10¼-lb. I-beams spaced 2 ft. on centers being imbedded in the concrete over the pipe as additional reinforcement. In the railroad property where there are no tracks at present and in the soft land the angle stiffeners are used and the concrete casing is carried up to the elevation of the center line of the pipe, where a square shoulder is left on each side, on which the concrete and I-beam arch can be built up if needed later when more tracks are laid. The concrete is a 1:3:6 hand-made mixture of Vulcanite Portland cement, sand and crushed stone.

The pipe laying was begun at the upper end of the sewer and has proceeded about 1,100 ft. All the unloading and other handling of the pipe and all excavation and backfilling has been done with a Brown locomotive crane, equipped with a Haywood 1-yd. orange-peel bucket or with hooks and chains, as the work required. This crane is

operated on a standard-guage track laid along the street in the center of a 21½-ft. strip between the south curb and the south edge of the 8½-ft. trench, which is dug close to the north curb. The track extends to the switch tracks of the Erie R. R. The pipes, which weigh about 6 tons each, are delivered on flat cars, two 18-ft. sections being placed on each car. They are unloaded by the crane and piled two tiers high along both sides of the crane track with their axes perpendicular to the track. At times as many as 75 pipes have been at hand. When one is needed the crane runs back, picks up the pipe, carries it to its place and lowers it into the trench. The time required to do this, when the distance traveled does not exceed about 500 ft. each way, has sometimes been as low as twenty minutes.

In excavating the trench the top 4 ft. of soil is delivered into 2-yd. dump wagons and hauled away. The remainder of the material is delivered at once over the first length of pipe behind the crane so that there is seldom more than 50 ft. of trench exposed at one time. About 5 ft. below the unpaved street surface, where the trenching is now in progress, is hard pan in which there are many small boulders and some large ones. This has to be loosened with hand picks before the shovel can handle it and even then the bucket is never well filled and sometimes picks up only a very little. Nevertheless this method is cheaper than digging the trench by hand.

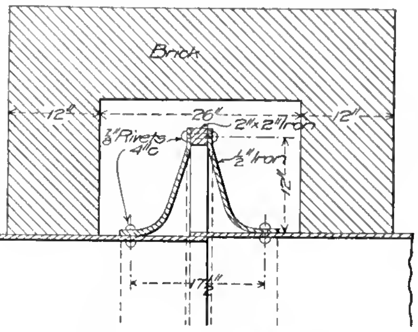
Two-inch yellow pine sheet piles are used. These have been driven with a 2¼-in. cylinder, 100-lb. McKiernan steam pile driver. This has proved too light to force the piles through the hard pan rapidly and a 3½-in. cylinder 600-lb. hammer of the same kind is to be substituted. To facilitate handling the hammer it is swung with a chain block and tackle from a four-legged tower about 18 ft. high, mounted on a small car which runs on a 30-in. track along the outside of the line of piling. The tower is formed by two braced A-frames, one on each side of the car, the one nearer the piles being vertical and the other inclined so that the four legs meet at the top. A platform is provided near the top of the tower on which the man hauling the hoisting tackle stands. The hammer operator stands on a lower platform. Steam is supplied to the hammer by a 40-h.-p. horizontal boiler, a line of 1-in. pipe with hose connections being laid between the rails of the crane track from the boiler to the hammer. This boiler is moved when necessary with the locomotive crane. In one instance it was swung across the track and carried about 300 ft. while under a steam pressure of about 40 lb.

While the pipe was being laid in the meadows a considerable quantity of water was encountered which was handled with an 8-in. Craft centrifugal pump. Later the quantity of water materially decreased and it is now collected in the pipe behind dams of bags of sand, three tiers thick, and pumped out with a 3-in. Maslin pulsometer, supplied with steam from the boiler that supplies the pile driver. When the water gains on the 3-in. pulsometer another is added. This second pulsometer is supplied with steam by a vertical 20-h.-p. Erie boiler mounted on a standard-gauge truck which can be run over the crane track to any point along the sewer. The truck is equipped with an A-frame and boom and tackle with which the pulsometer is lowered into the sewer through a manhole.

Manholes are placed at 500-ft. intervals and at similar intervals automatic duplex air taps and valves, made by the Eddy Valve Co. are installed. Expansion joints of the form shown in an accompanying illustration, are placed at 1,000-ft. intervals.

The sewage of the houses along Twelfth St. has been discharged in the past into a 3-ft. brick sewer built about 40 years ago, a part of which is being destroyed as the construction of the new sewer progresses. Eighteen-inch vitrified pipe lines will be substituted, placed close to the steel pipe one on each side.

A system of riveted-steel sewers of various sizes up to 8 ft., designed to relieve the present inadequate storm water sewerage system serving the Bergen district of Jersey City, has also been partly built. The conditions there are in many ways similar to those in the Hudson City district and the pipes and foundations in general are like those in Twelfth St. The 8-ft. sewer will operate under a head of about 35 ft. and its outlet will be in New York Bay. The construction of this system involved carrying the flow from a system of brick sewers over the Newark & New York R. R. on Jackson Ave. in a steel pipe line having an inside diameter of 4 ft. 5 in. The highway bridge over the railroad on Jackson Ave. is of the deck truss type and was originally designed for very light traffic. It has been reinforced from time to time with plate girders and trusses and now carries two street



Expansion Joint, Steel Sewer.

car tracks. The trusses and girders under the floor left no room for the pipe line, and because of this and the fact that the bridge is likely to be replaced before long, the pipe has been carried across by a through-truss bridge, the end bearings of which rest on the abutments of the highway bridge under the cantilevered sidewalk.

The trusses are of the riveted Pratt type, 6 ft. 4 in. deep. placed 6 ft. on centers and having a span of about 64 ft. divided into eight panels. Roller bearings are provided at one end. To facilitate easy adjustment of the structure and pipe to variations in length due to temperature, the pipe is hung at each panel point from the lateral struts with adjustable slings made of two lines of ⅞-in. square steel rods, as shown in the illustration.

The designs for sewers and bridges were prepared by Mr. Charles A. Van Keuren, chief engineer of the Board of Street and Water Commissioners, of Jersey City, under whose general supervision the construction work has been carried on. Work on the relief sewer for the Bergen section was suspended last summer owing to a disagreement with the New Jersey Central R. R., under whose tracks the sewer must pass, and the contractor, the B. M. & J. F. Shanley Co., was relieved of the contract and paid for the material on hand. Mr. P. Connelly is the general contractor for the Twelfth St. sewer, Mr. W. A. Connelly, superintendent, and Mr. O. C. Stringham, engineer in charge. The steel pipe is supplied by the Thos. C. Basshor Co., Baltimore, Md.

THE WATER UNACCOUNTED FOR at Yonkers, N. Y., where practically all service pipes are metered, was 51.37 per cent. of the quantity supplied in 1906, as indicated by plunger displacement estimates. This is about the usual discrepancy between plunger and meter readings.

Some Effects of the Recent Earthquake in Jamaica upon Railway Structures.

By J. Monk Fletcher, Assoc. M. Am. Soc. C. E.

The earthquake which occurred in Jamaica on Jan. 14 of this year and destroyed its chief city, Kingston, caused comparatively little damage outside that city. The damage was confined to a strip about 30 miles wide, running across the island from southwest to northeast. It seems probable that the centre of the disturbance was somewhere at sea opposite and not very far from Kingston, but it is certain that this principal shock and the many smaller ones which followed were felt to a greater extent in Kingston than at any other place on the island.

The almost complete destruction of the city was, however, largely the result of the unsuitability of the buildings for withstanding earthquake shocks of magnitude. The general offices, locomotive shed and stores of the railway were of brickwork in lime mortar, built upon a foundation of earth, and were wrecked or very badly injured as regards the upper stories, and severely shaken and cracked in the lower stories.

A clock tower of brickwork about 80 ft. high collapsed and fell upon one of the locomotive shops, damaging it considerably. The freight store, which is a wooden building supported upon brick pillars, was almost uninjured, though nearly shaken from the supporting pillars, which were badly cracked and in some cases twisted bodily upon the vertical axis, being broken at about ground level or just above.

Outside Kingston upon the railway the damage done was not great, and was confined almost entirely to brickwork structures. One station building of brickwork was wrecked and several others more or less severely damaged. Lime mortar had been used in the construction of the buildings damaged.

The more important structures, such as bridges, viaducts and tunnels, remained intact. The abutment and piers of bridges are nearly all of concrete without reinforcement and with the exception of a little spalling under the seat of girders, show no signs of the very severe strains to which they were subjected. Viaducts of concrete, without reinforcement, are uninjured as are 20 to 30-ft. span concrete arch bridges under and over the track.

The tunnels are, where necessary, lined with concrete and in some cases show slight cracks, commencing near the junction of the invert with the side wall and extending vertically about 6 ft. The cracks are superficial and do not weaken the structure appreciably. One tunnel has a brick in cement mortar arch 13½ in. thick and this shows absolutely no signs of injury, although the side walls, which are of concrete, have slight cracks as mentioned above.

Concrete retaining walls without reinforcement withstood the shock well and were not damaged. A concrete sea protective wall, which had been completed only 2 weeks, suffered no damage. The wall is carried below sea level 5 ft. and rests partly upon hard blue clay and partly upon igneous rock and extends 16 ft. above sea level. It is built of 1:3:6 Portland cement concrete below and 1:4:8 Portland cement concrete above sea level, clean sea sand being used for the mortar. Hard limestone broken to 2½-in. gauge by hand labor was used for the aggregate. The wall is 8 ft. thick at the base and up to sea level, after which it is battened and stepped to a thickness of 1½ ft. at the top. No reinforcement is used.

Retaining walls of dry rubble masonry were, in some cases, damaged seriously, but where particularly well constructed no injury was done. Rubble masonry walls in 1:4 or 1:5 cement and sand mortar were uninjured.

The effects of the earthquake upon the track were very marked where the embankment crossed swampy land or land which was at or near sea level, the setlement in some cases being as much as 12 in. in 3 ft. At these places the track was also thrown very badly out of alignment. Many small landslips occurred, blocking the track temporarily.

Considering the magnitude of the earthquake shock and the large amount of damage done in Kingston, it is remarkable that so little damage was done to the railway. Traffic was maintained without any break and many extra trains were run for the purpose of carrying the homeless people from the stricken city to their friends in the country parts, thus helping the authorities to bring order out of chaos.

Erection of a Short Bridge by Long Span Methods.

The Smallheath Bridge, at Birmingham, England, carries a very heavy highway traffic and includes one 120-ft. and one 145-ft. riveted pony truss span about 17 ft. in the clean above the surface of the ground. The space under the 145-ft. span is entirely, and that under the 120-ft. span is mostly, occupied by a large number of tracks of the Great Western Ry., which have a very heavy traffic during week days and part of Sunday. To avoid obstructing the tracks, the trusses, 42 ft. apart, are supported on very heavy vertical steel columns instead of masonry piers, and to avoid interfering with the traffic a special method of erecting was developed which, although sometimes used for very long, high, or difficult erection, is rather costly and elaborate.

The vertical pier columns were erected and long transverse girders were seated on them, overhanging them several feet at each end. A transverse timber trestle bent was built between the tracks in the middle of the long span and on it and on the transverse girders were supported four lines of longitudinal girders, one line at each side of each main truss. These were very heavy lattice girders of special construction, tapered from 5 ft. deep in the middle to 2½ ft. at the ends, where they had solid ½-in. web plates. The flanges were 20 in. wide and the web diagonals were 6-in. flats. A solid floor of 14x14-in. transverse timbers and longitudinal planks was laid on these girders and on it the span was erected and riveted. After its completion timber cribbing was built to the ends of the girders and received their weight when the cambre blocking was removed. The erection platform being thus released was removed and the 360-ft. span was gradually lowered about 7 ft. to its bearing by hydraulic jacks.

The bridge is of the ordinary English type with massive riveted construction and buckle plate floors. The details are not of special interest except for the fact that the main truss diagonals have approximately I-shape unbalanced cross-sections with a web plate and single flange angles, the latter reinforced with a wide and a narrow cover plate. The ends of the girders have pin bearings in cast steel shoes and pedestals which at the expansion ends are seated on sets of segmental rollers submerged in tanks filled with special non-evaporating oil to above the tops of the rollers, thus protecting the under surface of the pedestal base. The 32x40-in. vertical pier columns are made with closed cross sections having four longitudinal and four transverse webs with 24 flange angles and have extended cap and base plates stiffened with gussets. The bases are secured by anchor bolts 10½ ft. long to reaction beams embedded in the masonry foundation. The design and erection of this bridge was fully described in recent issues of "Engineering," of London.

The Construction of the Seligman Building, New York.

The 11-story Seligman building, New York, occupies the whole of an irregular lot, having an area of about 5,400 sq. ft., and a front of about 100 ft. on William St., 90 ft. on South William St. and 50 ft. on Stone St. The building is of fireprof steel frame construction with brick walls and stone facing in fronts. The lower floor is chiefly occupied by a very large and handsome bank room, two stories in height finished with Italian marble. The upper floors are devoted to offices and each have about 5,000 sq. ft. of rentable area. The exterior walls 28 in. thick at the base are self-supporting up to the 9th floor, where they are 16 in. thick, and above that are carried entirely by steel girders from the wall columns.

The removal of the old building that formerly occupied the site was commenced about the 1st of May, 1906, the debris was removed and the site was excavated to ground water level at a depth of about 8 ft. below the curb. From the bottom of the pit concrete foundation piers were carried down to solid rock from about 43 to 47 ft. below the curb by the pneumatic caisson process. The foundations for the wall columns were made continuous, forming a solid concrete wall 6 ft. thick and from 30 to 40 ft. high, which encloses the four sides of the lot and is designed, as in several other buildings described from time to time in these columns, to form a sort of dam resisting the heavy outward pressure and excluding ground water from the deep cellar excavated within it.

This dam was constructed in consecutive separate sections up to about 26 ft. long by the pneumatic caisson process. Each caisson consisted simply of a working chamber about 6 ft. wide and 6 ft. high inside, and from 20 to 26 ft. in length. The walls were made with solid horizontal courses of planed timbers sheeted and calked and the long sides were braced by transverse horizontal struts. They were built at the contractor's yard, delivered complete on trucks and set in position where required in the bottom of the pit by four large mast and boom derricks seated so as to command the entire area of the lot and the adjacent street and handle the caissons directly from the trucks to the required positions.

The tops of the caissons were covered temporarily with light roof boards above which molds were built, and in them were cast slabs of rich concrete. Collapsible steel air shafts were set in these slabs and the molds were extended above them by successive sections of detachable paneled courses with exterior horizontal frames of angle iron which were filled with concrete until the pier had been constructed to full height, clear above the bottom of the pit.

The caissons were put under air pressure, workmen entered them and excavated, and the great weight of concrete in position aided their rapid sinking to hard pan through very wet quicksand, gravel and numerous boulders, many of them of such large dimensions that they had to be blasted to clear the cutting edge of the caisson. One such was 10 ft. long, 6 ft. wide and 6 ft. deep and extended entirely across the caisson transversely. The cutting edge of the caisson was usually stopped near the upper surface of the hardpan and the excavation was continued below it from 4 to 8 ft. to the regular surface of the solid rock which was cleared off and received the concrete with which the caissons and air shaft spaces were filled after the steel air shafts were removed.

Caissons for Wall Columns.

The caissons were sunk with clear spaces of about 12 in. between adjacent ends, and in order to bond them together and close the intervening spaces, semi-octagonal wells about 3½ ft. in diameter were cored out of the concrete in the center of the end face of each caisson. The outer faces of these wells were closed with horizontal plans and after both adjacent caissons had been sunk, the planks were removed and the space between them was excavated, the well thus formed being enclosed on both sides by horizontal boards connecting the adjacent caissons as the excavation proceeded.

The well was carried down with the original diameter to a depth of about 4 ft. and a short section of steel air shaft was embedded in it and filled with concrete. An air lock was connected to it, pressure was put on and a man entered and continued the excavation of the well with a reduced diameter down to the top of the working chamber below which point there was not room to admit him between the caissons and the excavation was made as best might be with a post hole digger. When the excavation was complete it was filled with concrete placed under pressure and forming a heavy key binding both caissons together and tightly closing that joint of the dam. The construction of the caissons and the method of sinking and connecting them was substantially the same as that illustrated in the description of the foundation for the Trust Company of America Building, located near the

Seligman Building and executed by the same contractors, which was published in The Engineering Record of October 27, 1906.

The 12 caissons were sunk and air pressure was removed from the last one in exactly 30 days. A sump was dug and steam pumps installed to drain the area enclosed by the wall caissons, and it was excavated by hand to a depth of 26 ft. below the curb, the spoil being loaded in steel buckets and delivered by the derricks to wagons in the street. As the dam proved efficient to exclude most of the ground water, no difficulty was encountered in carrying the concrete foundations for the interior columns down to solid rock by means of seven open rectangular wooden cofferdams. These were made complete at the contractor's yards where they were built in 8-ft. courses, each side consisting of a single panel of vertical 3-in. planks bolted to horizontal transverse timbers. These panels were assembled at the site with the ends of the inside horizontal pieces overlapping and bolted together to form transverse frames connecting the structure and receiving the cross braces. They were sunk by open excavation and loading, and like the pneumatic caissons, were filled with 1:3:5 Alpha Portland cement concrete mixed in a Ransome machine.

Besides the foundations for the interior columns a 16x16-ft. concrete pier was sunk in the same manner to solid rock to support the large steel vault. The sub-structure work involved the excavation of about 8,000 yd. of material and the construction of 2,000 yd. of concrete. The mechanical installation included two 100-h.-p. steam boilers, one 80-h.-p. Ingersoll-Rand and one 80-h.-p. McKiernan air compressor and the usual equipment of hoisting engines, pumps, counter-weight iron and ordinary tools. The work was done with an average force of about 100 men working day and night.

A 12-ton derrick with a 70-ft. mast and 65-ft. boom was installed near the center of the lot, guyed with six lines and operated by a Mundy hoisting engine permanently located in Stone St. With this all the steel work was unloaded from wagons, swung to place, and erected, usually at a single operation. The column loads on the wall piers were distributed over them by grillage I-beams carefully leveled with shims and bedded in grout. The upper flanges of these I-beams, having been adjusted as nearly as possible in the same horizontal planes for each group, were carefully dressed and filed until a uniform bearing was secured and a hot pressed steel plate 1 in. thick was bolted on top which received the cast-iron pedestal for these wall columns. The pedestals of interior columns were grouted on the carefully cut surfaces of granite capstones about 2 ft. thick. Great care was taken to make the pedestals exactly level and to locate them precisely, and all adjustments were carefully checked with transit and level.

All columns are made with rectangular closed cross sections of standard type and were built in two-story lengths having a maximum weight of 5 or 6 tons. There are in the first story and basement 25 columns, some of which support three twin girders over the banking room which carry four additional intermediate lines of columns in the ten upper stories and provide for a large unobstructed floor space in the first story. These girders are much the heaviest pieces of steel in the building and one of them about 35 ft. long weighs about 15 tons and was handled by the derrick boom unshipped and used in a vertical position as a gin pole, secured by six guy lines each adjustable by a hand tackle. The girder was lifted with a 10-part tackle made with ¾-in. steel rope rove through a number of separate sheaves and single and double blocks combined together to provide for the required number of parts. The structural steel in the building weighs about 1,000 tons, and its erection was commenced on Sept. 15 and finished Dec. 15, with an average force of about 25 men.

Erection of Steel Framework.

The weight and the reach of the derrick was so great that the erection stresses transmitted from it to the steel framework were larger than usual and special provision was made to stiffen the structure to receive them before the completion of the masonry walls and floors gave it final stability. The panels between the floor beams and columns in each longitudinal row were X-braced with ¾-in. wire ropes extending across three stories and provided with sleeve nut adjustments. Each double panel thus braced was also stiffened by a single 6x6-in. diagonal timber wedged at the foot against the wall columns and serving as a kicking piece. The columns in the transverse rows were similarly X-braced with wire ropes made from 1⅛-in. guys crossing two panels horizontally and three panels vertically. This system left one panel vacant at one side of the building and was completed without the use of the kicking pieces used in the other systems. When the erection was commenced the systems of bracing were carried up continuously several stories above the ground and afterwards the diagonals were removed from the lower stories and added to the upper ones as the erection progressed. This method was followed not only to clear the masonry but because after the walls and floors were built they lent additional stability to the framework and rendered the bracing unnecessary.

An Ingersoll-Rand air compressor driven by a General Electric dynamo was installed on the first floor and provided air pressure for the field riveting. A 3-in. vertical main was carried from its receiver to the roof and was provided at every third story only with an outlet from which connections were made to flexible tubes by which Chicago and Boyer hammers were operated by three rivet gangs. It was at first intended to utilize one of the steam pipe risers for this pneumatic service, but finally a special pipe was put in rather than wait for the steam pipe to be installed.

The floors and roof are of Roebling cinder concrete construction 4 in. thick and comprise about 65,000 sq. ft. of surface. Their construction was urged forward as rapidly as possible and they were usually kept within two stories of the setting of the beam tiers. The exterior walls contain about 1,200,000 red brick and were built from movable scaffolds suspended by long steel cables from drums carried at the upper story of the building. They were moved almost continuously and permitted the brick-layers to work to the best advantage without interruption.

The wall on all street fronts is faced up to the first floor with polished Crotch Island granite and above that with Bloomington limestone, about 35,000 cu. ft. of which was used. This was unloaded from the street by three boom derricks operated by steam hoisting engines and was stored in large quantities on the working platform 15 ft. wide which extended around three sides of the building over the sidewalk. The stone was set with hand power breast derricks located in every panel between columns, and every block was anchored to the brick work or to the steel framework with from one to three steel anchors, most of them galvanized and with extra large cross section. The work was done by an average force of about 20 men who completed it in about three months.

Mr. Francis H. Kimball and Mr. Julian Clarence Levi were the associated architects, Messrs. Weiskopf & Stern were the consulting engineers for the structural work. Mr. J. S. Griggs and Mr. J. B. Holbrook were the engineers for the mechanical and electrical installation. The Geo. A. Fuller Co. was the general contractor and erected the steel work and the brick masonry. The Foundation Co. was the sub-contractor for the substructure, Mr. W. H. McWhirter, Astoria, L. I., was the contractor for the limestone, which was set by McWilliam Bros. The National Fire-Proofing Co. furnished the hollow terra-cotta partitions, McNulty Bros. were the contractors for the plastering, Herts Bros. for the mahogany trim, the Wells & Newton Co. for the plumbing, and the Marine Engine & Machinery Co. for the plunger elevators, the L. H. Prentice Co. for the steam heating, ventilating and the mechanical equipment; the General Electric Co. for two turbines for the electric lighting plant, the L. K. Comstock Co. for the electric wiring, the Traitel Marble Co. for all marble, and the Waterproofing Co. for the hydrolithic finish of the cellar and pavements.

The Supervision of Construction of the New York State Highways.

The methods of making surveys and plans for highway improvements which are described in the manual issued some months ago by the State Engineering Department of New York have been outlined in recent issues of this journal. These articles have not taken up the supervision of construction, which is covered by other regulations prescribing the following procedures:

Engineers assigned to construction duty are held responsible for the construction of the road in accordance with the plans and specifications, from which no deviation is permitted without the consent of the division engineer. Engineers and their assistants do not leave the road during working hours without the consent of the Division Engineer, unless it be upon some business connected with the work.

Immediately upon assuming charge of a contract the engineer carefully checks the levels and measurements for the entire length of the road and marks on the adjacent fences, telegraph poles or other permanent objects in white lead paint each full station number, where this may be done without damage to private property. If the even station does not come opposite the permanent object the plus station is marked. If discrepancies are found to exist in levels or distance notice of them is sent at once to the division engineer.

The grade and alignment are given according to the following rule: "Set stakes on each side of the highway at every station, or more often if necessary, and near the fences or other permanent objects, where they are not liable to be disturbed. Prepare two small note books in ink, giving the horizontal distance from each stake to the center line of the macadam, and the vertical distance from the top of each stake to the crown of the finished macadam. After these note books are checked one shall be retained by the engineer in charge and the other shall be given to the foreman in charge of the grading, so that he may set his own intermediate grade stakes. At times when the engineers are not needed elsewhere these intermediate stakes shall be set by them."

If, to secure better results, any work in addition to that provided by the plans is thought necessary or advisable by the engineer in charge, a careful plan and estimate of the cost of such extra work is prepared and the whole matter submitted as soon as possible to the Division Engineer.

Engineers are expected to observe carefully the drainage of the entire road, especially during or after heavy rainstorms, and any changes in location or size of culverts or ditches that are considered advantageous are brought at once to the attention of the Division Engineer. Attempts are made during wet seasons to discover all soft and poorly drained portions of the road and if, in the opinion of the engineer, these places are not properly provided for in the plan, the Division Engineer is promptly notified.

No engineer is allowed to give any advice to contractors as to whether or not they can safely take their road rollers or other equipment over bridges. The contractors must assume all risks for such crossings.

Forming Subgrade.—In forming the subgrade for the macadam, stakes are set every 50 ft., or more often if necessary, along the line of the edge of the macadam and the finished grade marked on them. The proper form is given to the subgrade by a string stretched longitudinally between stakes, and by a template conforming to the desired cross-section of the subgrade. The elevation of the subgrade is checked before any stone is laid.

Before any subgrade is prepared for the macadam, all embankment and excavation is made for the full width of roadway. On embankment the portion outside the macadam is thoroughly rolled and consolidated before the trench for the macadam is formed. In excavation, all drainage ditches are excavated before placing the macadam, in order to drain the work thoroughly during the construction.

Care is taken to give the subgrade a sufficient amount of crown, so that after the road is rolled and completed it will have the full crown shown on the plans. This result is best obtained, according to the Department's experience, by raising the center of the subgrade 2 in. or more to allow for settling while the stone is being rolled, leaving the sides as indicated on the plans. If the contractor objects to this method, he is informed that, if the finished road has not the desired crown, it will have to be supplied with additional macadam. This precaution is specially needed on a yielding or plastic soil, likely to flatten under the action of the roller or the traffic.

The result to be obtained, when forming the subgrade, is a firm and solid foundation upon which to place the macadam, one that will not weave under the action of the roller, and on which the stone may be bound and locked together.

When unstable material is of too great an extent to be entirely removed, the facts are reported to the Division Engineer, with a detailed description of the extent of the trouble, and with suggestions as to its proper treatment.

On the clay soil frequently encountered in New York State it is considered absolutely essential that the subgrade be so formed as to prevent the clay working into the interstices of the stone during the rolling of the macadam. The Department states that this can best and most economically be accomplished by placing a layer of gravel upon the clay subsoil, if a bank can be found within hauling distance. A layer of ¾-in. stone or screenings will often give satisfactory results, where no other material is available, and in the more unstable places a layer of field stone, varying in size, with the larger at the bottom, may be used.

During dry weather a subgrade of clay may be firm and hard, but immediately upon being wet it may become very soft. The sprinkling and puddling of the macadam often causes the latter condition, and hence the necessity of providing against the clay working into the macadam.

On sandy soil, rolling has little effect and is continued only long enough to settle the subgrade in place. If the sand is very fine, or is quicksand, a layer of gravel is considered the best treatment possible and will usually give as firm a subgrade as is desired.

Culverts.—Masonry design may be substituted for concrete design at the option of the contractor, the height of parapet above the top of cover being the same in all cases, 9 in.

In setting culverts of minimum length, where the channel is practically level, a fall of about 3 in. is allowed in the culvert and the shape of the shoulders of the road is varied slightly to bring the slope lines to the proper places. Where a culvert is under more than the minimum amount of embankment, either at one end or at both ends, the culvert is lengthened beyond the minimum length instead of raising the parapet and wings to hold the slope. It is not necessary in any case for the elevations of the tops of parapets to be the same, for if so placed, the one on the down-stream side usually appears higher than the other.

Quarries.—If a quarry, after being developed, contains layers of slate, shale, thin layers of soft stone or undesirable stone of any kind, the contractor is required to select from the general run only such stone as will comply with the requirements of the specifications and contract.

If, in the opinion of the engineer, the quarry should be discontinued as a source of supply, the contractor is directed to suspend immediately and a report is sent at once to the Division Engineer.

Field Stone.—Where "local stone" is permitted by the contract and the contractor proposes to use field stone rather than stone from quarries, the following directions are made binding:

"The stone must be selected from the general run of stone found in the fields and stone walls or fences; those used shall be hard, durable and of compact texture, and all disintegrated stone, as well as soft sandstone, shale and slate, must be rejected. Where the field stones are of the flat variety, the minimum thickness allowable for use is 2 in., and where the stones are round cobbles, the minimum diameter allowable is 5 in. unless otherwise ordered by Division Engineer. It will, therefore, be seen that old walls or fences can not be cleaned up entirely in crushing for macadam. When the quantity of harder stone is insufficient for the whole road the softer stone may, if of approved quality, be crushed and used for the lower course. This must not be allowed without the approval of the Division Engineer in each case."

Crushing.—The engineer in charge is required to note frequently the working of the crusher, in connection with the inspection of the crushed stone. If the product seems to run smaller than the screen should give, it may be due to the section of the screen being too short, or the screen may turn too fast, or it may have too great an inclination. The bins are often allowed to get too full and stone from one bin will run over into another. The specifications requirements regarding crushed stone are rigidly enforced.

Courses.—The thickness of the courses of stone are regulated by the use of several hardwood blocks, laid on the subgrade or on the next lower course, as the stone is being spread. These blocks will be one and one-third the required thickness of the course to be formed and the loose stone must be spread to the full height of the blocks.

Spreading Screenings.—The contractor is not allowed to haul heavy loads of screenings over the stone which has been placed, until the latter has been sufficiently filled and rolled to prevent its being displaced by so doing.

Where it is impossible to drive along the side of the macadam and spread the screenings directly from the wagon the contractor must dump sufficient screenings along the shoulder before the stone has been spread and rolled.

Rolling and Finishing Macadam.—In the preliminary rolling of both courses the large wheel of the roller is required to lap out on to the shoulder about 8 in., and after traveling the length of the portion to be rolled, the roller should cross over and return in the same manner on the other side. Crossing from one side to the other on unrolled portions is strongly opposed by the Department.

The rolling of the bottom course is continued until the stone are firmly locked together and do not weave to any extent ahead of the roller, or are not moved by the action of the feet in walking over the macadam.

Where the top-course stone must be hauled over the bottom course, the latter is well filled and rolled to sustain the travel.

No more water is used on the bottom course than is necessary in preparing it to sustain the travel of hauling the top course over it, without cutting or raveling. In most cases the desired result is obtained by dry rolling.

Where the subgrade is of clay, special care is taken not to soften it by the application of too much water, and in the final rolling the stone is not saturated but sprinkled just sufficiently to wet it without reaching the subgrade. It is then rolled several times and left until the next day, and this operation repeated from day to day until the desired result is obtained.

Under no circumstances is any driving allowed over the stone after the screenings have been spread, until the section has been given the first puddle. If the top-course stone is delivered faster than it can be rolled and puddled, it is spread and filled, but is not driven on until puddled and rolled.

It is seldom feasible to get any portion of the road thoroughly filled and puddled at the first operation. If, after the greater portion of the surface is filled with "grout," the road is left for several days to partially dry out, and then is again rolled and more screenings added, the final result can be obtained with less rolling and wetting than if attempted at one operation. Any depressions or hollows developed during rolling or puddling are filled with stone of the same size as the course being treated, thoroughly incorporated with the course before proceeding.

Sections of the road are opened to travel as soon as completed in dry weather, but in wet weather, when the travel brings on mud, the road is not opened in short sections, thus reducing to a minimum the number of places where mud is carried on to the road.

Guard-Rail.—In setting guard-rail the distance from the center of the road to the face of the posts is equal to one-half the width of the road-surfacing, plus two-thirds the width of the shoulder. Exceptions to this rule are made in setting short stretches of rail over culverts and in setting the end posts of all stretches. At culverts where only 24 ft. of guard-rail is used, the face of the middle panel is at the inside face of the parapet.

The end posts of all stretches of guard-rail are set at a distance of one-half the width of roadway from the center of the road and the entire top rail is a uniform distance above the center of the road. In setting the top rail a uniform side slope of 3 in. in 6 in. is used instead of allowing a 3-in. slope regardless of the width of the top of post. A guide for sawing the tops of the posts, similar to that used by carpenters in sawing miter joints, is the simplest method of securing this result.

Inspection.—There is constant inspection of all work and materials during the entire time the construction is in progress and the following rules are given especial attention:

"The thickness of each course of stone must be constantly watched by the engineer, or one of his assistants, during the entire time of spreading.

"The mixing of all mortar and concrete must be constantly watched to insure proper proportions and methods. In placing concrete it is very important to have the forms securely braced, so as to prevent any movement or misplacement. Masonry or concrete laid in warm weather should be protected from the sun by covering with burlap, grass or other satisfactory material, and kept damp until it has thoroughly set.

"Sand used for mortar or concrete must be carefully inspected, and if found to contain an injurious amount of foreign matter, it must be washed before using. Washing should be done by stirring the sand in running water.

"Paving must be watched to insure proper size and shape of stone and form of ditch. Care shall be taken to have the edge of the paving nearest the macadam slightly lower than the material of the shoulder, otherwise the paving will cause the water to follow along its edge, forming a ditch in the shoulder and tending to undermine the paving.

"Paving across drives or highways must be so formed that vehicles can pass over it without danger or inconvenience.

Cement.—No cement is used until it has been tested and accepted. Samples of cement are placed in paper bags, furnished by the Cement Testing Laboratory, Department of State Engineer, Albany, to which the samples are sent immediately after taking. The Laboratory is notified by standard notification cards when each package is forwarded, and a card is also enclosed in each package.

The contractor is informed that the cement he proposes to use on the work must be furnished with a view of being held for the 28-day test, as prescribed in the standard specifications, for only those showing very satisfactory tests are allowed to pass on the seven-day tests.

The contractor must provide a dry place, protected from the elements, for storing cement, and each shipment and each car lot must be kept separate, to enable the removal of any one lot in case of its rejection without causing the removal of a larger quantity.

Samples are taken by the engineer, or his representative, promptly on delivery, from every tenth barrel, or from the equivalent of the tenth barrel when packed in sacks. Each sample is taken to include cement from the surface to the center of the package sampled.

Each barrel or bag sampled is numbered consecutively throughout the progress of the work and its sample is marked in the same manner with the same number.

Results of tests are furnished in ten days from the seven-day test, and in thirty days from the 28-day test, but no cement is used until a notice of acceptance has been received from the Division Engineer. Any cement which has been rejected by the Department, because of failure to stand the required tests, is immediately removed at the expense of the contractor, under the general direction and in the presence of the engineer in charge.

Final Note Books.—For the purpose of making monthly and final estimates and for permanent record after the work is completed, all quantities, except as noted below, are recorded as the work progresses in standard note books furnished by the Division Engineer. Separate headings are made for each item of work, and under each heading is given the station or stations at or between which the item was used and the amount used in each case. If the item were used in a structure reference is made to the page in the book where the structure is shown, as described below. The following data must be given:

"Clearing and Grubbing: Give station, width of cutting and number of acres.

"Excavation or Embankment: Give the contract amount and show by stations any additions or deductions from this amount.

"Macadam: Give the contract amount and show by stations width, thickness and amount of any additions or deductions.

"Concrete: Give the station and nature of each structure, with amount in each, and refer to page where details may be found.

"Masonry: Same as concrete.

"Riprap, Telford Base, Paving and Cobble Gutter: Give station, width, thickness and amounts. If paving is at a culvert, refer to page where details may be found.

"Flagging and Expanded Metal: Give amounts by station and refer to page where details of structure may be found.

"Pipe: Give station, kind, size and length. If in a culvert, give page where details may be found.

"Steel, Cast Iron and Timber: Give stations, amounts and page where details of structure may be found.

"Guard, Bridge and Pipe-Rail: Give stations and side of road on which rail is used.

"Guide-Boards and Road-Signs: Give station and side of road where each post was erected and inscription on each."

Drawings to approximate scale of each structure are shown, with all dimensions and computations and a list of all items and amounts in each structure. When the work is completed, a general summary of all items is made in the back of the book and a final account compiled. This account shows the exact quantity of every item used in the construction of the road.

All final notes are entered neatly and legibly in ink in such a manner that they can be easily interpreted after the work is completed. The final note books are kept as a part of the permanent records of the office of each Division Engineer.

Acceptance.—After the completion of a road and before notifying the Deputy State Engineer of its completion, the Division Engineer has a profile of the center of the road made by a reliable employee not engaged upon the construction of the road. This profile is plotted upon the original working profile or upon a set of original blue prints in such a manner that it may readily be compared with the original profile and a written certification as to its correctness is placed on it by the engineer making it. In like manner an occasional cross-section is made at the places of the heavier cuts and fills. These data are presented for the inspection of the Deputy State Engineer when making his final inspection of the road.

Book Notes.

It has doubtless been a matter of surprise to a good many engineers that there has been no general book on the subject of clay and its products written in this country. While considerable information is available in the publications of the national and state geological surveys, it is not of a comprehensive character and these reports are often difficult to obtain. Accordingly Prof. Heinrich Ries has prepared a useful book in his "Clays; their Occurrence, Properties and Uses," which furnishes in compact form information that could only be obtained by prolonged search and correspondence before the book appeared. The author is particularly well qualified for his task, as he has investigated clays for a number of geological surveys and has made a special study of them in his laboratory at Cornell University. In the first chapter he describes the origin of clays and explains the various classifications of them that have been proposed. In doing this he carefully points out that a great deal must still be learned before our knowledge will be in a satisfactory condition, and in many parts of the country a great deal of investigation of clay beds may still be profitably carried on. In the second chapter the chemical properties of clay are discussed and the effect of various constituents is explained. The author rejects the common statement that all clays contain kaolinite, and points out that chemical analysis alone is unable to determine definitely what are the mineral constituents of clay. Attention is also called to the effect of certain minerals, such as titanic oxide, on the properties of clay of technical importance. The physical properties of clay are taken up in the third chapter, and it is interesting to observe that in respect to the most important of them, plasticity, the author takes a broader conception than that usually held, defining plasticity as the "property which many bodies possess of changing form under pressure, without rupturing, which form they retain when the pressure ceases, it being understood that the amount of pressure required and the degree of deformation possible will vary with the

material. The available information concerning the causes of the physical properties is reviewed and criticized and the changes in the properties due to manufacturing processes are explained. The fourth chapter is an attempt to classify clays from a manufacturing point of view, something which ceramic specialists seem to regard as unadvisable although it is but natural that people looking into the industry for the first time or desirous of ascertaining if a given clay can be used for some purpose should urge the necessity of something of the sort. The chapter also contains a section explaining the general methods followed in manufacturing different classes of clay products. No attempt is made to go into details or to give directions for producing any given class of material, and it is not unlikely that in making general statements the author has occasionally not cared to indicate the exceptions to them. This portion of the book is a useful introduction to a more detailed knowledge of the manufacture of brick, terra cotta, pipe and pottery, when its limitations are borne in mind. The remainder of the volume is a description of the extent and nature of the clay deposits in different States. (New York, John Wiley & Sons. $5.00).

Letters to the Editor.

AN UNUSUAL BRIDGE WRECK.

SIR:—The accompanying picture may interest some of your readers, as it shows a wreck of an unusual nature on the Nashville, Chattanooga & St. Louis Ry. near Lookout Mountain. In the background of the picture is the new road that the Southern Ry. is building between Chattanooga and Stevenson, Ala., where it will connect with the present line of the Southern Ry. to Memphis. The tunnel through Lookout Mountain is just to the right of the picture. Just to the left of the picture is a high hill, the face of which had to be cut off in order to get the approach to the tunnel. This hill is nearly all earth excavation, and is being removed by steam shovels after being loosened by blasting. The bridge which was wrecked is a two-span structure across Chattanooga Creek.

About 3 o'clock on the afternoon of May 16, a blast went off in the earth excavation just mentioned. Whether this was premature or intentional I do not know; the man who set it off disappeared and has not been seen since. A mass of earth from the blast struck the bridge just as a freight train was entering it and wrecked it, dropping eleven cars through, as shown. This was a Southern Ry. train running to Chattanooga. Just to the river side of the picture the Nashville, Chattanooga & St. Louis Ry. was building a trestle across Chattanooga Creek to connect its line around Lookout Mt. with a freight yard which it is constructing on the Chattanooga side of the stream. Rubbish from the blast struck a pile driver on this work, killing a couple of men. In all seven lives were lost as a result of the blast, and a few houses on the hillside were damaged.

The tracks of the Nashville, Chattanooga & St. Louis Ry. at this place are also used by the Alabama Great Southern Ry. and by the Memphis division of the Southern Ry. All traffic was suspended, but passengers were transferred around the wreck. The trestle connecting with the freight yard was completed and the first train was run across it about 10 o'clock on the evening of May 18. The wreckage was then cleaned up and a temporary trestle put in, and the old bridge put in service again on May 23.

I do not know just why this blast did so much damage, but the most plausible explanation seems to be about as follows It is said that about 275 bbl. of powder were used in the blast. It is claimed that instead of the powder going to the bottom of the hole it caught about half way down and lodged there, with disastrous results when it was set off. C. E.

Wreck at Lookout Mountain Tunnel.

UNIFORM CONTRACTS FOR GOVERNMENT WORK.

SIR: By direction of the President, a committee has been appointed from the various executive departments in Washington to prepare uniform contracts for use by the Government. The committee consists of Mr. J. S. Wetmore, of the Supervising Architect's office, Pay Inspector J. S. Carpenter, of the Bureau of Supplies and Accounts of the Navy, Mr. Maurice Bien, of the Reclamation Service, and Messrs. W. W. Warwick and John Mason Brown of the office of the Comptroller of the Treasury. The committee is singularly well constituted to represent all phases of this question in Government work. The contracts with which Mr. Wetmore is directly concerned are contracts for architectural work. Mr. Bien is especially acquainted with engineering contracts, having had charge of the preparation of the forms of contract in use in the Reclamation Service, and Pay Inspector Carpenter in his official duties is necessarily concerned with the purchase of supplies and materials of every sort for the Naval service. The representatives of the Comptroller's office are both of them lawyers of ability, who have dealt especially with the construction of the various provisions of public contracts now in use. Mr. Warwick is chief law clerk in the Comptroller's office and Mr. Brown is the author of a brief but valuable work on the law of contracts, which has been very extensively purchased by the government.

They are to take into consideration the forms of government contracts for all purposes. These may roughly be divided into two classes, contracts for the purchase of supplies and material, including all classes of machinery, and contracts for the construction of the numerous public works in which the United States is engaged, including river and harbor improvements, irrigation projects, public buildings of all classes and wharves and docks.

It is found upon investigation that the forms used in the different departments vary widely, having been modified from time to time by the heads of different departments as conditions arose. The attention of government officers has been of late directed to the fact that the general use in government contracts of provisions vesting a very wide discretion in the government engineer or superintendent and provisions bearing with special severity upon the contractor, while nominally to the advantage of the government, have operated greatly to its disadvantage.

Contractors of wide experience who have large demands upon them for their services prefer to work under contracts which are drawn with a due regard to fairness upon each side. When specifications disclose that the contractor is placed at the mercy of the other party and is subject to the exercise of an uncontrolled discretion, he is not inclined to bid under such specifications. The government has failed to receive bids from many contractors of high reputation because they did not like the conditions under which the work is to be done. Then, too, a contractor who understands the conditions of government work under these severe restrictions, finds it necessary to add an emergency percentage for the risk which these require of him. Consequently, the bids upon government work, when made by contractors of experience in it, have often been considerably higher than their bids upon private work of the same kind. It is common to hear successful contractors say, either that they will not take Government work at all or that if they do take it, they will take it only upon their own terms. The result of this is to the disadvantage of the Government, both in paying higher prices and in losing the benefit of the work of many of the best-equipped contractors in the country.

Much of this difficulty can be avoided by the adoption of a form of contract which will be satisfactory both to contractors and to the government. It is understood that the committee will take ample time for deliberation and discussion on this subject, in the hope of creating better conditions so far as the fault lies in the present forms of contracts. The Committee of the American Public Works Association appointed to prepare a uniform contract for engineering work, of which Mr. G. O. Tenney, of Richmond, is chairman, has placed itself in communication with this official committee and will present to it the result of its labors in the draft of a uniform contract.

Yours truly, OBSERVER.

HYDRAULIC RAMS driven by artesian wells are used in the lower Potomac valley and along Chesapeake Bay. The well pressure is ample to furnish supplies at the shore but does not serve the higher banks, so the artesian flow is used to run rams for the high service.

THE ENGINEERING RECORD

PUBLISHED WEEKLY BY THE

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:
114 LIBERTY STREET, NEW YORK.

BRANCH OFFICES:

CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.

LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico..........$3.00 a year
Canada ....$4.50 a year
Foreign subscription ....$6.00 a year
25 shillings 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGES OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1905, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,250 copies are printed. Total circulation for 1907 to date 420,500 copies, an average of 14,500 copies per week.

TABLE OF LEADING ARTICLES.

The Enforcement of Specifications.

The presidential address of Dr. Charles B. Dudley before the American Society for Testing Materials, published in The Engineering Record of June 29, is suggestive of many important questions which arise in the execution of engineering works of magnitude. Dr. Dudley's observations naturally bear chiefly upon the quality of materials to be delivered to the consumer. His life work, although thorough and most extended, has been devoted with highly excellent results largely to investigations regarding the quality of a great range of materials used by the Pennsylvania Railroad Co., and yet his treatment of the subject as a whole is applicable in essence to the broad field of engineering construction as well as to engineering materials, the former in general terms including the latter. As indicated by him the necessity of inspection in order to secure the enforcement of specifications does not in the slightest degree, as a matter of fact, reflect upon the integrity or the motives or the capacity of the producer of materials or of the contractor who undertakes to build great engineering works. The conditions under which materials are produced or work performed are of almost limitless variety, and it is to the real interest of the producer and the contractor as well as to the engineer and owner to secure in every part of it excellence of material as well as efficiency in structural procedures. Further than this, it is one of the duties of the engineer to supply to his client an authoritative certification that the latter has obtained precisely what he has contracted to receive. It is not an uncommon experience where there is a suitable and reasonable co-operation between engineer and contractor to attain enhanced economy for the contractor as well as improved quality of material and work for the owner. One of the most common instances of this kind, although many might be cited, was the result of the cement inspection in connection with the construction of the Rapid Transit Subway in New York City. The engineering inspection of the cement was carried on in connection with that of the manufacturers to the marked mutual advantage of both parties concerned, and what was accomplished there has many times been accomplished elsewhere and will be again.

Although it cannot be denied that the enforcement of specifications in many engineering works has led to sharp friction between engineers and contractors or producers, it can be said almost without exception that had there been a reasonable attitude of each party in interest to the other with even a moderate amount of tact on the part of the engineer, even such difficulties would largely, if not entirely, have disappeared. It is excessively difficult, in fact practically impossible, for any engineer, however experienced and highly qualified he may be to set forth correctly all the important conditions affecting both the quality of the materials and the character of procedures required in connection with the prosecution of an engineering work of unusual magnitude. The natural conditions affecting such work are never identical in any two cases and seldom nearly so. These differences of natural conditions which occur in the development of field and other structural procedures are so marked in passing from one work to another that, however scrupulously careful the fundamental features of construction are specified, it is simply impossible to anticipate all the exigencies that may arise and hence to formulate specifications which may not need modifications in the interests of both the client and contractor. Under such circumstances it is the part of the engineer to consider well to what extent he shall hold to the literal requirements of the specifications. It is his first duty to secure every excellence of material and structural procedure which the specifications call for: on these points there must be no concession and no reasonable contractor either desires or expects it. There may be, however, a wide legitimate range in opinion as to the ways and means of securing the essential ends set forth in the specifications and therein lies the necessity for the exercise of judicial functions by the engineer. It is precisely in this part of the work that unnecessary and even inexcusable friction so frequently arises between engineer and contractor. Even though specific procedures are prescribed for the accomplishment of certain portions of the work, if either the contractor or the engineer can independently or in co-operation devise more effective procedures for the attainment of the necessary ends, the mere letter of the specifications should not stand in the way of obtaining such an advantage. It matters little whether the contractor will save expense by such a procedure or not. It is his legitimate object to increase his profits if he can do so without prejudice to the quality of the work or materials. No engineer goes beyond a reasonable and proper concession in considering a proposition of this character from a contractor if he constantly keeps in mind the real purpose of his specifications and yields nothing which prejudices either the quality of material or efficiency of the work.

The specifications form a part of the contract which is essentially no less important than those parts which secure payment for the work done. In fact, it may be stated that the specifications form the real substance of the contract, the other portions being incidental although essential, and clearly the engineer cannot properly consent to any modification which militates against the real spirit of the agreement; nor should a contractor be permitted any modifications of procedures, or modifications in the supplying of the materials, which are not absolutely in harmony with the same spirit of the specifications. Neither of these observations, however, prevents to the slightest degree any reasonable modifications necessitated by conditions developed in the progress of the work and not originally anticipated. Such exigencies frequently cannot be met in a reasonable manner under a drastic, literal interpretation of contract conditions. It then becomes the duty of the engineer to exercise broadly his proper functions so as to relieve situations which might otherwise be unreasonable or even intolerable; and thus secure, in the completed work, precisely what was really contemplated by the specifications. It is only the part of wisdom to make specifications sufficiently elastic to permit such an enforcement which, while guarding the interests of the client, is also consistent with the highest efficiency in the contract operations and amenable to any exigencies of natural conditions that may arise.

The Street Lighting Situation.

Indications are very plain that within a short time city engineers and electricians and others who represent the public interest will be hard up against some new and revolutionary propositions in street lighting. At its recent convention the National Electric Light Association adopted a series of specifications for street lighting which are of very grave import and of which the association itself has probably hardly grasped the full significance. The specifications, printed on page 71 of this issue, on their face look somewhat crude, but nevertheless innocent. In point of fact, the cloven hoof of ill-disguised commercialism protrudes from their raiment. This journal gladly acquits the committee that framed them of wilful guile as a whole, yet it certainly has managed to draw up a document that will lend itself readily to ends which its authors would hardly care to stand for were they plainly expressed. With malice toward none and charity toward all, this journal feels compelled to let the cat out of the bag and to show the dangerous issues that lurk in these mild-mannered specifications.

To go back a little, street arc lighting up to

about the year 1898 was carried on to all intents and purposes exclusively by means of the familiar open arcs, of two general patterns, one taking about 9.6 amperes at 45 to 50 volts at the arc, the other about 6.8 amperes at the same pressure. The former was known to the trade as the 2,000 c.-p. or "full" arc, the latter as the 1200 c.-p. or "half" arc. Now, these candle-power ratings were a commercial fiction. The "full" arc gave a maximum candle-power of roughly 1,200 when operating normally, throwing it about 45 degrees below the horizontal, while the "half" arc gave somewhat more than half this light under the same qualifications. Both lights were subject to considerable fluctuations and were weak in rays near the horizontal, so that they gave excellent light near the lamp, but rather poor light at a couple of hundred feet away.

In 1898, the enclosed direct-current arc pushed its way to the front. This was usually a 6.6 ampere arc taking about 72 volts. This gave a smaller maximum than the old full arc, but a more even distribution and a steadier light. It required trimming only infrequently and therefore saved much in carbons and labor, but required to be run from arc machines similar to those already in use, which were rather inefficient. The new light was a pretty effective substitute for the old, lamp for lamp, and took about the same energy. In 1894, the National Electric Light Association, to simplify the situation, agreed to consider the then standard open arc to be of 2,000 nominal candle-power when it took 450 watts at the arc and the usual lamps construed this rating rather liberally. On the new lamps the wattage was liberal enough but the lower current density in the arc lowered the light to an extent that was not compensated by the higher voltage, and the chief gain was in steadiness and better distribution. The old wattage rating was tacitly retained. Had the matter stopped here disputes would have been few, but almost at once the alternating-current series arc at 6.6 amperes appeared, taking only about 410 watts at the arc. Now, alternating-current arcs are intrinsically considerably less efficient light producers than direct-current arcs and this alternating-current lamp was, in spite of a still further improved distribution, decidedly a less effective illuminant than the 450-watt arcs, open or enclosed.

Its gain to the station was considerable, both in trimming and in the substitution of very efficient transformers for rather inefficient arc machines, and therefore, by hook and by crook, it was pushed rapidly into use. Incidentally, it was a good thing for the manufacturers, since the stations had to secure a new equipment. It was not a bad light this 6.6 ampere alternating-current lamp gave, and when sold for what it was and not as an equivalent of the old "full" arc, nobody was the loser. Most contracts specified the lamp fully and fairly and the price was made satisfactory to the users. But later came a somewhat insidious tendency to push this lamp as an equivalent of the full arc, and here the trouble began. This attempt received a severe setback in the Colorado Springs decision of last winter, but at the recent convention, the National Electric Light Association attempted by a rider upon its committee report to resolve that three quarts make a gallon by extending its old 450 watt rating to cover alternating-current lamps. Now a "standard" alternating-current series lamp pushed to 450 watts by raising the current or voltage a little is distinctly inferior for the purposes of its use to the direct-current lamp of similar wattage. Look out for it! There is an alternating-current lamp, taking [illegible] amperes and [illegible] 500 watts which is up [illegible] of pow[illegible] were [illegible] the direct-current lamp, [illegible]w, to side-step the difficulties of this situation, the committee resolved that instead of a watt or candle-power specification, street lighting should be sold by illumination, saying very truly that illumination is the end of street lighting and hence should be ultimately the goods delivered. Unhappily, illumination on the street is measured only with very great difficulty, so that it will produce unlimited litigation as the subject of contracts, while wattage or standard candle-power can be measured with relative ease.

Had the committee stopped here it would simply have endorsed a logical but somewhat impracticable method. It went on, however, to specify that the lamps should be rated solely by the light given at a distance of not less than 200 feet, that is, by the light given nearly horizontally, utterly irrespective of the perhaps very brilliant results over three-quarters of an acre or so of ground nearer the lamp. Right here, kitty pops out. A new form of arc, the so-called luminous arc, has been devised and is being introduced, which throws its maximum light very near the horizontal. It is highly efficient and, if measured in the way proposed by the committee, will enable an illumination specification at 200 feet distance to be met at an expenditure of little more than half the energy of the usual arcs, at the cost, however, of the brilliant effects produced by common arcs at shorter distances.

The luminous arc has many good qualities and will surely make a place for itself, but let it be sold for just what it is, and not by means of a disingenuous method of comparison. The luminous arc gives a capital distribution for street purposes, but one can ill afford to ignore the light given within 200 feet, since only within that distance of any commercial arc yet produced does the illumination rise to a value that is of much use for seeing purposes. The German Association of Lighting Engineers rates arcs on their mean lower hemispherical candle-power, thus taking full account of the total flux of light available on the street. This plan perhaps overvalues light close to the lamp but it is far fairer than that proposed by the National Electric Light Association's committee and is not open to the objection of deliberately favoring a particular form of lamp at the expense of all others. When a proposition for changing the street lighting system arises it is up to those who guard the public interests to see that they are not persuaded to pay for light which they do not get. If highly efficient lamps are available they should be so freely used as to raise the general average of illumination instead of lowering it.

Building a New City.

The industrial city which the United States Steel Corporation is building at Gary, Ind., to provide homes for the employees of the immense new steel mills under construction at that place, is being developed according to a broad general plan of greater scope than heretofore attempted for such a community in this country, if not in the world. The new steel plant will have 12,000 to 15,000 employees soon after it is started. The Steel Corporation also controls seven miles of water-front on Lake Michigan, extending from Gary to Indiana Harbor, which it is expected will be occupied almost entirely comparatively soon by the plants of the subsidiary companies or by those of allied industries. As a matter of fact, the American Car & Foundry Company has already decided to erect a plant in the vicinity of Gary which will give employment to about 3,000 men. Mill towns in this country, in which no outside interests are centered, have a general population of about five to each mill worker. On this basis, the population of Gary ought to be in the neighborhood of 75,000 within two years. The plans for the new town contemplate, however, that latter will be the residential center for the great industrial district which is certain to be developed at the lower end of Lake Michigan on account of the possibility of shipping iron ore by water from the mines around Lake Superior directly to the furnaces, and by the short haul from the extensive coal fields in Illinois and Indiana.

An idea of the scope of the municipal improvements and public service systems for this community, which it is expected will have an important part in the development of the new industrial district, may be obtained from a description published elsewhere in this issue of The Engineering Record. From this description it is evident that the best of modern engineering practice has been applied in the design and construction of these improvements and service systems. Many interesting and novel questions arise in planning and building such a city as Gary, and it might be considered that in this case the opportunity would be presented for improved and original methods of providing for urban population. At the same time, when the arrangements which have been developed for the benefit of existing communities are investigated, it is apparent that they cannot be varied to any appreciable degree without occasioning unreasonable cost, unexpected inconvenience, or the creation of new and undesirable conditions. The adoption of numerous innovations in the arrangement of different features of the public service systems at Gary has been practicable, nevertheless, and advantage has been taken of these possibilities in the work that has been done.

The expense of all the improvements which have been undertaken is borne entirely by the Steel Corporation and is added to the cost of the business and residence lots. These lots are sold subject to reasonable building restrictions that are designed to regulate the character of the city and of different districts in it. Contrary to the general conception, the Steel Corporation will exercise no further paternalism over Gary, which will not differ in its government from any existing city incorporated under the laws of Indiana, except that it is to be finished before being occupied. The outcome of providing such a complete, modern and substantial city as is being built under these conditions by the Steel Corporation for its employees will be of no small degree of interest. The undertaking is practically certain to be successful, nevertheless, because it should be borne in mind that before the new steel plant and other industrial plants which may locate in its vicinity can compete for labor, or for skilled labor, at least, with industries in settled communities a satisfactory place of residence must be provided in the practically barren sand wastes of northern Indiana.

Notes and Comments.

A BUILDING PARTIALLY COLLAPSED in San Francisco early this month, but up to the present time there have been no indications of a massing of technical experts and photographers to describe and illustrate every detail of the design and of the wreckage, although a number of men were hurt. Possibly, the fact that the structure was steel rather than reinforced concrete may be an explanation of the lack of interest shown in the accident by esteemed contemporaries. Just why they have spasms over similar insignificant accidents with reinforced concrete and disregard them when other building materials are concerned is a puzzling conundrum. The accident in this case was apparently due to the removal of bracing before enough rivets were driven; something likely to happen with any kind of construction when work is being driven at high speed and rigid

inspection is not maintained. Every builder knows the danger and tries to avoid it, but foremen will occasionally take the risk of loosening up supports too early and a collapse sometimes occurs. It hardly seems likely that deep technical sermons will be preached on this accident or the use of steel on the Pacific Coast will be at all affected by it, but had it been a concrete floor that dropped what a fine stir it would have made in the trade press.

THE POSTPONEMENT OF ROAD IMPROVEMENTS owing to the unwillingness of those paying for them to have their lives endangered by automobile scorchers was briefly mentioned last week. The subject is one that deserves a good deal of attention. The most destructive user of macadamized roads is unquestionably the automobile, and the time is fast approaching when some method of making the owners of motor cars pay a fair proportion of the maintenance expenses for highways will have to be rigidly enforced. The reasonable use of the roads by automobiles is a distinctly legitimate matter, but their unreasonable use is something entirely different. There is some difference of opinion between road engineers concerning the effect on highways of cars when running at high and at low speeds. Some engineers consider that a speed of 25 miles per hour or less does not work much injury, while others hold that the rate of speed of the car makes very little difference. It goes without saying, however, that a car habitually run at high speed covers so much more ground that it is more destructive than one which is run a shorter distance owing to its lower power, and on this account there is some justification for the tendency to tax cars according to their horse power rating.

THE JUMP IN VALUATION of real estate wanted for public improvements is one of the interesting features connected with the prosecution of any large undertaking involving the condemnation of land. The taxpayers of the city of New York have become accustomed to such large payments for property needed for the public works that the enormous prices they are sometimes forced to pay do not arouse the general condemnation they should. The Board of Water Supply has evidently felt that the expenses for land connected with its works for bringing water from the Catskill Mountains will be so high anyway that every flagrant case of hold-up should be made public. Accordingly, one of the New York papers last week published an illustrated description of some property belonging to a man named Le Vino, situated on the line of the proposed Croton Aqueduct, for which the sum of $545,000 is asked. It is claimed that this property includes a railway, a valuable medicinal spring with improvements connected with it, and a natural park. All these things are shown by photographs to be mere fakes and the man is now the laughing stock of everybody who takes any interest in public affairs. It is to be hoped that such a course will be followed with every other flagrant attempt to extort ridiculously large sums from the city in connection with the new water works. There is nothing so much disliked by the man trying to pry open the public treasury as publicity, and the Board of Water Supply should continue its course of giving out illustrated information regarding these extraordinary properties for which enormous sums are demanded by their owners.

THE BROKEN STONE INDUSTRY seems likely to develop before long in a way that will surprise a good many people. A good bank of building sand has long been recognized as a valuable asset, but it will not be long before a ledge of rock suitable for concrete and highway work will be equally prized. A few far-sighted people have already bought quarries and erected plants for crushing rock for sale as a commercial product, but the present price of broken stone in the vicinity of many cities indicates that more plants can be constructed without materially affecting the market. Any attempt to get out rock economically from most of the little beds developed for small pieces of work is entirely out of the question. The cost of quarrying and breaking the stone is quite high and the expense of transporting it to its place of use is generally equally high, so that it is often the case that a contractor can purchase broken stone from a large crushing plant many miles distant cheaper than he can obtain it from some small ledge in the vicinity. At present most contractors and dealers in broken stone zealously guard the cost of such material, but it is well established that the expense of quarrying and crushing stone is extremely low when the work is done according to a carefully arranged plan and with plant designed be somebody who appreciates not only the special conditions of rock breaking on a large scale, but also the importance of such items of expense as interest charges, depreciation and the like. It is reasonable to say that some of the neglected ledges in the more populated sections of the country will become as valuable assets as the undeveloped water powers which have but recently begun to attract attention.

THE BOARD OF EXPERTS appointed by the Interstate Commerce Commission to investigate the value of safety devices on railways is thoroughly well qualified for its task. At the present time such devices, especially signal systems, are so closely associated with various commercial interests that independent investigations are very much needed. There is no question about the value of most of these appliances, but there is considerable lack of definite information concerning their field of satisfactory usefulness. There is also much misinformation floating about concerning just what safety appliances can accomplish. Oftentimes, after an accident, there is a strong feeling manifested in newspapers that sufficient or proper safety appliances were not at hand, whereas railway men will generally acknowledge in private conversation that the trouble was due to some employee's carelessness. This misapprehension has sometimes been unquestionably increased by attacks on the railroad where the accident occurred by men who have probably had their passes cut off in the past and wish to get even. The way in which newspapers hail them as experts seems to be some recompense for the fact that they no longer travel for nothing on roads where their transportation was formerly furnished free. The work of the Board of Experts is consequently of deep interest to the traveling public, and it is to be hoped that the Board will issue progress reports from time to time so that a knowledge of what it is doing may be had. Such investigations will clear up the uncertainty regarding about only three-tenths of the railroad accidents, and it would be a very good thing indeed if more railroad systems than the Harriman lines were to adopt the method of publicity regarding accidents which Mr. Kruttschnitt recently announced. On that system it is held that personal responsibility for accidents, whether officers or laborers, should be known to the public. It has been determined that there must be a closer observance of rules and greater respect for danger signals than is now obtained from employees. The method of accomplishing this which the officers of the company have adopted is to give the widest publicity to every accident. It will be recalled that this view was expressed in a signed editorial by Mr. Joseph Ramsay, Jr., published in The Engineering Record two years ago. Mr. Ramsay pointed out that until it is possible to secure laws which will make railway employees legally responsible for accidents due to their negligence or carelessness, it is hardly posible to insure much greater safety to travelers than is now afforded. So long as train crews can not be punished for accidents due to their carelessness, it is not worth while to expect any very great increase in safety from mechanical appliances except on roads which have not yet adopted them to the extent their traffic warrants.

A NEW EDUCATIONAL SCHEME called a co-operative course in engineering has been established under the direction of Prof. Herman Schneider, dean of the College of Engineering at the University of Cincinnati. It is a six-year course, during which the students work alternate weeks in local shops throughout the scholastic year and full time in the summer. They have a week's vacation at Christmas and two or three weeks during the summer. The practical work at the shop is stated to be as carefully planned as the theoretical work at the university, and the students are paid about $2,000 for this work during the six years. The students who take the electrical course and work at the shops of the Bullock Electric Co. spend the first year in the foundry, the next year and a half in the machine shop, the next two years in the graduate-apprentice course, and the subsequent time in the drafting room and sales office. The aim of the course is, according to Prof. Schneider's paper before the Society for the Promotion of Engineering Education, not to make a so-called "pure" engineer, but to make an engineer able to take an important position in commercial work. The course is the result of an investigation which showed that a great majority of engineering graduates are employed in commercial production, whereas the present college courses were considered to contemplate only "pure engineering." The advantages claimed for this new educational course are that the extra two years give the student plenty of time to assimilate the theory he learns under the direction of his professors, the shop work has a valuable effect on the application of the theoretical studies he has carried through, the work is a change for the student and valuable as physical exercise, the student gains a knowledge of phases of the labor problem which he cannot obtain except by working in shops, and, finally, he learns to appreciate the importance of time in all commercial work. The course is an interesting innovation and the results of it will be followed with much curiosity, particularly if it is carried forward long enough so that the future careers of the graduates from it can be studied. In one sense, it is a return to some of the ideas which were firmly held when technical colleges were established in this country, for the attention given to shop practice is out of proportion to what is considered desirable in most colleges. If the object of a technical school is to turn out shop superintendents and managers, then it is safe to say that the course is likely to prove successful, for only those fitted by temperament and ability are likely to take its full six years of work. On the other hand it may be questioned whether so much shop practice is of any value to a good many engineers, for it seems to be pretty well established by experience that excellent designing engineers may be trained in the drafting rooms of establishments from students who have never had shop practice. It is safe to say that not one architect in a hundred can do a good job of plastering, yet all are perfectly competent to prepare the specifications and the drawings for such work. Probably very few of the best designers of electrical machinery at the present time have the ability to themselves execute their designs in a shop.

THE MUNICIPAL WORKS OF GARY, IND.

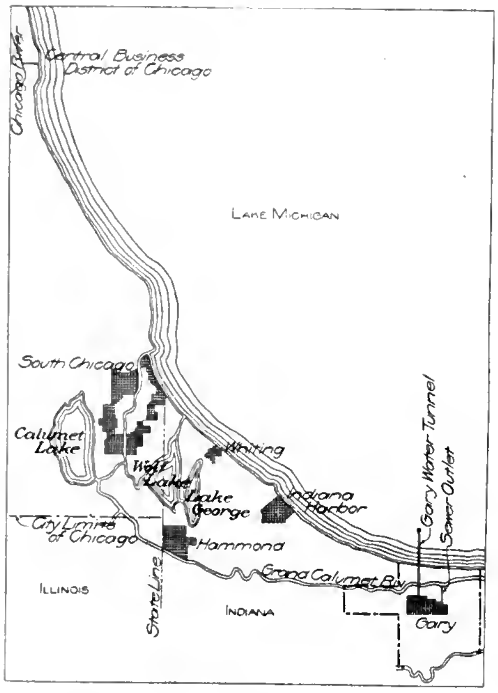
The city which is being built in connection with the new plant of the United States Steel Corporation at Gary, Ind., will have on the whole what are believed to be the most complete and extensive municipal improvements and public service systems that have ever been provided for a new community. The new steel plant will occupy a site about one mile square on the shore of Lake Michigan at the extreme southern end of the latter. 26 miles from the central business section of Chicago, and 12 miles from the South Chicago plant of the United Steel Corporation. This corporation owns seven miles of water front extending along the lake to the west from Gary to Indiana Harbor, the ultimate plan being to establish on this property the plants of allied industries, as well as those of subsidiary companies of the steel corporation. In fact, at least one large independent manufacturing plant employing 3,000 operatives has already been located in the immediate vicinity of Gary, the American Car & Foundry Co. having decided to erect such a plant.

The city of Gary is entirely distinct from the new steel plant, both in regard to location and ownership. The site is immediately in the rear of the steel plant, a sluggish stream, called the Grand Calumet River, separating them. The land on which the city is built, and, in fact, all of the land in that vicinity consists of pure lake sand, which lies in a series of alternate ridges and hollows, roughly parallel to the shore line of the lake. The tops of the ridges are 25 to 45 ft. above the water level of the lake, the general elevation of the hollows being 12 to 20 ft. above that level. The land was originally covered with a scanty growth of vegetation and small oak trees, for, except in some of the hollows, soil was almost entirely lacking.

The construction on such a site of a city which would provide a desirable place of residence for the families of the large number of mill operatives to be employed in the new plant, involved a great expense for preliminary grading before any municipal improvements could be made or public service systems installed. It was imperatively necessary, nevertheless, to afford homes for the 12,000 to 15,000 employees which will be required from the start in the new steel plant alone, and for the population which is expected to be drawn to the city by other industries in the vicinity. In fact, since these various industries will have to compete for workmen with settled communities in which all conveniences are available, the new city had to be a desirable and attractive place in which to live.

The town site was purchased in the first place by the steel corporation, by which it was divided according to what is considered to be the most satisfactory arrangement for an industrial town. Although the topography of the site of the city was very irregular, uniform grades for the streets and alleys were adopted, the streets varying from 19 to 25 ft. above lake level, with the grades of the building lots still higher, so that contrary to the general conception the new town is well above the lake. The adoption of these uniform grades necessitated several million cubic yards of sand to be moved to reduce the sand dunes and to fill the hollows and the waterways of the small sluggish creeks which traversed the site. As little of the sand had to be moved any distance, the grading has all been done with dump cars and horses, and with clam-shell buckets handled by traveling stiff-leg derricks with long booms.

The streets of the city are laid out on the gridiron system. A principal business street, 100 ft. wide, called Broadway, extends due south from a bridge which forms the entrance to the steel works through the center of the first subdivision of lots that has been made; a second business street, 80 ft. wide, called Fifth Ave., intersects this 100-ft. street at right angles near the middle of the subdivision. The lots on both these streets are 25 ft. wide and all face at the rear on an alley, 30 ft. wide. As all other streets in the subdivision are reserved for residences, the business houses will be concentrated on these two streets, the intersection of which is being made the commercial center of the city by the erection of large permanent business buildings, frame buildings being prohibited on these two streets. The residence streets are all uniformly 60 ft. wide, with alleys 20 ft. wide between each two streets. The blocks in the residence districts are 270x450 ft. and 270x630



Map Showing Location of Gary.

ft. in plan, making the depth of the lots 125 ft., when the 20-ft. alleys are considered, the width of the lots being 25 or 30 ft. Space has been reserved in these districts for two recreation parks, one on each side of Broadway, the two being separated about ¼ mile. One of these parks covers an area of four city blocks, and the other an area of two blocks.

Unlike many other similar communities which have been started in the vicinity of large industries in this country, the greater part of the lots along the two business streets in Gary were offered for sale with quite strict requirements, which are calculated to prevent any land-jobbing schemes and to produce a desirable business district, free from the objections so common to such districts in factory towns. The corporation reserved the balance of the lots on these streets, however, including a number of the more desirable business sites, and is erecting on them modern, substantial brick and stone buildings for banks, hotels, a theater, and so forth. The residence districts, on the other hand, being entirely reserved for homes for the employees of the steel corporation, will be free from business concerns of every kind. The houses, which are being erected by the corporation for its employees vary in cost from $2,000 to $15,000 each, and will be sold to the employees at cost. About 500 such houses are now under construction, one company having contracts for over $5,000,000 worth of these dwellings. A noticeable feature of these houses is that over fifty different designs were employed, but as no two houses in the same locality have the same treatment, the architecture of all is apparently different. The lots on the residence streets are wide enough and the houses are far enough back from the sidewalk line to present the appearance of a first-class suburban town. Cheaper homes and large boarding houses for the day laborers are also being erected in one section of the city, but the restrictions governing the erection and maintenance of these structures are such as to bring them far above the average.

Street Pavements.—The two principal business streets, Broadway and Fifth Ave., are paved with concrete; the remainder of the streets of the present subdivision are being paved with macadam. The concrete pavement on Broadway is 66 ft. wide between curbs and is flanked on each side by a concrete sidewalk, 17 ft, in width, which extends to the building line. The pavement is omitted for a width of 20 ft. along the longitudinal center line of the street to provide for the track structure of a double-track street railway which is to be built the length of the street. A concrete curb, 6 in. wide at the top, 12 in. wide at the base and 18 in. high, is placed along each side of this space for the car tracks, the front face of these curbs being vertical so the track structure will be entirely independent of the pavement. Fifth Ave. is being paved with concrete to a width of 46 ft. between curbs.

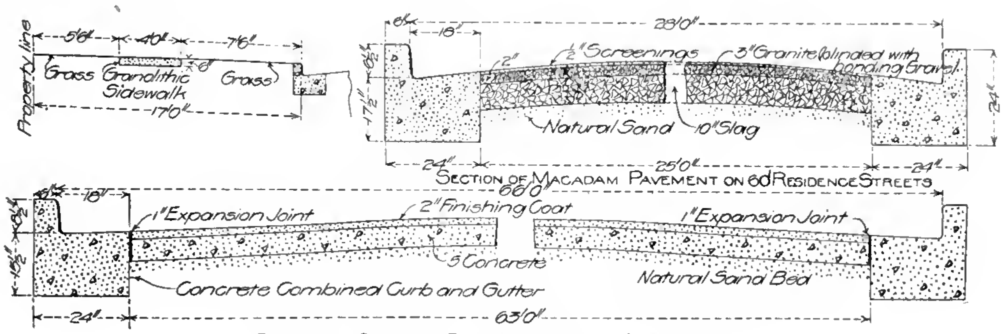
The concrete pavement which is being laid on these two business streets of the city has a total thickness of 7 in., made up of a 5-in. base course of 1:2:4 concrete covered with a finishing coat of about 5:7 mortar. The base consists of 1 part Universal Portland cement, 2 parts coarse sand and 4 parts crushed limestone ranging in size from ½-in. to 1-in. pieces. The finishing coat consists of 5 parts Universal Portland cement to 7 parts red granite screenings. The surface of this finishing coat is marked into 4½x9-in. blocks by grooves, ½ in. wide and ½ in. deep, this marking extending transversely across the pavement. Joints, 1 in. wide, which extend entirely through the pavement are placed across the street, 75 ft. apart, to allow for expansion and contraction, these joints being filled with asphalt mastic.

A combined concrete curb and gutter is placed along each side of the pavement, a 1-in. joint being left between the edge of the pavement and the curb and gutter. A true joint is placed in the curb every 6 ft. and a joint extends through both curb and gutter every 24 ft. Where the sidewalks extend out to the curb a 1-in. joint is made between them and the curb. The curbs are formed into steps at the street intersections, and at the corners special joints are provided in the curbs to prevent the latter being displaced or cracked. The street grades are arranged to carry the drainage to the center of the blocks, thus avoiding a high step at the street crossings.

The natural bed of sand on which the pavements are laid is merely leveled to conform to the grade of the pavement and the base course of concrete is laid directly on this natural sand bed. The concrete in most of the pavement that has been laid was mixed by hand, but a concrete mixer is used for the work that is now in progress. The finishing coat is laid immediately following the placing of the base course, in order to insure a bond between the two. The marking of the finishing coat is done before the latter has taken an initial set. This marking is done by men working on a traveling bridge which spans the pavement and runs on wheels on the gutters. Four men have marked as high as 6,000 sq. ft. in a day when working from this trestle.

In all, nearly three miles of the concrete pavements are being laid. The pavement on a portion of Broadway over 3,000 ft. long was laid last season; Fifth Ave. is now being paved for a length of nearly 1½ miles. The paving is being done by the Rudolph S. Blome Co., of Chicago, and is very similar to a large amount of such work which has been done by this company. Descriptions of some of these concrete pavements in Chicago built in this manner were printed in The Engineering Record for June 9, 1906.

The 60-ft. residence streets of the city are being paved with macadam to a width of 28 ft. between curbs, thus leaving a space, 17 ft. wide, between the curb and the lot line. This space is divided into a 7.5-ft. parking next to the curb, then a 4-ft. granolithic sidewalk, with a 5.5-ft. grass plot between the latter and the lot line.



SECTION OF MACADAM PAVEMENT ON 60' RESIDENCE STREETS

SECTION OF CONCRETE PAVEMENT ON 100 FT. BUSINESS STREETS

Sections of Street Pavements in Gary.

The macadam pavement is laid on a layer of slag which is 6 in. thick at the curbs and 10 in. thick at the center of the pavement. This slag is laid directly on the natural sand, and over it is placed a layer of 1-in. crushed granite varying in thickness from 3 in. at the crown of the pavement to 2 in. at the gutter. The voids in this layer of granite are filled with cementing gravel, the whole layer being thoroughly rolled and sprinkled as it is laid. A finishing course of ½-in, red granite screenings is spread over the surface to fill the voids which may appear in the macadam with use. The granite was chosen for the macadam instead of limestone on account of the glare from the latter, although the granite is much more expensive in this section.

Water-Works.—The water supply for the city is to be derived from Lake Michigan through an intake crib submerged in 40 ft. of water at a point 1½ miles from the present shore line. This intake is 12 miles southeast from the mouth of the Calumet River at South Chicago, which is the nearest considerable source of pollution. The water will be conveyed from the intake crib to a pumping station in the city through a 6-ft. tunnel 3 miles long. This tunnel will be driven 95 ft. below the level of the lake, in the hard clay which underlies the latter and the site of the city at that depth. Three shafts will penetrate to the tunnel, one connecting it with the intake crib; one on the shore of the lake, in which gates will be set to control the supply; and one at the pumping station, 1½ miles inland. The capacity of this tunnel is about 80,000,000 gal., and as the municipal water works are entirely distinct from the water-supply system of the steel plant, it will provide an ample supply for a population of over 300,000.

The two land shafts for the tunnel have to be driven through 50 ft. of fine sand and 40 ft. of clay. One of these shafts has already been sunk by the contractor for the construction of the tunnel, the Great Lakes Dredge & Dock Co., of Chicago, and work will be started at once on the tunnel bore.

The water-works pumping station will be placed at one corner of the larger city park. It will be constructed of heavy masonry according to a design that will render it an ornament to the park. The water will be drawn from the intake tunnel by large centrifugal pumps which will lift it to a water tower, 125 ft. high. This tower will be built of steel and masonry, conforming in architectural design with the surroundings. The pumps will be driven by electric motors supplied by a large electrical generating station in the steel mills, the original source of power being gas engines operating on waste gases from the blast furnaces. The combined capacity of the pumps will be about 20,000,000 gals., the plant being so arranged that under ordinary conditions water will be furnished at a pressure of 50 lb. per square inch, while in case of fire the pressure can be increased to 100 lb. per square inch.

Well-Point Pumping Outfit in a Sewer Trench.

The distribution system of mains is of seamless wrought-iron pipe, with unions forming the joints. The distribution system for the present subdivision is now completed and is arranged to supply every lot in this area. The gridiron system of mains was adopted, the different districts being cross-connected by large feeder lines, controlled by valves, which are so arranged that a broken pipe may be isolated quickly without interfering with the general distribution. The mains have an aggregate length of 22 miles, varying in size from the minimum of 6 in. for residence sections, to 30-in. for the main feeder lines. In order to avoid the necessity for tearing up the streets to make repairs or connections, the distribution mains are all placed in the alleys. The fire hydrants are, on the other hand, all located just inside the curb line of the streets, each city block being provided with four hydrants, one at the middle of each of its four sides. These hydrants are connected to the distribution mains in the alleys by pipes extending through the lots, so the pavement does not have to be crossed to reach them.

The whole water-works system has been designed so provision may easily be made for a supply for a considerable addition to the population and to the size of the city. The capacity of the pumping station may be increased readily and large feeder pipes radiate from the station to the borders of the present subdivision, in order that water may be furnished to additional subdivisions from this station.

The distribution mains were all laid to a depth of 5 ft. below the established grades. The irregular character of the site required a large amount of grading to be done in the alleys before the pipes could be laid. Grading and pipe laying were started in October last, and were carried on simultaneously during the winter, the work being now practically completed. As the grading was all in the fine sand, the pipe laying could follow it quite closely where necessary. Where the pipes were laid across low places in which the grade was to be raised they were placed on small wooden bents pending the filling of the low areas with sand.

The intake tunnel will require some time to complete, so a temporary water supply is obtained from six 6-in. wells driven in the sand at the northwest corner of the present subdivision, in a locality isolated from swamps and all sources of pollution. These wells are all connected to one suction main which is extended into a temporary pumping station. This station contains a belt-driven centrifugal pump which will supply the distribution mains until the intake tunnel and the permanent pumping station have been completed; additional pumps will be installed in this temporary station, if required.

Sewerage System.—The ridges and hollows which make up the site of the city were so formed that the natural drainage was poor, the greater part of the rainfall being obliged to escape by percolation through the underlying 40 to 50 ft. of sand over the hard clay. The direction of ground water flow is toward the Grand Calumet River, which flows westward along the northern boundary of the town site, parallel with and about 1 mile from the shore of Lake Michigan, the river

emptying into the lake at a point some 12 miles to the northwest at South Chicago. The flow in this river is very sluggish, its water level varying only slightly from the level of Lake Michigan. The reduction of the sand dunes to the uniform grades of the streets and alleys and the construction of an adequate sewerage system has entirely changed the natural surface conditions, and to a very considerable extent the ground-water level as well.

The sewerage system is designed according to the combined plan. Provision has been made for substantial growth in the areas on three sides of the present subdivision of two square miles, the steel plant being on the third side. The drainage of the present subdivision is carried to the Grand Calumet River by a 96-in. reinforced concrete sewer, which is sufficiently large to provide an outlet for a system for at least twice the area at present improved. An outline plan has also been made for draining 5 additional square miles through separate outlets. Several small sloughs in the hollows, which formerly carried considerable water at certain seasons, extended from the east to the west through the area that is being sewered and discharged into a small creek, called Gibson's Run, which emptied into the river at a point nearly a mile downstream from the outlet of the 96-in. outfall sewer. These sloughs are all being filled, and the water from them will be taken directly to the 96-in. outfall by a 72-in. sewer instead of passing through the improved area to reach the river through the small creek.

From the junction of the 96-in. and 72-in. sewers a main sewer extends to the east and one to the west, these main sewers reducing from 5 ft. to 24 in. in diameter. The lateral sewers vary from a minimum of 10 in .to 30 in. in diameter. All sewers 24 in. or more in diameter are built of brick, except the main outfall. The smaller sewers are vitrified tile with cement mortar joints. The depth of the sewers ranges from 9 to 23 ft., the deepest sewer being placed in the business districts, or in localities which are likely to become business districts in the future. The lateral sewers are all placed at right angles to these mains, all the main and lateral sewers being placed in the alleys for the same reason the water pipes were so located. The gas pipes are also placed in the alleys, the sewers being at the middle of the alley with the water pipes 5 ft. from one lot line and the gas pipes, 5 ft. from the other. All house connections are made through the rear of the lots. Where catch basins in the street come at the middle of the side of a block parallel with laterals they are connected through the lots to the lateral sewer in the alley, one connection serving two basins. The only sewer connection under the street pavement is thus the single pipes from the catch basins on the far side of the street.

Until the town attains considerable size it is quite possible that the flow in the river, augmented by the large volume of pure water which will be discharged from the steel plant will give sufficient dilution to render inoffensive the discharge of raw sewage into the river. The entire sewerage system has been designed, however, with a view to the purification of the sewage as soon as conditions warrant it. The location of the purification works has not been determined beyond certain limits. At the same time these limits are such that the invert of the main outlet sewer can be constructed on a slight down grade away from the river so the dry weather flow will not reach the river, but will be pumped to the purification works from a sump some distance back from the outlet. During flood flows, though, this arrangement will not interfere with a free discharge into the river. The purification works will consist of septic tanks, followed by percolating filters.

Construction of the Sewerage System.—The natural conditions existing in the area to be drained have occasioned no small amount of difficulty in the construction of the sewers. The ground-water level was originally very nearly the same as that of a large portion of the surface of the land, although the sand dunes rose 15 to 20 ft. above it. Part of the first work done last season after the completion of main outfall sewer was to excavate a trench along the site of one of the main sewers, in order to drain the water from the hollows in the central part of the city and to lower the ground-water level. This trench was dug with a clam-shell bucket handled by a traveling stiff-leg derrick. It was carried to a depth of 15 to 28 ft. below the surface, the botom 4 to 5 ft. being finished by hand and very closely and heavily sheeted to hold back the fine sand through which the excavation was made; the top of the trench was also made as much as 50 ft. wide through the highest sand dunes. This trench had much to do with lowering the ground-water level, and with draining the central part of the town site, but the fine, loose sand on the surface of the ground drifted into the sheeted portion of it to such an extent that the lower part of it had to be partially excavated again before the sewer could be built.

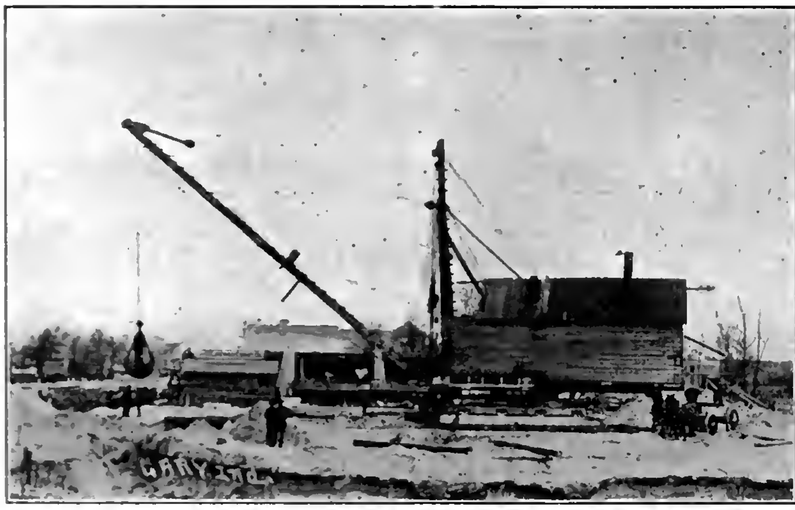
All of the sewer trenches have to be very closely sheeted, and pumping has to be carried on continuously in the vicinity of the pipe laying. Messrs. Green & Sons, of Appleton, Wis., the contractors for laying the water pipe and the lateral sewers, have used a system of well-point strainers in connection with portable pumping outfits, which have proved especially valuable in keeping the trenches entirely free from water even where the ground-water level is practically at the surface of the fine sand. The trenches in which these outfits have been used vary from 2 to 4 ft. in width, and hav depths of 9 to 15 ft. They are in all cases closely sheeted, the sheeting generally being driven after the excavation has been opened to a depth of 2 ft. or more, unless the trench is at a point where the ground-water level is too near the surface.

The portable pumping outfits each consist of a triplex pump, belt-driven by a gasoline engine, the pump and its engine being mounted on a platform carried by the running gear of an ordinary wagon. One of these outfits is placed at the side of the trench where pipe laying is in progress. The pump has a twin 6-in. suction, each branch of which is attached to one of two 6-iin. pipes placed horizontally in the trench, one along each side. These pipes are in 20-ft. lengths, which are connected together by flanged joints. Every 2.5 or 3 ft. a 2-in. connection is made to these 6-in. pipes, each of these connections having two short flexible pieces of 1½-in. hose attached to them. A 1½-in. pipe carrying at its lower end a 1½-in. well-point strainer is attached to each of the hose couplings, the strainer being driven into the sand until it is below the grade of the sewer. The trench is generally opened in sections 60 to 100 ft. long, that is from the point where the excavation is just starting to the place where back filling can be done. In this way it has been found that the pump can remove the water so effectually through the strainers that the work is carried on entirely free from water in the trench, although much trouble is occasioned from water when the latter is drawn from the surface only.

The pumping outfit can be left at one place until 100 ft. of trench has been completed, as the 20-ft. lengths of 6-in. pipe are each fitted with a valve so those at the end where back-filling is being done can be cut off and carried forward to the point where the excavation is just starting. The siamese connections on these pipes are also each provided with a valve so any two strainers may be cut out of service. The well points are jetted down into the sand without any difficulty, and have been used repeatedly with scarcely no damage to them.

The water-works and sewerage systems were designed and are being constructed under the supervision of Messrs. John W. Alvord and Charles E. Burdick, sanitary and hydraulic engineers of Chicago. The main sewer, including about 3 miles of the deepest and most difficult work, is being constructed by the Nash, Dowdle Co., of Chicago.

Gas Plant.—A water-gas plant, with ample capacity to meet the demands to be expected from a city of 75,000, is being built. This plant and the system of distribution mains connected with



Traveling Excavator for Grading.

Type of Business Building.

it are modern in every particular. The main building of the plant, now practically completed, is at the north side of the city on the bank of the Calumet River. It is 63x141 ft. in plan and is built of red pressed brick, with sawed Bedford sandstone trimmings and a book tile roof, the latter being carried by structural-steel trusses.

Two gas-generating plants, each with a capacity of 300,000 cu. ft. daily, are being installed in the building by the Western Gas Construction Co., of Fort Wayne, Ind. In these generators live steam is passed through a bed of incandescent coke in which it is decomposed; oil is then admitted through a carburetor, the mixture passing to a superheater, where it is fixed in permanent form. The gas passes from the superheater through a scrubber, where the tar, ammonia and other impurities are removed, thence to a condenser to reduce the temperature, and finally through four 12x16x5-ft. Lloyd purifiers containing oxide of iron to absorb the sulphur impurities. The finished gas flows through an 84-in. American meter into a 250,000 cu. ft. double-lift steel gas holder in an above ground steel tank, a 10,000 cu. ft. relief holder also being provided.

Water Mains before Grading.

View in Residence Section.

The coke is dumped from the cars in which it is deliverd into a hopper under a track along one side of the building. The coke feeds by gravity from this hopper into a crusher which delivers to a bucket conveyor that elevates the crushed coke to a steel bunker over the generators, the latter being fed by gravity. The ashes from the generators are also removed by this conveyor. Two 75-h.-p. O'Brien boilers supply steam for use in the generators, for the mechanical equipment of the plant and for heating the building.

The distribution system of mains consists appromixately of 17 miles of steel pipe ranging in size from 4 in. to 12 in. The same difficulties encountered in laying the water-works mains had to be overcome in the construction of the gas distribution system. The freedom from danger of settlement in the sand in which the pipe is laid permit very accurate grades to be maintained, thus securing effective drainage for the system with a small number of drainage outlets. The pipes are all coated with asphaltum before being laid. As each section of the system is completed and before the pipe is covered it is tested at a pressure of 40 lb. per square inch, all leaks being carefully caulked. House connections are made to the lateral pipes in the alleys, with heavy saddles clamped to the street mains, thus obviating the necessity for cutting the pipe and inserting the usual tees.

The gas plant was designed by H. M. Byllesby & Co., of Chicago, and is being built under the supervision of that company, which will also direct the operation of the plant after it has been placed in service.

Electric Lighting System.—The present intention is to secure power for electric lighting from a large generating station in the steel plant. A distributing system of wires extending to all parts of the town will be provided, however, and current for power as well as for lighting will be available.

Miscellaneous.—The town site being entirely sand which contains no soil, except in a few places, it will be necessary to provide soil before grass or trees of any size can be grown. The valley of the Grand Calumet River in the vicinity contains a large amount of vegetable loam and black soil which can be brought to the land and distributed at a low cost. When the other improvements have been more nearly completed this work will be undertaken and a general endeavor will be made to cover the whole site with sufficient soil to produce good grass and trees.

The time consumed in building these comprehensive municipal improvements and public service systems, and in fact, the city itself has been remarkably short. Ground was broken for the first time in August of last year, when the paving work and grading was commenced. The construction of the water works distribution system, the gas plant, and many of the dwellings was started about the first of last November, but work on the sewerage system was not well under way until January of this year. The immense amount of grading required, involving several million cubic yards of sand to be moved, has been largely completed; the paving that has been undertaken will be finished soon; over 17 miles of the water distribution mains are laid and are being supplied with water from the temporary pumping station, pending the completion of the intake tunnel and permanent station; the gas plant and distribution mains will be ready for service before the end of the summer; the most difficult portions of the sewerage system are finished and work is progressing rapidly on the lateral sewers, and a large majority of the dwellings are nearly ready for occupancy, while a number of permanent business buildings are completed and occupied.

All of the municipal improvements that are being made at Gary will be paid for at the start by the steel corporation and are charged pro rata to the land, the charge being paid by the purchaser when the land is bought. When the improvements are all completed the steel corporation will relinquish all control of the property that has been sold, the restrictions in the deeds covering the sale of property, the unusually complete public service systems that are provided and other municipal improvements that have been made, being expected to preserve the character of the city well above that of the average mill town.

The population that may be expected in Gary in the near future has been variously estimated. Conservatively, it may be taken to reach 75,000 to 90,000 in five years. The new steel plant will employ 12,000 to 15,000 men, and the new plant of the American Car & Foundry Co., 3,000 more. The population of industrial towns in this country averages about five persons to each mill worker; based on this average, a population of 75,000 is evidently certain. The location of allied industries in this vicinity within comparatively short periods, and the expressed intention of the United States Steel Corporation to make its plant at Gary the one in which the expansion for western business, at least will be handled, give good ground to believe that the permanent and extensive improvements which have been undertaken to found a city of the better class under such adverse conditions are justified.

The construction of the new steel plant is being directed by Mr. G. G. Thorp, vice-president of the Indiana Steel Co. Mr. A. B. Neumann is chief engineer and Mr. W. P. Gleason, general superintendent, of that company. The town of Gary is being developed by an independent company under the general supervision of Mr. Thorp.

A Sand Roadbed has recently been constructed by the Atlantic City & Ocean City R. R. to carry its electric line over a long stretch of salt marsh. A number of highways have been built in this neighborhood by confining a sand fill between lines of plank attached to posts, and this roadbed follows the same general plan. Two rows of posts are driven, one on each side of the 48-ft. roadbed, with their tops level with the surface. The inner face of each row carries planking for a depth of 5 ft. below the tops of the posts, leaving an open space of variable depth between the bottom course of plank and the top of the meadow. Sand is filled into the space between the rows of posts up to their top, as before stated, some of it running out at the bottom below the planking. Outside the row of posts on each side of roadbed, sand is filled in at its natural slope until it is within 2 ft. of the top of the posts; this fill acts to prevent the confined sand from slipping sidewise under the planking and allowing the track to settle.

Standard Sand for Cement Work.

An investigation of sands for cement work has been made at the Iowa State College, Ames, Iowa, by Mr. M. J. Reinhart, to ascertain what the best sand should be like and how ordinary sands can be improved by screening or by adding the proper material to give the resulting mixture the least percentage of voids. From the account of the investigations presented by Mr. Reinhart before the convention of the Iowa Cement Users' Association these notes have been taken.

The sand used in the experiments was bank sand of exceptionally good quality, comparatively coarse and largely free from earthy materials and having about 30 per cent. of voids. All that failed to pass a No. 2 sieve was rejected. This was about 3 per cent. of the original sand and it was the grades from this size down that were used in making the mixtures.

The screens used in separating the sand into the various sizes were as follows. The No. 2, or two meshes per lineal inch, the No. 4, or four meshes per lineal inch, the No. 8, No. 16, No. 30 and the No. 50 screens. With the above screens a given amount of material was divided into the six graded sizes as follows: That which passed the No. 2 and was retained on the No. 4: passed the No. 4 and was retained on the No. 8; passed No. 8 and was retained on the No. 16; passed No. 16 and was retained on No. 30; passed No. 30 and was retained on No. 50; and finally that which passed the No. 50 sieve. In each case the per cent. of the whole was determined by weight and the voids in each separate part determined.

In determining the voids the following method was used: A cylindrical vessel holding about a pint was carefully filled with sand up to a horizontal line around the jar, and settled somewhat by shaking and tapping the sides of the vessel, but not tamped, and then weighed. The vessel was then emptied and a certain amount of water poured in, approximately equal in volume to the voids ÷ total weight of water × 100 per cent. carefully put back into the jar and water enough removed or added to cause it to stand just to the level of the line around the glass. The difference in weight between the vessel filled with sand and water, and the weight of the vessel and sand alone is the weight of the water required to fill the voids of the sand. Next the weight of the water required to fill the vessel up to the horizontal line was determined and by the following expression the percentage of voids was calculated: (Weight of water required to fill the voids ÷ Total weight of water) × 100 per cent. = percentage or voids. In all cases two determinations were made and the average taken.

Next, a properly graded sand was attempted, by putting the right amount of each grade of sand into the mixture. The weight of a certain amount of the coarsest material was found, and to it was added just enough of the next size to fill the voids. This gave a material made up of particles or pebbles which passed the ½-in. mesh screen and were retained on the ⅛-in. sieve. The voids of the large size was 44.2 per cent. of the small size 42.4 per cent., and of the mixture 38.0 per cent. To the mixture was then added enough of the third size to fill the voids, and so on down to the finest material, which passed the No. 50 sieve. The table shows the weight and voids of each material and mixture. The final mixture contained 24.4 per cent. of voids, a reduction in voids of nearly 19 per cent. as compared with the 30 per cent. of voids in the natural sand. This was the second mixture tried, the other by adding an excess of fine material each time gave a slightly larger per cent. of voids.

Next a mixture that would be practicable for improving sand was tried, on which by one screening of the sand the voids could be materially reduced. It is a generally known fact that if to ordinary sand fine pebbles as an aggregate be added a stronger mortar can be made from the sand, if mixed in a given proportion. So it was decided to add to the ordinary sand a certain amount of aggregate which passed a No. 2 sieve and was retained on a No. 16 sieve. To determine the correct proportion to add, a

Main Diagonal Intersections, Quebec Bridge.

determination was made to find the per cent. of aggregate larger than that which passed a No. 16 sieve as well as the voids of the aggregate.

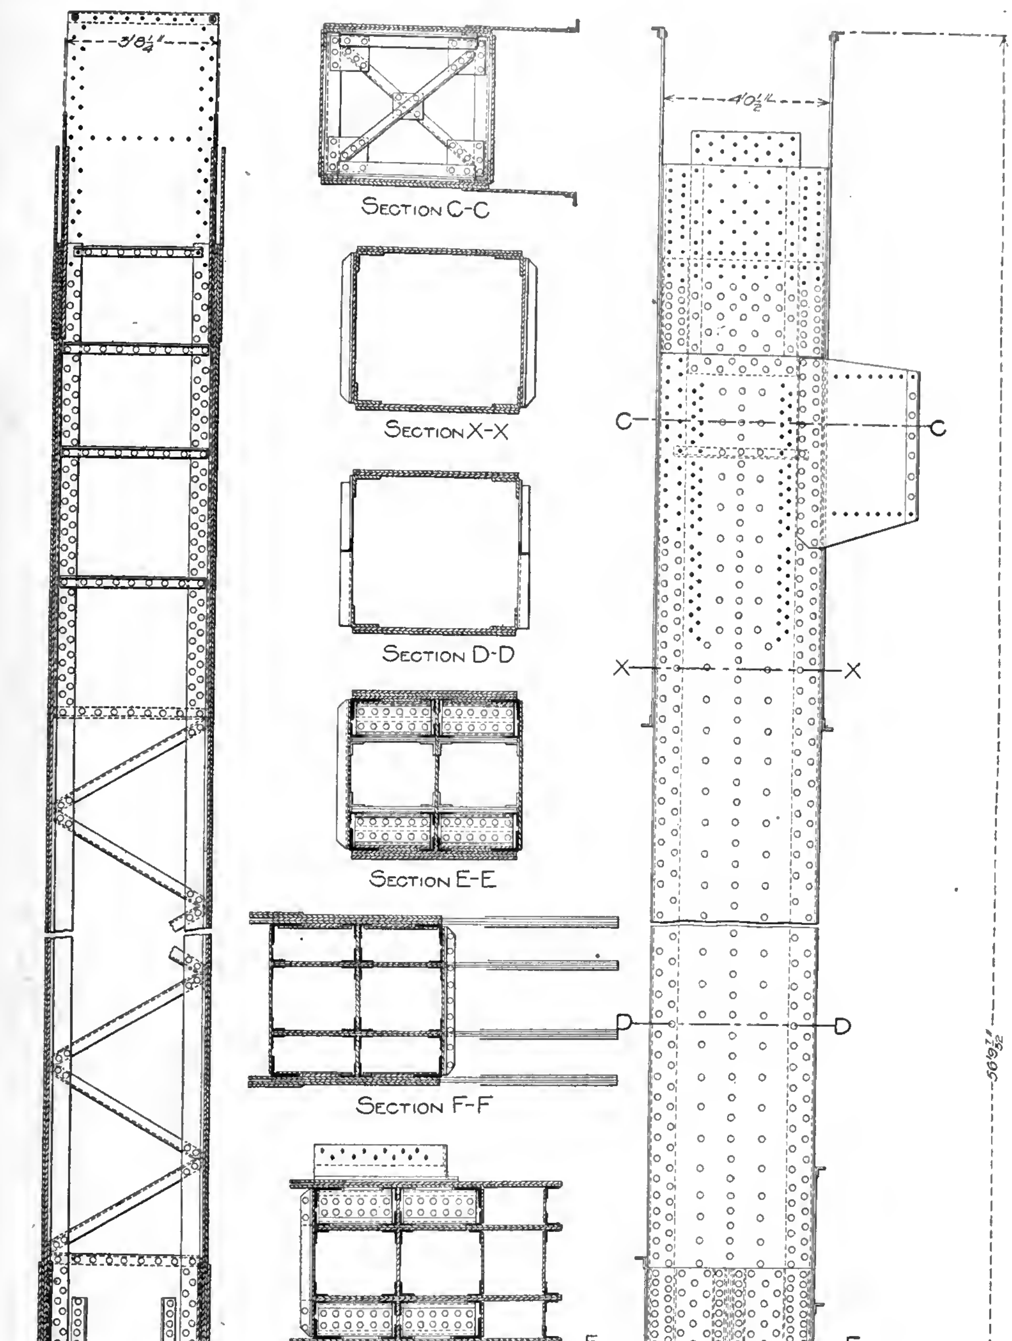
It was found that 34 per cent. stopped on the No. 16 screen and that this material had 34.2 per cent. voids. Starting thus with a given amount of this coarse material (16 lbs.), the proper amount of natural sand to add in order to just fill the voids was calculated thus: Let $x =$ the amount of coarse material or aggregate in the sand. Let $y =$ the total weight of sand. Then $(16-x) \times 0.34 = y-x$, and $x = 0.342\ y$. Solving, $y = 10$ lb. In other words, to 10 lb. of sand was added 16 lb. of the coarser material, and this mixture contained 25 per cent. of voids, a reduction in voids of nearly 17 per cent. By the same method of determination the proper amount of aggregate to add to any sand or gravel might be determined.

In order to show the comparative strengths of mortars made from the three sands, the natural, the properly graded mixture, and the mixture improved by one screening only, tests were made, both for tension and compression. The specimens tested were ordinary briquettes for tensile strength and 6-in. cubes for compressive strength.

The mortars used in the tension briquettes were all 1:3 mixtures and the compression blocks were all made of 1:4 mortars. Three briquettes of each class were tested after seven days and six others were reserved, three to be tested at three months and three at one year. One compression block of each mixture was broken when seven days old and two others made at the same time and from the same mortars will be crushed when three months and one year old, respectively The mortar in which natural sand was used showed an average tensile strength of 367 lb. per square inch and a compressive strength of 1,889 lb. The mortar made with sand improved by one screening developed a strength per square inch in tension of 397 lb. (average) and in compression crushed under 2,611 lb. per square inch. The specimens made with properly proportioned sand showed an average tensile strength of 403 lb. and a compressive strength of 2,139 lb. The values developed in tension were quite consistent.

The results show the value of having the graded materials in a mixture of sand, and the fine material in the proper proportion to fill the voids in the larger aggregate. This was not a concrete but a mortar of about the consistency for cement blocks, tile, posts, etc. In the natural sand there was a deficiency of both the coarse and fine material, while in the other mechanical mixtures this fault had been largely overcome. In the former, mixed in a proportion of 1 to 4 the cement was insufficient to fill the voids, while in the latter case it was just sufficient, and hence the results.

EROSION OF STEAM FITTINGS by water in the steam was recently demonstrated by a test made by Mr. James F. Hobart. Two ¾-in. pipes were used, one known to carry water with the steam and the other dry steam. A flange union was put in each line and between each pair of flanges a diaphragm of thin sheet iron was inserted, pierced by a ⅛-in. hole in the center. Steam was then allowed to pass through both pipes for 6 hr. a day for 6 weeks. At the end of the time the unions were taken apart and the diaphragms removed. The hole in the disk exposed to dry steam was unaltered but that in the disk exposed to wet steam had been worn away so much that it resembled a key-hole.



Lower Part of Intermediate Post 4.

The Quebec Bridge Superstructure Details; Part IV.

Upper Part of Vertical Post 4.—Intermediate vertical post 4, adjacent to the main post, is the largest of the vertical posts in the anchor arm truss and was shipped in two separate sections successively erected and connected by a field riveted splice 2 ft. above the center point of the completed member. The dead load stresses are uniform throughout the member, but the wind load stresses vary in the upper and lower parts, being somewhat greater in the former where the total maximum stress is 3,620,000 and is provided for with a gross sectional area of 174.3 sq. in. The total length of the post is 224 ft. from center to center of chords and the normal section is a 3-ft. 8-in. x 4-ft. rectangle.

The upper section of the post has a total length of 94 ft. over all and weighs about 92,000 lb. It is made of two built channels 4 ft. deep with their flanges turned in and latticed with angle bars in the spaces not covered by continuous flange plates. The channels are made with double 48x11/16-in. web plates 79 ft. 7 in. long riveted together and with pairs of 8x6x13/16-in. flange angles about 89½ ft. long, with double rows of rivets at about 6-in. pitch in each flange. Additional section is secured by a full-length 7x¾-in. flat riveted between the web plate and each flange angle. The joint between the upper and lower portions of this member is made with four flange and web cover plates, having in each end about two hundred ⅞-in. field-driven rivets.

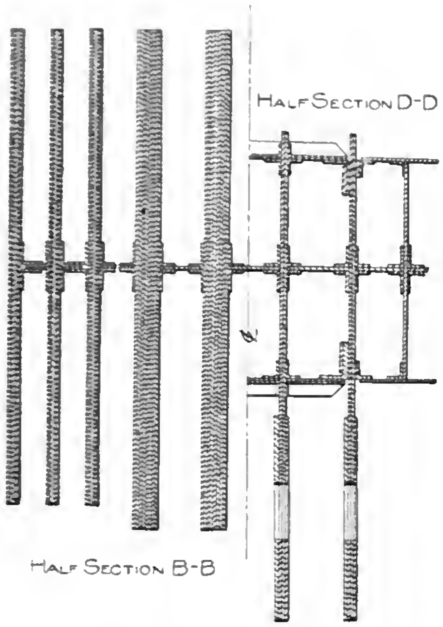
Just above the splice the sides of the posts are stiffened and the rectangular cross-section is maintained by an interior transverse horizontal diaphragm made with a rectangular angle iron frame-work having intersecting diagonals shop riveted to the web plates and flange angles. About 33 ft. above the splice both flanges of the post are covered with a 50x½-in. plate 20 ft. long with one edge projecting beyond the flange angle to provide for the field riveted connection to the transverse bracing. The flange plates are stiffened with exterior 3x3-in. horizontal angles 3½ ft. apart and, completing the closed cross-section at this point, serve to distribute the transverse stresses uniformly between both main webs of the post.

The upper end of the post is connected on one side to 28-in. and on the other side to 30-in. top chord eye-bars, which, as already explained, in order to reduce the size of the pin and promote ease of fabrication and erection are connected to it with separate pins 14 in. in diameter, while a third pin 12 in. in diameter is provided for the connection of the diagonal member. For the proper packing of the chord pins each of them requires ten different bearings in separate longitudinal webs, the four center ones also providing bearing for the pin of the diagonal member.

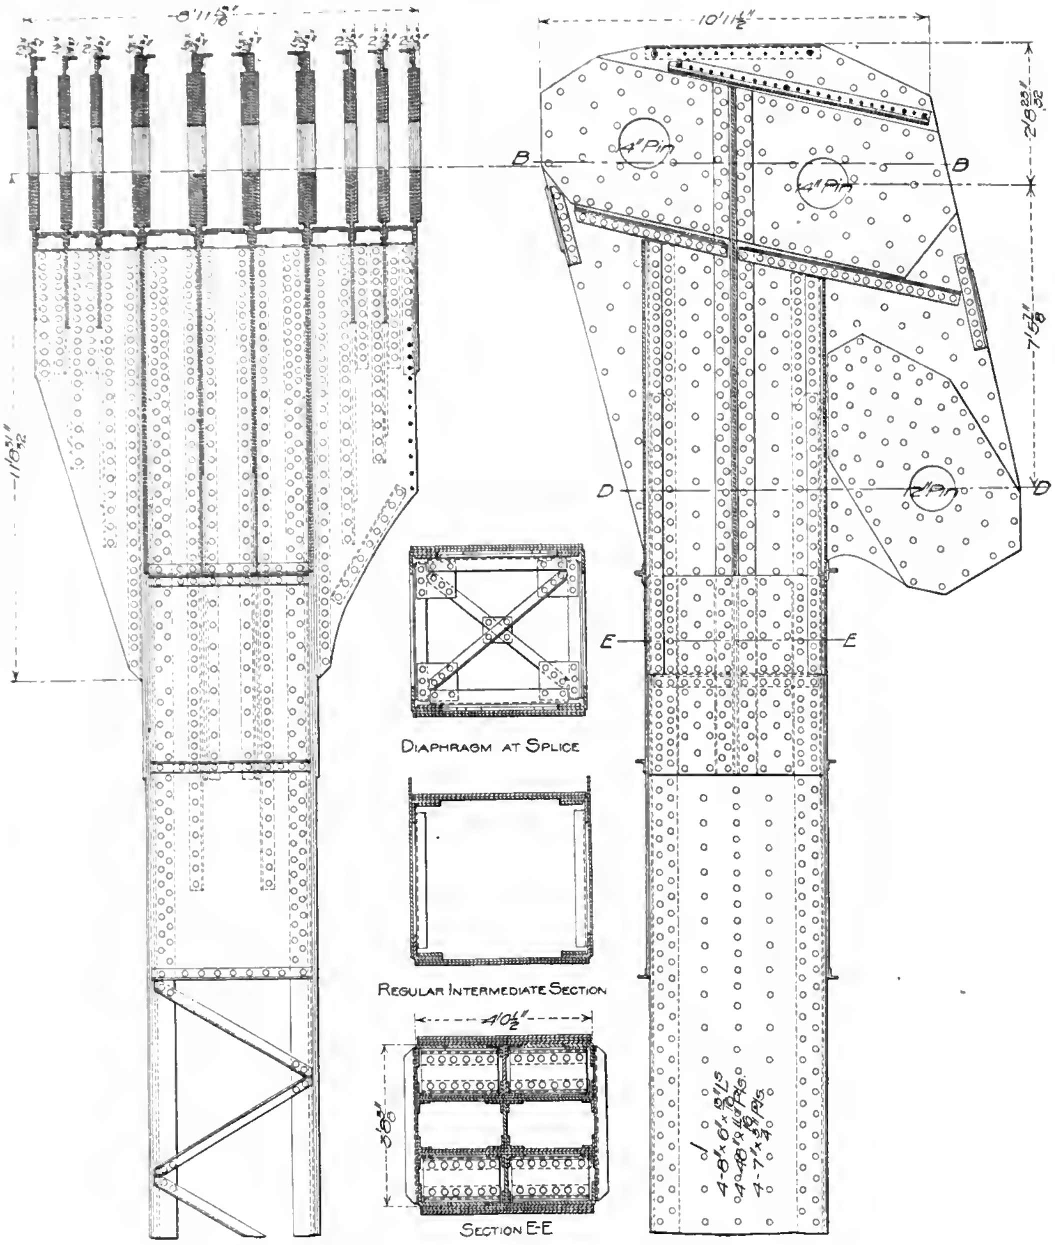
To give clearance for the large eye-bar heads and other members converging at this point and to provide for a sufficient length of pin it was necessary to materially increase the dimensions of the post in both horizontal directions. This was accomplished by building up a series of longitudinal plates parallel to the web plates of the built channels and projecting beyond them on both sides. The upper end of the post web was connected by a single center transverse diaphragm projecting beyond their extremities to the end of the post and connecting them with the auxiliary web. Its construction virtually makes a 9 x 9-ft. cap about 17 ft. long, shop riveted to the main body of the post and integral with it. The longitudinal webs are reinforced to a maximum thickness of 5¾ in. by full-length side pieces riveted to them and serving as ribs to connect the opposite panels of eye-bars. Four of these webs are continuous at the foot of the

cap and receive the pins through the upper ends are exterior to the regular cross section of the flange plates. The remaining six webs post and engage the top chord eye-bars only. Wherever possible, the different pieces are riveted together but in some cases the connections have so little clearance that they have to be made with turned bolts, which are inserted through hand holes provided for that purpose. The lower part of the post is 50 ft. 9 in. long over all and weighs 75,000 lb.

The stress in different parts of the post varies on account of the different increments from the transverse bracing. The total maximum static and wind load stresses are 3,208,000 lb. for which there is a cross-sectional area of about 163 sq. in., diminished slightly from that of the upper part of the post by the omission of the 7-in. reinforcement flats under the flange angles. At both ends the flanges are covered with wide



Sections, Upper Part of Post.



Upper Part of Intermediate Post 4.

Intersection of Top Chord and Vertical Post.

plates completing the closed rectangular sections everywhere except for a distance of 22½ ft. in the middle of the post where the flanges are latticed by zig-zag 3 x 3-in. angles. The flange and web cover plates in the splice are shop riveted to this section of the post and project beyond it to form double jaws receiving the web and flange plates of the next upper section, through which they are connected with about 220 field rivets. The angles are continuous through the full length of the post, but the web plates are cut about 18 ft. short of the lower end, where they are replaced by much wider plates projecting beyond both flanges to provide for the field riveted connection to the diagonal strut and the pin connection to the main digonal. These plates are about 9 ft. wide and have on one side about 150 holes for ⅞-in. field rivets to the inclined members. On the opposite side two parallel plates are riveted in and connected to the outer plates with diaphragms stiffening them to distribute the stresses from four bearings for each 12-in. pin. The 12-in. lower chord pin also takes bearings in the four web plates which are connected below with diaphragms made by pairs of 8 x 8-in. angles with flanges engaged.

(To be Continued.)

Pumping Water by Producer Gas Plant at St. Stephen, N. B.

Abridgement of a paper presented at the convention of the American Water-Works Association by Mr. F. A. Barbour.

St. Stephen is on the St. Croix River, which at this point forms the boundary of New Brunswick and Maine. On the opposite side of the river is Calais and upstream a short distance, are Milltown, Me., and Milltown, N. B. For twenty years these communities have been supplied with water taken from the river by the Maine Water Co. Increasing pollution of the stream had given rise to dissatisfaction with the water and on the expiration of the twenty-year contract St. Stephen determined to establish municipal works. Many surface supplies were investigated but in all cases the water was found to be so impregnated with vegetable coloring matter as to be unfit for use. Attention was then turned to ground water supplies. The first wells yielded only a limited amount, but finally water was found in large quantities. A test of several weeks' duration in the driest period of a dry year developed a supply of more than 2,000,000 gal. per twenty-four hours from a test well 6x8 ft. in horizontal dimensions and 13 ft. deep. The normal ground water level at this point of supply is 150 ft. above the principal streets in the town, thus greatly reducing the necessary pump lift. The Canadian Pacific Ry. runs within a few hundred feet, permitting economical construction of side track. It was accordingly determined to construct an open well, 20 ft. deep and 30 ft. in diameter, and to erect a pumping station at this point, lifting the water into a concrete reservoir situated on a hill some 1,500 ft. to one side of the main pipe line to town.

Up to the time the work was ready for receiving tenders the water company looked upon the municipal investigation as merely a piece of strategy to obtain better rates in a further contract but when fully convinced that an economical supply had been found and realizing that their present source must be abandoned, negotiations were begun by the company to obtain from St. Stephen the water required to supply the adjoining towns on the river. Since such an arrangement greatly reduced the cost of water per gallon this proposition was accepted by the authorities of St. Stephen, and it was finally agreed to furnish water at $24 per million gallons by Venturi meter measurement. The total daily quantity thus made necessary will run from 1,200,000 to 1,600,000 gal. Incidentally, it may be stated that with an actual pump lift of 135 ft. into the reservoir a pressure of 80 lb. at the hydrants when drawing ten standard fire streams, will be maintained in the principal streets of the town.

Steam, gas producers and electric power merited consideration for pumping. Electricity to compete in the pumping of water, especially where the transmission line is relatively long and a relay engine of some type is necessary for emergency use, must be obtained at less than three-quarters of a cent per kilowatt-hour. This could not be done at St. Stephen and the choice, therefore, narrowed to steam and gas producer plants. In relative reliability Mr. Barbour believes there is very little difference between these types of plants; in point of attendance there would be but little difference in the ordinary water-works station. The actual labor in handling the fuel is much less in such plants and the attendant has more time for other work. While the operation of producer plants is simple, it is more difficult at the present time to obtain attendants who appreciate the requirements and are in sympathy with this type of apparatus than in the case of steam plants. An engineer who has long been running steam engines if put in charge of a producer plant is apt to be prejudiced.

Believing that the choice at St. Stephen rested on the relative economy in first cost and cost of fuel, bids were asked on both steam and gas plants—the propositions to be based on two complete units, each of 1,800,000 gal. capacity in 24 hours and the bidder to name a guaranteed duty.

In order that the bids might express the actual relative value to the town, as far as possible, it was required that the duty should be based on the total coal used in a three days' test, engines to run eight hours and fires to be banked sixteen hours—all coal used in banking and all standby losses to be charged against the plant. Such a test is absolutely necessary in producer work, as no reliable results can be obtained in short runs and in steam plants, where boilers are included, the average ten-hour test is often very misleading. In the latter case if the run is started and stopped without drawing the fires the difference in amount of combustible on grates at start and stop, as manipulated by a clever fireman, will frequently involve an error of from 5 to 6 per cent. in the duty obtained. In producer work it is much more difficult to estimate the relative amount of combustible in the producer at any one time, and the period of the test run must therefore be extended long enough to eliminate, so far as possible, the personal equation and reduce the percentage of error. In power plants of different types the relative fuel consumption during hours of banking is most important. In the average high duty steam pumping plant running 8 to 10 hours and banking the remainder of the day, as observed by the writer, the coal used in banking will run from 20 to 30 per cent. of the total coal used or from 0.4 to 0.6 lb. per nominal boiler horse-power of banking. Such plants in actual operation usually develop a duty in hours of running equal to from 80 to 90 per cent. of that developed in a 10 to 12-hour duty test and, including banking, usually develop a station duty from 60 to 70 per cent. of the test duty. The short run test does not always develop he relative commercial or station economy of steam installations and in a comparison of steam and producer plants the standby losses must be taken into consideration. It is claimed that gas generators can be banked with less than one-tenth pound of coal per horse-power hour of banking.

Proposals were received on two steam plants and three gas producer plants. The first costs of the steam plants varied from 60 to 80 per cent. of that of the gas plants, but the duties guaranteed were more than correspondingly reduced. On the basis of using pea anthracite in producer and Nova Scotia bituminous coal for steam work, both at $5.00 per ton, there was no doubt but that the producer plants were much the cheaper proposition.

Some of the gas propositions were based on the use of centrifugal pumps, connected to the engine by silent chains, but the reduced efficiency, as estimated by the bidder, more than made up for the less cost of this type as compared with triplex power pumps. Apparently an efficiency of 60 per cent. was estimated in the case of centrifugal pumps and 70 per cent. with triplex pumps.

The proposition accepted included two Pintsch suction gas producers with necessary accessories, two 4-cycle single cylinder engines, and two double acting, triplex power pumps, each of 1,250 gal. capacity per minute. The contractors guaranteed a duty of 115,000,000 ft.-lb. per 100 lb. of pea anthracite coal having a thermal value of 13,000 B.t.u.'s per pound, with not to exceed 10 per cent. ash nor 8 per cent. volatile matters nor 2 per cent. sulphur.

The generators, which have each a rated capacity of 125 h.-p., are constructed of boiler iron, 12 ft. 9 in. high and 4 ft. 3 in. outside diameter, lined with fire brick and the space between fire brick and shell filled with mineral wool. The fuel is fed through a double-closing shotpouch hopper. This hopper is mounted on a cast-iron plate which is pivoted on a vertical pin and can slide on another cast-iron plate which is bolted to the outer lid of the producer. The lower plate has an aperture which leads to a conical fuel magazine in the upper part of the generator. This sliding lid, with ground joint surfaces, serves to permit of charging the generator with fuel without allowing the escape of gas or inrush of air.

The grates are of the so-called shaking basket type, especially adapted for the pea anthracite coal which this producer is to use. Large cast-iron doors with ground joint surfaces are placed above and below the grate on the two opposite sides of the producer, rendering the fireplace and ash pit readily accessible. A cast-iron pipe extends vertically from the ash pit into a concrete sump in the floor below the generator, which is kept filled with water and thus provides a water seal. In this way the ashes can be discharged through the ash door or through the water seal.

The gas after leaving the generator passes through the vaporizer, which is a cast-iron shell containing a number of vertical tubes, the space around the tubes holding water and the gas passing through the tubes on their way to the scrubber. The steam formed in the vaporizer is led through piping provided with the necessary valves to a steam jet, where it is mixed with air and led under the grate through the water seal pipe. This latter arrangement insures the air being admitted at the centre of the grate, resulting in an even distribution through the overlying mass of fuel.

The steam jet works under a pressure of less than 1½ lb. per square inch and is designed to secure a constant and uniform mixture of air and steam in excess of the requirements under any varying load conditions, the excess steam being carried away through a galvanized iron pipe to the outside of the building.

The lower part of the vaporizer is formed by a casting having openings leading to the scrubber and one to the relief pipe, which serves as a chimney during the hours when the engines are not taking gas from the generator. A cast-iron wall divides this lower portion of the vaporizer along a vertical line, extending from the top of this section of the vaporizer toward the bottom in such a way as to form, by the admission of water, a seal which, when the engine is stopped and the relief pipe open, prevents gas from the vaporizer entering the scrubber. The manipulation of this water seal is effected by valves provided in the piping.

The scrubbers are made of boiler iron 12 ft. 8 in. high and 3 ft. 2 in. outside diameter and contain a removable grate for the support of the coke. The gas enters the bottom and leaves at the top, coming in contact in its passage through the scrubber, with water which is admitted to a sprinkler system attached to the scrubber cover. After passing the scrubber the gas is led by a vertical pipe to a cleaning pot, which serves to collect large particles of moisture which may have been carried over by the gas, and thence to the cleaner, which is a circular boiler iron shell, 5 ft. 6 in. in diameter and 32 in. high, fitted with two wooden trays, supporting layers of sawdust through which, by baffles, the gas is forced to pass vertically downward. The provision of this ample capacity in scrubber and cleaner is believed to be a valuable insurance against the passing over to the engines of dust and tar products, which lead to the minor difficulties in operation sometimes attributed to the use of this type of plant.

Each producer is equipped with a gauge board with water gauges showing the vacuum in the different parts of the apparatus. The piping is so arranged that either engine can be operated from either producer.

For blowing the producer when starting an air jet is provided, the air being taken from the compressor used for starting the engine.

The engines are 4-cycle, horizontal single cylinder, with one fly-wheel and outer bearing, with shaft extended to receive friction clutch by which the engines are connected to the pumps. The engines are nominally of 115 h.-p. and are designed to operate at 150 r. p. m.

The engine has a combination, starting, blow-off and relief valve. The valve proper consists of a casing containing three poppet valves, dividing the casing into three chambers. When starting, the levers that operate these three valves are brought into contact with an auxiliary cam by means of a special hand lever. The engine having been barred into position and the hand lever thrown to the starting point, compressed air is admitted into the cylinder, resulting in the piston, crank-shaft, lay-shaft and auxiliary cam moving, until by the action of this cam, the compressed air valve closes. On the return stroke of the piston the valve leading into the cylinder opens and also the valve into the vent pipe, thus allowing the compressed air to escape. This operation is repeated automatically until the engine starts to fire. The operation of blowing off while the engine is running, to remove impurities and excessive oil from the cylinder, is accomplished by throwing the hand lever in an opposite direction from that necessary for starting; the result being that the valve between the cylinder and vent pipe is open during a certain part of the explosion stroke.

Gas and air are admitted to the cylinder head valve chamber through a cast-iron pipe, divided by partition into two conduits, one for the gas and the other for the air, with provision for controlling the amount of gas and air in order to obtain the desired mixture. The air is taken through piping from above the roof of the building.

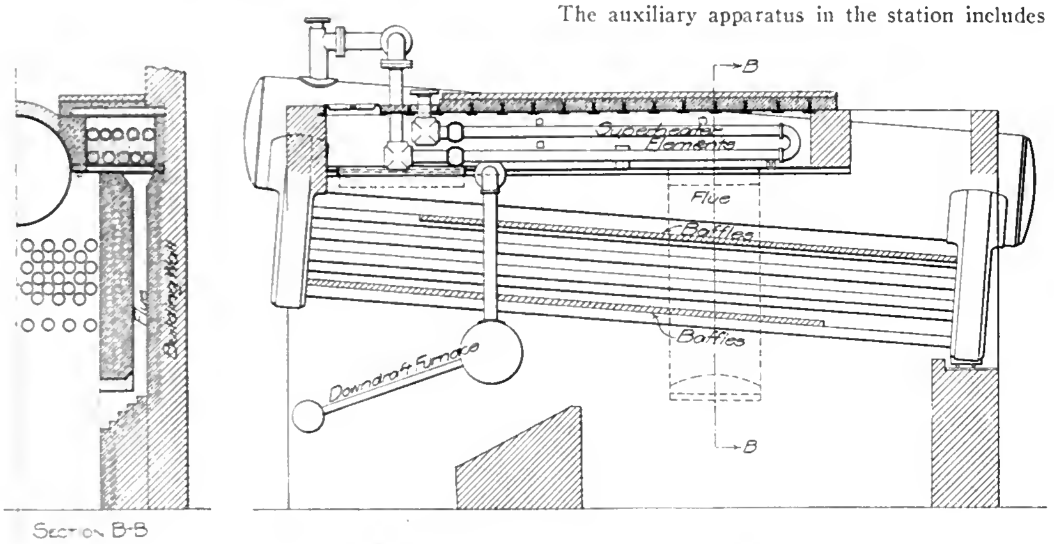
The exhaust gases are carried through one length of water cooled pipe and then through a non-jacketed cast-iron pipe to a combined muffler and heater below the floor of the engine room, from which they are carried to an exhaust funnel above the roof. The muffler and heater is a double walled cast-iron cylinder, with a section of tubes inserted between two headers, the gases passing through the pipes which are surrounded by water. By this muffler it is proposed to provide the necessary hot water for heating the building.

The engines are larger than necessary for the economical operation of the pumps, the size being determined by the intention of the authorities to employ these engines in the future development of electric current for lighting. The engines are connected with the pumps by means of a heavy duty friction clutch.

The pumps are of the ordinary triplex, four-stand, double acting type, geared to run 32 r. p. m. Rawhide pinions keyed to the shaft extending from the clutch, transmit the motion of the engine to the gears of pumps. The pump cylinder is 13 in. in diameter and the stroke 12 in. The two pumps have a common suction pipe, 18 in. in diameter, leading from the well with individual suction pipes 14 in. in diameter. The discharge pipes are 12 in. in diameter and connect with 14 in. force main leading to the reservoir. Check valves are provided in the discharge of each pump and also straightway valves in the discharge and suction pipes, thus permitting the entire isolation of either unit. Relief valves, with outlets piped into the suction, are also provided.

The auxiliary apparatus in the station includes an air compressor, driven by a Pelton wheel with water taken from the pressure main and returned to the well. The compressed air is piped to two receivers erected on the producer platform, each 32 in. in diameter and 6 ft. high. Compressed air is also employed in two stationary air-lifts, provided to raise or lower the exhaust valve of the engines. These lifts are attached to the engine foundations and facilitate any repairs or inspection of the exhaust valve or its mechanism.

The station building is of red brick and includes the engine-room, generator room and coal-shed. Above the engine room and connected with it by an iron spiral stairway is the office and bath-room. The generator room has a concrete platform, 11 ft. above the floor, and at the same elevation as the floor of coal-shed, thus permitting all coal to be transferred from the point of storage to the producers without lifting. A railroad siding permits the coal to be shovelled directly from the cars through the roof of the coal-shed. Care has been taken in the producer room to use concrete or brick throughout, both in walls and floors. Windows are provided in the wall between producer room and engine room so that the operation of the engine may be observed by the attendant, either when on the ground floor or the charging platform.



Arrangement of Boiler Setting in Flour Mill.

Electric Towing was tried on July 13 on the canal of the Lehigh Coal & Navigation Co. at Mauch Chunk, Pa. A narrow-gauge track was laid along the towpath and on it a 10-ton electric motor truck was operated. This was connected by a hawser with a canal boat and dragged the latter satisfactorily.

The Power Plant of a Small Flour Mill.

The power plant of the 400-bbl. mill of the Washington, Mo., Flour Mill Co. is an example of the economies which can be secured in a well-designed power installation of small capacity. The original power plant of this mill contained an 18x42-in. Corliss engine, operating non-condensing at 70 r.p.m., to which steam was supplied by two 48-in. by 20-ft. return tubular boilers. The latter had 33 sq. ft. of grate surface, or 1 sq. ft. to each 33 sq. ft. of heating surface, and were operated at approximately 100 lb. steam pressure. Under these conditions, on an average 43.5 lb. of coal were required to each barrel of flour that was produced by the mill. As this coal consumption was excessive, plans for reconstructing the power plant were made and carried out.

The two return tubular boilers were replaced by a single 100-h. p. O'Brien water tube boiler, having 1,003 sq. ft. of heating surface and 18.34 sq. ft. of grate surface. This boiler was equipped with an O'Brien down draft furnace, the upper grates of which consist of a row of 2-in. boiler tubes, inclined upward at a pitch of 4 in. to the foot, and attached at the front and rear to water drums connected with the main drum of the boiler. The latter is also equipped with a Foster superheater which is placed at the level of the drum of the boiler in a compartment at one side of the latter. A flue leading to this compartment is built in the side of the boiler setting and opens in the furnace just back of the arch. A part of the hottest gases are thus diverted through the compartment and over the superheater, which produces steam at about 100 degrees Fahr. above the temperature of saturated steam. The gases from the superheater pass out of the rear end of the compartment for the latter and mingle with those which have come up through the tubes of the boiler.

The cylinder of the original engine was replaced by a 12-in. high-pressure and a 24-in. low-pressure cylinder, making the engine a tamdem-compound machine, which is operated condensing. A Wheeler jet condenser served by a wet-and-dry vacuum pump was also installed, and a natural-draft cooling tower with a capacity of 2,700 lb. of water an hour was erected on the roof of the building, as the water supply is limited.

Tests made since the reconstructed plant was placed in service determined that on the average only 19.6 lb. of coal of the same quality previously used are required to produce a barrel of flour, or a saving of 120 per cent., as compared with the original plant.

The plant was reconstructed under the direction of Mr. William H. Bryan, consulting engineer, of St. Louis.

An Insulating Joint to prevent electrolysis has been used in the 6-in. water service pipe that enters the power station of the Cleveland Electric Ry. It consists of a large wooden washer bolted between special castings forming adjoining ends of the service. Each casting has an 11-in. flange with eight ¾-in. holes by which it is attached to the service pipe and a 13½-in. flange with a dished face and eight 1⅛-in. holes to form the insulating joint. The wooden washer is a piece of hard maple boiled in paraffine and having a ¼-in. boss on each side, which fits into the recess in the face of the flange of the casting. The bolts at the joint pass through rubber hose and their nuts press on large fiber washers.

It may be added that there is a difference of opinion among engineers regarding the usefulness of any insulating joint. Fortunately, the engineering department of the Metropolitan Water and Sewerage Board of Boston has been carrying on investigations as to their value which will furnish definite information.

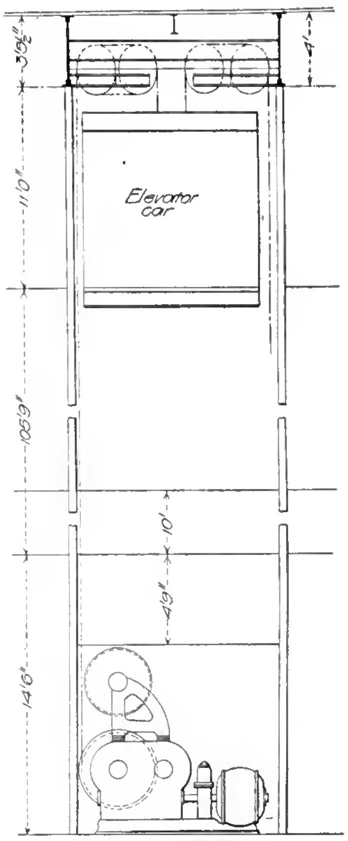
The Elevator and Escalator Equipment of the New York Subway.

In the construction of the New York Subway the topographical irregularities of the upper portion of Manhattan Island caused considerable differences in elevation between the track grade and the surface of the ground at certain points, notably at Manhattan St., 167th St., and 181st St. on the Broadway Division, and at Mott Ave. on the Bronx Division. At 167th St., 181st St. and Mott Ave., the tracks are 100 ft. or more below the street surface, which renders access to the stations by stairways extremely difficult. At Manhattan St., on the other hand, the line is carried on a viaduct with a station at its centre where the grade of tracks is some 50 ft. above the street level. Electric elevators of large capacity have been installed in pairs at each of these three underground stations, and a duplex escalator at the viaduct station.

The electric elevator was selected so that the machine, as well as also the escalator, might be operated by direct current from the subway. As it is necessary to handle large crowds during rush hours, large elevator cars were required, necessitating special elevator machines and other mechanical features. The six machines have the largest capacity of any electric passenger machines installed in this country by the Otis Elevator Co., and are equalled in size only by the machines recently installed in new stations of the London Underground system. The cars are all 8¾ x 11½ ft., with a capacity of 8,000 lb. A load of 73 men and boys has been safely carried in one of the cars in a period of heavy traffic. Owing to this extremely heavy load, machines of the duplex type were installed, consisting of two large multipolar motors, mounted side by side on a single base plate to drive the hoisting drum through tandem worm-gear drives of the type usual in the Otis machine.

The installation of the equipments at 167th and 181st Sts. was attended with considerable difficulty owing to the location of these stations under sidewalks, with stair entrances at the street line, which prevented the projection of any structure above the street level to house the overhead gear. Furthermore, as it was desirable to have the upper landing as high as possible in the elevator shaft, it was necessary to minimize the space occupied by the overhead sheaves and supporting beams, which resulted in the location of the machines at the base of the shaft. Special overhead work was accordingly designed, which is particularly compact for the capacity for which it is designed. The upper landings in the shaft are within 14 ft. of the underside of the sidewalk vault light at 167th St., and within 15 ft. at 181st St., so that, with the total height of elevator cage of 9 ft., but 5 and 6 ft. overhead clearances, respectively, are obtained at the two stations. The supporting beams for the overhead sheaves were accordingly located 3½ and 4 ft. under the sidewalk vault lights, giving total clearances over the uppermost sheaves of 5 in. Details of the sheave supports are indicated in an accompanying illustration. The 30-in. sheaves carrying six ⅝-in. cables from both the counter-balance weights and the machines to the car are supported by two 15-in., 42-lb. I-beams, between which and two outer 12-in., 31½-lb. I-beams, are supported two auxiliary sets of 30-in. sheaves, each carrying two ⅝-in. cables from the machine drum direct to the counterweights. Owing to the width of the car and the limited overhead clearance, the use of single sheaves to pass the cables from the counterweights and the elevator machine to the car was prevented, necessitating the four 30-in. sheaves instead, two over the center of the car, one over the machine drum and one over the counterweight guides. The bearings for all sheaves except those over the center of the car, rest upon short 6-in. channels separated from the I-beams by 8-in. spacers, with flanges riveted to those of the lower channels and the I-beams. The large six-cable sheaves are so confined by adjacent beam supports that journal box bearings of the usual type were impossible, and the sheaves are accordingly arranged to turn on large 4-in. shafts or spindles passed through the large I-beams.

The cars of the 167th and 181st St. elevators are steel cages 8¾ x 11½ ft. outside measurement, designed for operation between corner guides in a hatchway, 10 x 11¾ ft. in size. The cases are of ornamental iron work, enclosed at the top and sides, and the floors are finished with interlocking rubber tiling. Each car has openings with folding gates at either end, and there is a 5-ft. double folding gate on both sides of the shaft at every landing, in order to facilitate the handling of crowds, for which purpose ample corridor spaces have been provided at every landing. The guides for all electric machines are 4x6-in. posts of yellow pine, bolted to 10-in. channels supported on the steel work of the shaft.



Elevator Mechanism.

The elevator machines at 167th and 181st Sts. stations are at the foot of the shaft in cellars with 10½ ft. clear head-room under the shaft pit for cars at the lower landing, but for the Mott Ave. station, the location was such that an overhead station building was permissible, allowing the elevator to travel up to street level with ample room for the overhead sheaves and supports. The building was accordingly arranged to accommodate the machines in the space above the shaft, the shafts themselves therefore extending but the necessary 4 ft. below the lower landing level. The machines used in this station are identical with those at 167th and 181st Sts., but the details of supporting structural work and arrangement of overhead sheaves is different. The cars are here 8½ x 12 ft. in size, traveling in a 9¼x13-ft. hatchway, over which the elevator machines are supported on four 18-in. I-beams spanning the hatch lengthwise. In order to prevent interference with the support beams, the guide posts on these cars are arranged at the side in the usual manner, the posts being here also of 4x6-in. yellow pine fastened to 10-in. vertical channels. The drums of these machines are so located that overhead sheaves are eliminated, except for the counter-balance weights, the car cables passing vertically downward from the inner face of the drum to the car fastenings, while those from the drum to the counterweights pass over sheaves at the rear to the counterweight slides. The cables extending directly from the counterbalance weights to the cars are carried by sheaves over the counterweight slides and an upper sheave mounted above the drum so as to clear the drum cables.

The elevator machines are all of the duplex tandem worm-gear type, equipped with two four-pole compound wound motors designed for operation on 500-volt current from the railroad propulsion system. The motors are specially designed with compound windings for rapid acceleration and the gear of the drive is proportioned for a car travel of 250 ft. per minute under all conditions of loading. The vibrating sheaves above the drum of the 167th and 181st St. machines automatically traverse in guiding the cable off the drum, the conditions of clearances and manner of running the cable permitting this to be done there without difficulty. The machines are all controlled from the cars by the latest type of magnet controller of the Otis Elevator Co., with duplicate control switches on either side of the car for convenience of operation from either doorway, and switch panels near the machines on which are mounted the solenoid switches, resistances and connections. These controllers have the usual features for utilization of the increasing counter electro-motive force of the motors, in starting, to cut out gradually the armature resistance and finally the series-field coils, by means of a series of magnets while retarding magnets are similarly used for slowing down. Special features of the control as applied to these cars are gate contacts by which the machine cannot be started until all gates in the elevator and hatchways are closed, the control circuits being made through contacts on all gates arranged in series, so that if any gate is left open the control circuit cannot be closed and the machines started. The machines are all equipped with the safety car switches, the slack cable switches, the limit switches and governors which are usual in electric machine installations.

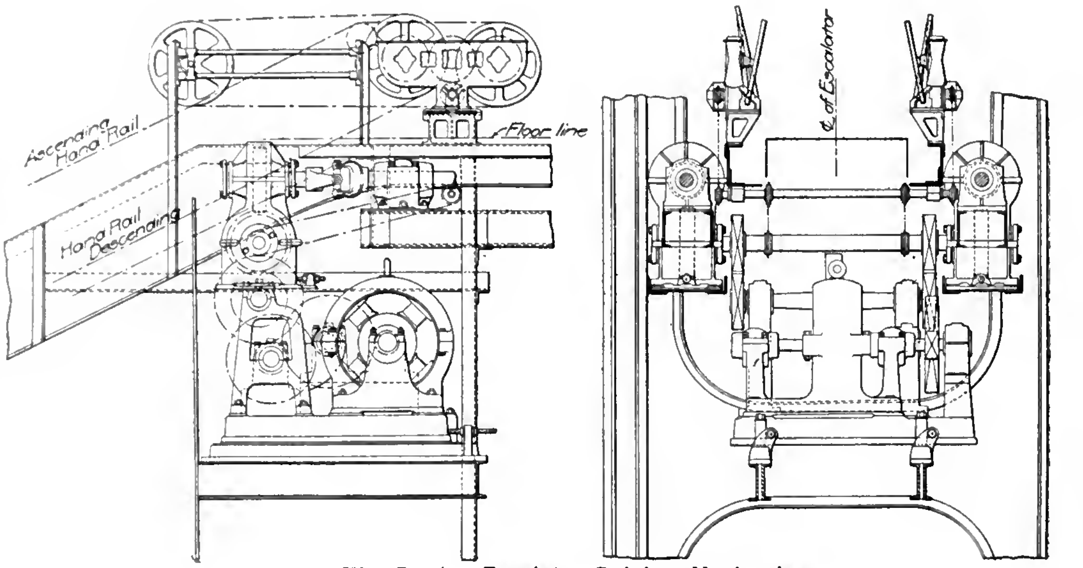
The escalator installed at the Manhattan St. station is a moving stair of the traveling flight type, similar in general construction to those installed at the 23rd and 33rd St. stations of the Manhattan Ry., in New York, but differs in that it is of the duplex type, the flights being reversible and made to serve for both ascending and descending travel. As the station platforms are some 50 ft. above the street level, and it is necessary to elevate the passengers a distance of 33 ft. to a cross passage connecting both uptown and downtown platforms, it was desirable that the elevating mechanism be made available for travel in either direction. This was accomplished by the use of the one position treads of the Otis escalator construction which travel in an endless chain through both the up and down runways, offset arrangements at both top and bottom landings preventing interference of the returning flight with the loading and unloading landings as shown in the accompanying elevation detail of the escalator runways.

The general arrangement of the escalator involves an up-travel flight, 74 ft. long and a down-travel flight 80 ft. in length, including a 6-ft. level landing, midway in the run, to serve as an eye rest to the passengers looking down from the upper end of the long flight. The loading and unloading divisions are level, those for loading at both upper and lower levels being about 8 ft. in length, while those for unloading at both levels are approximately 15 ft. in length. The de-

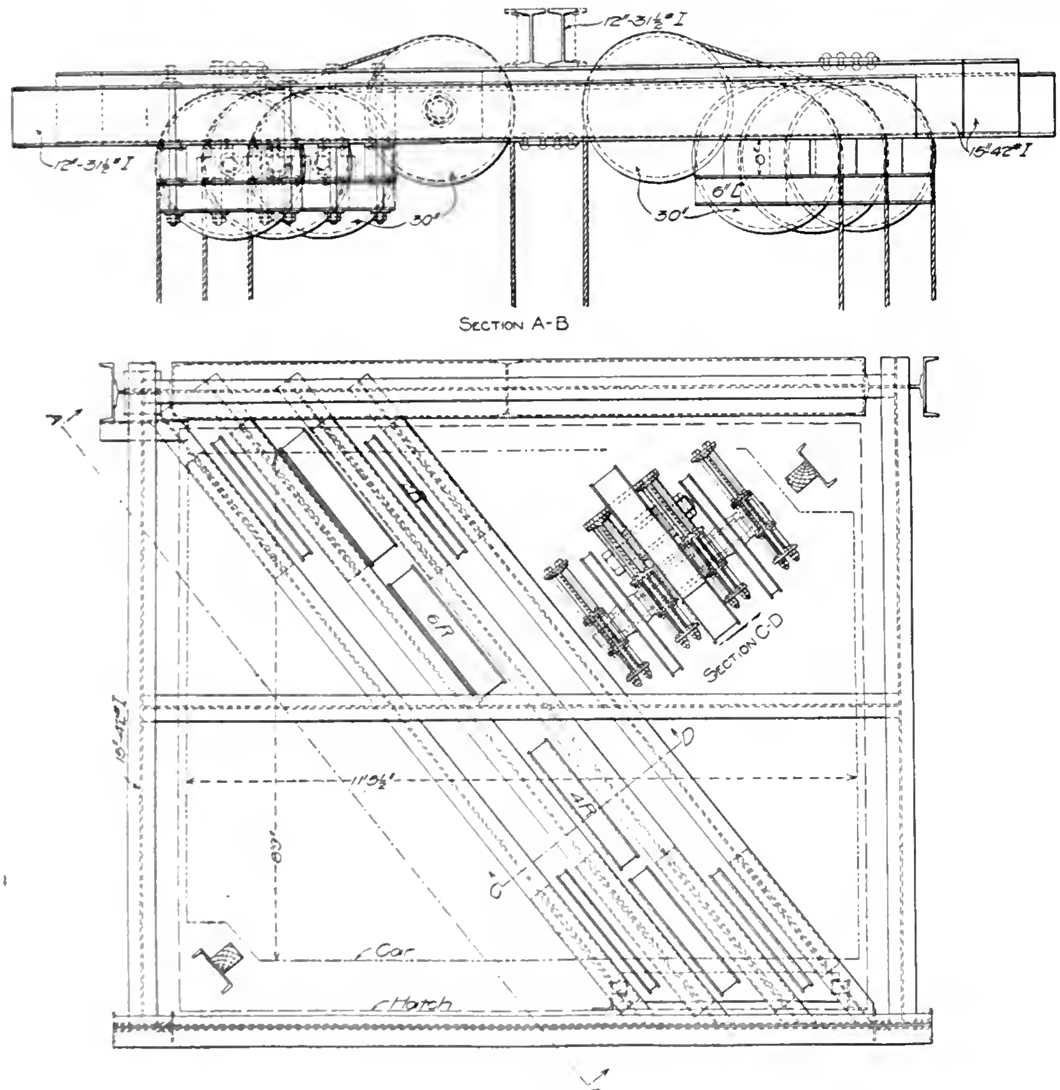
tail of arrangement of the unloading division with oblique wainscot rail follows the usual escalator practice. Moving hand-rails are also provided on both ascending and descending flights, which travel at the same speed as the stair flights.

The escalator is driven by an intersecting mechanism which applies the driving force equally to both ascending and descending flights at upper points on the stairway run. It consists of a 60 h.-p. Otis motor mounted under the upper landing at the top of the ascending flight and arranged to drive through three gearing reductions, the shaft carrying the sprockets meshing in the flight driving chain. This gear is supplemented by a similar sprocket driving shaft under the loading landing at the top of the descending flight at the rear, which is connected to the ascending flight sprocket shaft by two 5-in. longitudinal steel shafts which are connected to the sprocket shafts at either end through spiral gearing. By this arrangement, the driving force, which amounts to an average power consumption of 25 h. p. is effectually equalized between the two halves of the endless chain of stair flights and the duty imposed on the sprocket and chain at either driving point lessened by approximately one-half. The driving gears are, however, both designed for ample strength to carry the entire driving strain if this should become necessary in case of emergency. The 5-in. interconnecting shafts between the two driving gears are of considerable length, approximately 35 ft., and in order to provide for possible deflections of the viaduct on which the mechanisms are supported, each shaft is connected to its spiral gear at either end through a universal joint. In practice it is found that the structure deflects under certain conditions sufficiently to throw the shaft out of alignment by as much as one inch. The spiral gears of the drive are entirely enclosed and fitted with an oil bath for lubrication and protection from dirt and dust. To the sprocket driving shafts of either flight there is connected by a chain drive a supplementary hand-rail driving mechanism of the endless cable type with rubber-covered hand grips. The rail for either flight is driven over pulleys carried in the upper surface of the banister and moves at a speed corresponding to that of the stair flight, returning within the boxing underneath the banister. Three sheaves above the driving mechanism for either flight carries the hand-rail, and by a turn around a third adjustable sheave provision is made for taking up slack in the cable.

The important feature of the escalator is its large carrying capacity. The flights are of unusually large size, each step being 18 in. in width by 4 ft. long, so that under conditions of maximum loading, three persons might be accommodated on each step. From actual practice it is found that under conditions of rush-hour travel an average of 2½ persons are carried per step continuously for considerable periods of time.



The Duplex Escalator Driving Mechanism.



Special Overhead Construction for Subway Elevators.

With the normal speed of operation, of approximately 4,000 steps passing a landing per hour, the maximum carrying capacity of the escalator is, as determined by the average of 2½ persons per step, 10,000 persons per hour, for both the ascending and descending runs, making the total capacity of the station 20,000 per hour, as guaranteed by the builders. This is, moreover, accomplished by a continuous uni-directional movement of the apparatus and devoid of stopping and accelerations of the driving motor, as in the case of the usual elevator apparatus. While the escalator occupies more space than an ordinary elevator installation, it requires far less than that necessary for an elevator equipment of equal capacity and its advantage over the latter is obvious in view of the maximum carrying capacity of each of the above elevators at the above mentioned stations of approximately 1,000 persons per hour. An interesting feature of the escalator installation is the effect upon travel at that station. Aside from the fact of the general novelty of the escalator as a means of elevator travel, it has been found from studies of the actual station records of the subway operating company that the escalator station is one of the most popular stations on the line, and that a most decided preference is shown to it over other nearby stations of the subway and elevated lines in the city. In the hot summer months when the travel by way of all-stair stations decrease by from 10 to 15 per cent. over that of other times in the year, the travel at the escalator station remains constant or even above normal. The escalator at this station is operated constantly throughout the day and evening, and is shut down only from one o'clock to five o'clock in the morning of each day.

PLUGGED CROSS-TIES have been used with marked success in large numbers by Chief Engineer Fredericia, of the Danish State Ry. A plain 1½-in. cylindrical creosoted plug of beech or birch is driven tight in a 1⅓-in. hole bored in the tie and the spike is driven in a hole bored in this plug. Worn-out ties plugged in this way have been found to give good service, as the rail seems to be held down with exceptional firmness and deterioration due to the pounding of loose rails is prevented.

Suggested Specifications for Street Lighting.

Report to the National Electric Light Association by a Committee consisting of Dudley Farrand, Chairman, A. E. Kennelly, Charles P. Steinmetz, Louis A. Ferguson and Paul Spencer. Comments on the report are given in the editorial pages of this issue.

In the year 1894 a committee of experts, appointed by the Association to consider the rating of arc lamps, reported at the seventeenth convention, then in session at Washington, a preamble and resolution which was adopted as follows:

"Recognizing the difficulty, if not impossibility, of measuring with any degree of accuracy the illuminating power of the arc lamp, and the great necessity for a more precise definition and statement of the obligations of the producer of electricity for illuminating purposes to the consumer thereof, be it

"Resolved, That in the opinion of this convention what is ordinarily known as a 2,000-c.-p. arc lamp is one requiring on the average 450 watts for its maintenance, the measurements being made at the lamp terminals, where no sensible resistance is included in series with the arc. In case such resistance is used, it must be excluded in the measurement of the voltage."

The rating of arc lamps on the basis of energy consumed, as set forth in the resolution, was then and would now be satisfactory as an equitable means of determining either a proper rate of charge or illuminating value for street arc lighting furnished by a company to a municipality, under the same conditions, but at the time of the adoption of this resolution there was in use in the United States no type of arc lamp other than the open arc, which, although of many makes and designs, gave approximately the same illuminating power for a given amount of energy. Wherever the rating adopted by the committee in 1894 has been employed in connection with open-arc lamps of the general type then in use, little or no difficulty has been experienced in the adjustment of differences arising from the interpretations of contracts.

During the very year in which this rating was adopted, however, the commercial introduction of enclosed-arc lamps began, and within the past ten or twelve years the gradual displacement of open-arc by enclosed-arc lamps has taken place. The manufacture of open-arc lamps has practically ceased as a result of their inability to compete with the enclosed type, and manufacturers have devoted themselves almost exclusively to the latter unit quite recently. During the past four or five years there have been placed upon the market a number of distinct new types of lamps, which have been known by the general designation of "flaming carbon" or "luminous arc" lamps, some of which originated from American ideas, while others were imported.

The characteristics of the various lamps mentioned, taken either individually or grouped in classes, are so widely at variance in performance in the ratio between light produced and energy expended that the difficulties experienced by operating companies are greater now than they were in 1894, and the preamble then adopted is equally applicable to-day by reason of the introduction of these new devices.

In addition to the new types of arc lamps, there have also been placed on the market and are now offered for sale certain kinds of mercury-vapor or vacuum-tube lamps, which can be used for street lighting, as well as a considerable number of new incandescent lamps constructed of some form of metallized filament. Quite a number of the latter are already in use, with every prospect of their general introduction within a reasonable time.

Any attempt to compare the illuminating value of these latest forms of lamps, which are or may be used for street lighting, on the basis of energy consumed, is not only futile, but would be ruinous to the contracting company, for while the so-called high-efficiency lamps operate on a lesser expenditure of energy, they also give a larger volume of light. No reason can be given why a contractor should be penalized for giving more light than contracted for, after having made considerable investment for that purpose, simply because the number of watts consumed is less, notwithstanding that other items of expense and renewals may be considerably increased.

Your committee, after a most careful consideration of the difficulties to be met and for the purpose of establishing a definite basis, assumed: That, inasmuch as the lighting of streets by contract is a matter of illumination produced rather than of apparatus employed, the terms used in specifications should be in terms of illumination and not of energy consumed; that the individual lamp of each class should be the unit of number charged for; and that the average illuminating power of each unit should be comparable with and have a value equal to a known standard at proper relative distance.

The following report is submitted as the best provisional solution of the problem of street lamp specification that the unsatisfactory existing state of the science and art of outdoor photometry permits.

The committee considers that street-lighting lamps should not be rated in candle-power under contract specifications; because unless qualified as to the space distribution of the candle-power, such rating may be entirely misleading. The lamp may, by suitable reflectors, be made to possess a large candle-power in some particular direction or zone, and yet be very ineffective as a practical street illuminant. Consequently, the committee considers that the rating of street lamps in contract specifications should be in terms of the mean normal illumination cast at a considerable distance from the lamp, along the street which it illumines, i. e., the mean illumination thrown by the lamp upon a plane surface at a considerable distance from the lamp and supported perpendicularly to the rays.

The following specifications are drawn to cover the ordinary conditions of street lighting, and are recommended to replace previous specifications, such as those appearing in the Report of the Committee on Rating of Arc Lamps of the National Electric Light Association at the meeting of 1894, a copy of which is reported above:

(1) Under ordinary conditions of street arc lighting, with lamps spaced 200 to 600 ft. apart, specifications for street lamps should define the mean illumination thrown by the individual lamp, in position in the street, as measured at the height of the observers' eye and perpendicular to the rays, at some point not less than 200 ft. nor more than 300 ft. distant, along a level street, from a position immediately below the lamp, with all extraneous light screened off and with no reflection from surrounding objects not forming part of the lamp equipment.

The reason for leaving the horizontal distance flexible along the street within the range between 200 and 300 ft., is that a definitely specified distance such as 250 ft. might be unsuitable for the purpose of the measurement.

Within the horizontal distance in excess of 200 ft., the distance correction for the height of the lamp above the observer's eye is ordinarily unimportant.

(2) When using smaller units of light, such as series incandescent lamps spaced shorter distances apart, a correspondingly shorter distance from the lamp could be chosen in measuring the illumination.

(3) The lamp contracted for should give a mean normal illumination at the test point (selected as in Sections 1 and 2) not less than the illumination given by the stationary standard incandescent lamp of 16 c.-p. at 1/x of the distance. The said standard incandescent lamp should be a standardized seasoned lamp having a determined candle-power in a fixed direction.

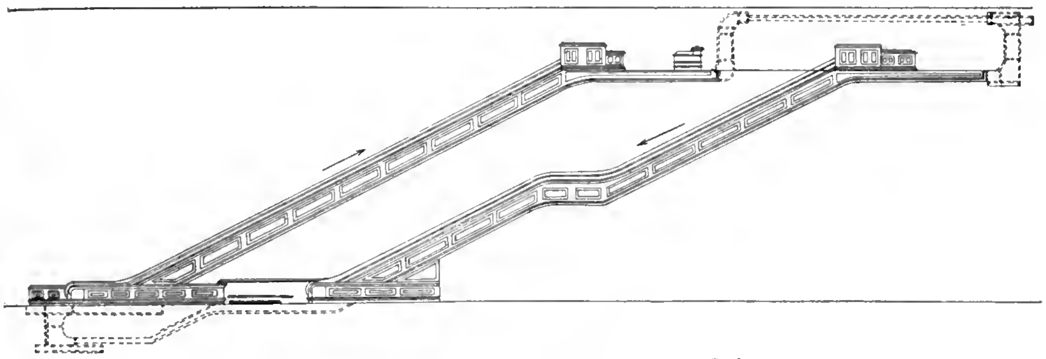
(4) When the lamp tested fluctuates in intensity, a number of observations of the maximum normal illumination should be made at a distance of not less than 200 ft. horizontally from beneath the lamp, and the average of these measurements should be taken as the average maximum illumination. A similar number of observations of the minimum normal illumination should be made, the average of which should be taken as the average minimum illumination. The arithmetical mean of the said average maximum and minimum illuminations should be taken as the mean normal illumination called for in Section 1.

(a) When a reading-distance instrument is used for measuring the mean normal illumination at specified horizontal range, the average of a number of maximum distances at which a certain size of print can be distinguished may be called the average maximum distance, and the average of a similar number of minimum distances the average minimum distance. From these, the mean distance at which an illumination is cast normally, sufficient for distinguishing that size of print, can be determined. This mean distance must lie within the 200-300 ft. horizontal range specified in Section 1. In most cases the arithmetical mean of the average maximum and average minimum distances may be taken as the said mean distance with an accuracy sufficient for practical purposes. The illumination needed for distinguishing the size of print may be determined for each particular observer from measurements of the reading distance with the standard incandescent lamp referred to in Section 3.

(b) When a portable photometer is used at a fixed horizontal distance, such as 250 ft., the mean normal illumination of a fluctuating lamp may be obtained by taking the average of not less than 50 observations at intervals of not less than one-half minute.

(5) A reasonable number of lamps covered by the contract should be tested.

(6) For measuring the mean normal illumination of a lamp, comparison with the standard incandescent lamp may be made either with a



Scheme of the Duplex Escalator on the Subway.

suitable portable photometer or with a reading-distance instrument, such as the so-called "luminometer."

(7) The unobstructed mean normal illumination must not be less at shorter distances than at the point of test.

(8) An approximate list of the mean normal illuminations thrown by street lamps of standard manufacture, at horizontal distances within the 200-300-ft. range, hung approximately 20 ft. above the level of the observer's eye, is given in the following table: (Data from which table is to be prepared are not yet completed. Table will be furnished later.)

Your committee during the consideration of this subject invited to its meetings and sought the advice and assistance of a number of the most prominent illuminating engineers and are lamp experts, and in that connection hereby expresses its appreciation for services rendered by Dr. Clayton H. Sharpe, Mr. Caryl D. Haskins, Mr. Frank Conrad, Mr. Carl Hering, Mr. Louis B. Marks and L. D. Howard Gilmour, and especially to Mr. W. D'A. Ryan for the quantity of data furnished to the committee for its use and the large amount of labor performed in the collection of additional data required in the preparation of the schedules.

Swamp Drainage on the catchment area of the Wachusett reservoir of the Metropolitan water-works has been resumed. As a rule, the ditches cut for the purpose have a board bottom 1 ft. wide, with 4 x 4-in. triangular wood strips rabbeted at the square corner to the edges of the board. The board is nailed to 2 x 4-in. cross pieces 2 ft. long and about 3 ft. apart, laid on the bottom of the excavation. The triangular strips make wooden sides to the ditch 3 in. high and serve as a footing for the stone paving on the slopes of the ditch. As the bottom of the excavation for the ditches is generally in water and the material is very soft, it is necessary to use some form of board bottom in order to preserve the grade of the ditch and afford a support for the slope paving, and the form of the bottom used facilitates cleaning the ditches. Where the ditches have steep grades and the ground is more firm, the bottom is also paved with stone; where the ground is stony, no paving is used. This type of ditch construction has been very successful in earlier swamp drainage operations in the Wachusett basin, resulting in a marked reduction in the color of the water

The Nine-Mile Power Station of the Spokane & Inland Empire Railway.

By H. Cole Estep.

Twelve miles below the city of Spokane, Wash., on the Spokane River, the Spokane & Inland Empire Railway Co. is constructing its new 15,000 kw. hydro-electric station, as described in this journal on March 2. The work of construction, which has been in progress since August, 1906, is now about half completed, and is in many ways in its most interesting stage. After several delays on account of floods and high water, the subaqueous work has been completed. To obviate as much as possible further delays caused by a rising river, a rather novel method of construction has been adopted.

The river is 250 ft. wide at this point, and the power house, which is built, as is usual in such cases, against the back wall of the dam, extends out to mid-stream, the generator room being 127 ft. long by 20 ft. wide.

The method of construction adopted consists in building the power-house half of the dam first, the foundation work being subaqueous. Then while the other half of the dam is being constructed, the river is diverted through temporary openings left in the base of the power-house dam for that purpose. When the whole structure is completed these temporary openings will be sealed.

To accomplish this the upstream face of the dam at the elevation of the generator room floor is left open, the upper part being supported by heavy cross walls located between each of the four generating sets. Between these cross walls are left four 20 x 30-ft. openings. I-beams bedded firmly in the cement at the top and bottom, spaced 12 in. apart, are placed vertically in these openings, forming a grid. When the power-house is completed and the coffer-dam thrown across the east half of the stream, the water will pour down through this grid and find its exit through temporary openings in the dam floor. After the east half of the dam is completed this grid will be sealed by driving sheet piling between the I-beams. This rather novel design has already proved its efficiency and will materially reduce the time and cost of construction.

The dam is being very thoroughly and substantially reinforced. The lower courses are tied together and stiffened by diagonal rods 20 ft. long, made of 1¼-in. twisted steel squares. The reinforcement of the upper courses consists of 20-ft., 1¼-in. twisted steel squares, laid in horizontal courses 2 ft. apart and tied together by short rods of ¾-in. twisted stock.

No penstocks are used, the wheel chambers being constantly under full head. The water is controlled by ordinary vertical lift gates located at the face of the dam. From each turbine the water is carried away by two draft tubes, each 8 ft. 6 in. in diameter.

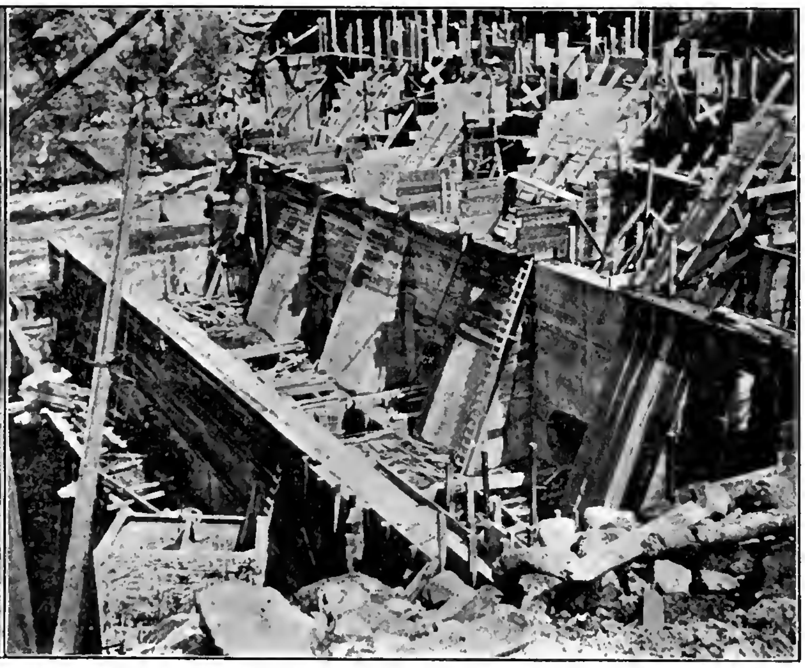
A feature of the design of the dam is the hatchway provided for gaining access to each wheel chamber. This chamber, ordinarily under full head of water, is located between the sealed grid, mentioned above, and the main wall of the dam. At the top of the chamber the dam wall forms a corner, and in this corner, swung 45 deg. to the vertical, is fitted the 16 x 16-ft. hatchway. The hatchway itself, made of channel iron and reinforced concrete, is supported against the upward water pressure by removable girders. In one of the accompanying photographs the location of the hatchways is indicated by white crosses.

The plant will operate under a head of 60 ft. The flow of the river varies from 25,000 to 1,400 second-feet, the normal flow being bout 6,000 second-feet. The river canyon is deep and wide enough to provide sufficient pond area to enable the plant to develop 15,000 kw. continuously. Two 3,750-kw., three-phase, star-connected Westinghouse alternators are to be installed immediately; one more is to follow before the end of the year, while eventually the plant will contain four 3,750-kw. machines. Each generator is to be driven by a 6,000-h.p., direct-connected, horizontal, parallel-flow turbine.

The switchboard gallery is located at one end of the generator room. Remote control will be used throughout, the main oil switches being each located in a separate fireproof compartment at the rear of the switchboard gallery.

Each generator is supplied with its own 3,750-kw. 2,300-60,000 volt, oil-cooled, three-phase Westinghouse transformer. The transformers are located in fireproof pits situated adjacent to the generators along the back wall of the dam. The generator room crane is used to handle the transformers. This brings out another of the features of the design. On account of the hatchways leading to the turbines, the transformers and the generators can be placed under the same crane runway; every part of the machinery is thus made exceptionally accessible, served by one main crane and can be moved rapidly and economically.

Sand Pit and Gravel Sluice.



Dam under Construction, Nine-Mile Station.

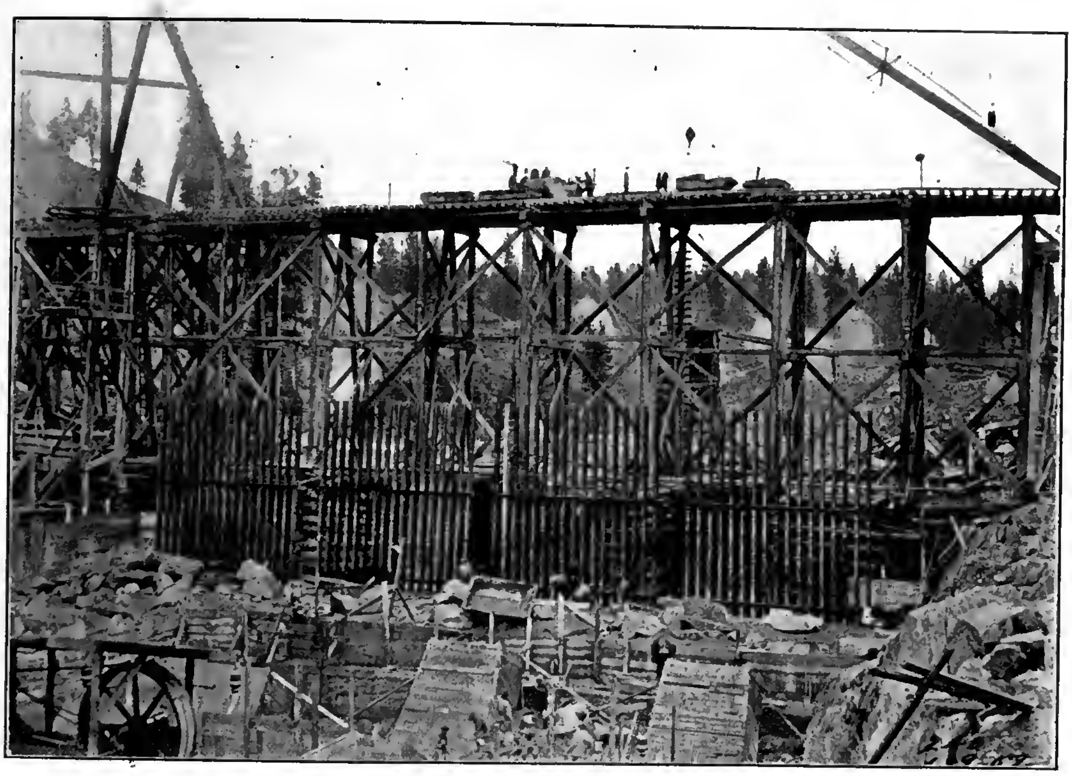
One of the causes contributing to the economical construction of this plant is the exceptionally fortunate location of the sand and gravel pit. At the site of the dam on the east bank of the river is found the finest natural deposit of sand and gravel that could be desired. The here rises about 300 ft. above the river. The concrete mixing plant, in which are installed two steam-driven Smith mixers, is located on the hillside about 100 ft. above the river. From this point to within 100 ft. of the top of the cliff is situated a bed of fine, pure sand. The sand is transferred to the hoppers of the mixing plant in small, horse-drawn tramcars. Above the sand bed and extending to the top of the cliff is a deposit of clean gravel. The gravel is sluiced down to the concrete mixers by the common method used in hydraulic mining. On its way down the boulders are removed and diverted to a stone-crusher. By virtue of this natural gravity system of transportation and the close proximity of the material, the concrete at the spout of the mixers costs 13 cents per cubic yard, exclusive of the cost of the cement.

Except at prohibitive cost, the plant is inaccessible by rail. All the heavy machinery will have to be transported over the county road. Although the road is steep and crooked in places, the machinery can be moved in this way cheaper than by building a costly railroad spur.

The location is twelve miles from the center of distribution at Spokane and the electricity will be transmitted at 60,000 volts over this distance. The pole line is now completed and is being used temporarily for the transmission of electricity from Spokane for light and power purposes at the plant under construction. The transmission line follows the county road most of the way and is not on a private right-of-way.

The energy generated at the Nine-mile station will be used for commercial and street station purposes in Spokane and also for power on the extensive electric railway system of the Spokane & Inland Co., which operates 200 miles of standard gauge electric railway traversing the Inland Empire district of eastern Washington.

Messrs. Sanderson & Porter, of New York, are the contractors in charge of the construction of the Nine Mile Power Station. Mr. W. F. Zimmerman, of Spokane, representing the Inland Empire System, is the consulting engineer.



I-Beam Grid, Nine-Mile Station.

Carrying Capacity of Reinforced Concrete Floor Construction.

By Messrs. A. E. Lindall and G. R. Heckle.

Many causes contribute to the diversity of opinion among engineers regarding the design and load-carrying capacity of floor panels, the principal ones being the variation in strength of material and class of workmanship, but more particularly the tests that are published with a view of exploiting the merits of a particular system, which tests are frequently executed in such a manner as to give entirely false impressions regarding the strength of the structure. It is a common practice to test a portion, or a strip of floor panel a few feet wide and judge from the load thus carried, the load which the whole panel could carry; or pile up bags of cement, sand or gravel and call each bag in height 100 lbs. per square foot, whereas the load averages more nearly 50 per cent. of this amount—that is to say, a pile ten or twelve bags in height will give about 600 lbs. per square foot of area. Materials such as pig iron, brick, pig lead, and so forth, unless special provision is made, may be suspected of carrying a portion of their load to the supports, by interior arching action.

The situation outlined is unfortunate, in so far that those who are interested, instead of being instructed are unconsciously misled, and until a great number of experiments have been made, placing the whole subject of reinforced concrete on a solid foundation of experimental data, this phase of the matter is really serious.

In justice to all who have made floor tests, it must be said that it is difficult to eliminate many inaccuracies. Laboratory apparatus can seldom be obtained; the heavy loads required to test to destruction full-sized floor panels can be secured in practice only by the piling up of a large number of comparatively small loads, probably giving a very fair uniform load, but uncertain, nevertheless, as regards its exact amount and point of application.

It is hoped that the following record of a test on a full-sized panel will be found generally interesting and useful, although subject to most of the criticism noted above.

The panel was built near the Intercity Viaduct, Kansas City, Mo., because the reinforced-concrete viaduct floor was under construction, and the convenience in securing material and labor very greatly reduced the cost of the panel. The foundation, however, was very poor, and the precaution that was taken to spread the footings under the corner posts was not sufficient to avoid serious settlement, and even cracks in the panel, as will be noted later.

The general plan and arrangement of reinforcement are shown in an accompanying illustration. The corner posts were made rather heavy for two reasons—to give as much continuity to the girders as possible, there being no surrounding panels as is the case in buildings, and to distribute the load on the foundation.

The reinforcement was corrugated high-carbon bars. The concrete was made of one part of Iola Portland cement, two parts Missouri River sand and five parts crushed limestone graded from ¼ in. to 1 in. in size.

The concrete was placed during cold weather in February and protected with manure—or in other words, subjected to the same unfavorable conditions that may obtain in practice. Tests were made sixty days later, on April 11, 12 and 13.

The slab was tested first, and in order to avoid loading the beams and girders they were blocked up, the idea being that the slab should be tested

Table 1, Total Loads and Deflections.

Slab.			Beam.		
Total Load.	Load per sq. ft.	Deflection.	Total Load.	Load per sq. ft.	Deflection.
lb.	lb.	in.	lb.	lb.	in.
40,000	220	⅛	132,200	367	3/16
60,000	330	¼	138,600	385	¼
105,000	580	⅜	154,800	430	5/16
113,000	630	⅝	171,200	470	⅜
118,000	655	¾	182,500	510	7/16
135,000	750	1	193,800	540	⅝
155,400	865	1⅛	205,100	570	¾
162,000	900	1¼	220,120	611	1

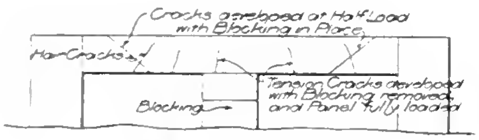
to practical destruction without injuring the beams, and then test the beams, blocking up the girders, and finally the girders. For loading material, cement sacks were filled with sand and twenty-five of these were weighed, the average weight being found to be about 113 lbs. per sack. This weight was then used to calculate the total weight by counting the number of sacks placed on the panel. The sacks were so placed as to load the area included between the center lines of the beams and girders, this area being 10x18 ft. in plan, or 180 sq. ft. To avoid arching action, a space was left between the piles in the center of the panel, as shown in one of the illustrations. Deflections were read in the middle of the panel, by means of a multiplying device, level readings were also made on the north corner posts. When the panel was only half loaded settlement began, cracking the outside beam on the north side, the cracks extending diagonally upwards toward the supports, or in the reverse direction to the ordinary diagonal tension cracks, the nature of these cracks being shown in an accompanying sketch. The total load, load per square foot, and the deflection in the middle of the panel are given in Table 1. Correction in the deflection had to be made because of the settlement, and this makes the deflection readings uncertain by perhaps as much as ⅛ in. An attempt to show by a curve the general relation between the load per square foot and deflection has been made in the accompanying diagrams, in which the deviation of some of the points from the average curve is probably due to causes enumerated above. At a load of 750 lbs., the loading was discontinued for the day, and an examination was made, which failed to show any cracks. The next morning, however, fine cracks about 3 ft. long were found in the under side of the slab, at right angles to the reinforcement, showing that the deformation had increased beyond that

which the concrete could stand. Settlement became so troublesome that it was thought best to measure deflections from a string stretched from the under side of the girders: this would have been done in the first place only that it made it impossible to use the multiplying device. By the addition of another 100 lbs. per square foot the deflection increased 1/8 in., and by adding sufficient to make the total 900 per square foot, or the addition of about 40 lbs. per square foot more, increased the deflection another 1/8 in. As the deflection was rapidly increasing, and the cracks in the under side becoming more numerous and distinct, it appeared probable that the ultimate strength had about been reached.

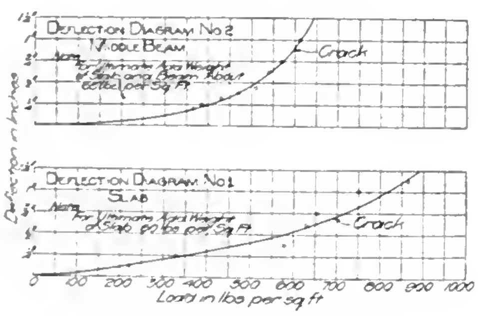
One of the photographs shows the load at 900 lbs. per square foot over one full panel of the slab, which is one-half of the total floor panel, and gives a good idea of the amount of load required to produce 900 lbs. per square foot.

In arranging the test for the middle beam, part of the load was entirely removed from the panel and the balance distributed over the total area of 20x18 ft., or 300 sq. ft. The blocking was removed and a deflection of 3-16 in. noted, the total load being 132,200 lbs., or about 367 lbs. per square foot. Before the blocking was removed it was noticed that the beam, as well as the outside one previously noted, had a fine diagonal crack extending upwards toward the girder, probably due to unequal settlement, because upon removal of the blocking the cracks closed a trifle; in any event, it seemed to exert little influence on the strength of the beam, as it behaved in the ordinary manner upon the addition of load.

Referring again to deflection diagram No. 2



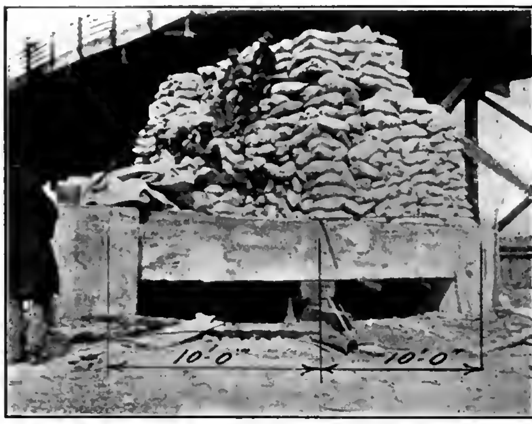
Cracks In Outer Beam.



Load-Deflection Diagrams.

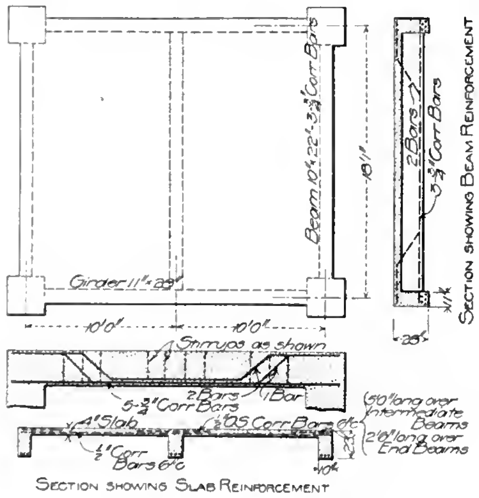
the relation between deflection and load per square foot can be seen. In this case the points noted agree very closely with the average curve. As the deflections were all noted with reference to the girders, the influence of the settlement was eliminated. At a load of 385 lbs. per square foot, two fine cracks appeared near the middle of the beam on the side adjacent to the slab previously loaded with 900 lbs. per square foot. These cracks extended less than 2 in. on the bottom from the edge of the beam, and showed no further development until a load of 430 lbs. per square foot, when cracks were found to extend entirely across the bottom of the beam. At 470 lbs. a fine crack appeared across the upper corner of the beam at the west end, intersecting the slab at about 12 in. from the end of the beam, and the girder the same distance down. The loading was continued with increasing deflections as shown on the curve until 611 lbs. per square foot was reached. The beam was allowed to stand over night with this load, and the deflection increased 1/8 in.; the cracks at this stage were about 1-16 in. wide at the bottom.

About 24,300 lbs. of the load was then taken off the two outside beams and placed directly over the central beam, with a space in the middle to prevent arching of the load. This left a uniformly distributed load of 544 lbs. per square foot over the entire panel; the 24,300 lbs. directly over the beam would be equivalent to 135 lbs. more, or a total of about 680 lbs. per square foot. If to this is added 60 lbs. per square foot for the floor and beams, the ultimate load at which the beam failed was approximately 740 lbs. per square foot. The failure took place along the crack previously noted as running across the upper corner of the beam. With the dropping of this beam, the slab sheared off at right angles to the beam for a distance of about 3 ft. on each side, about 24 in. from the girders, and the lower inside edge of the girder was broken off, exposing the bars in the bottom for a distance of nearly 3 ft.



Uniform Load of 900 Lb.

Loading to Prevent Arching.



Details of Reinforcement.

In order to obtain a full loading of the west girder, a false work was erected by making a cribbing of ties about 10 ft. from the girder and spanning the distance between the ties and the girder with old rails. The distance from the bearing points of the rails on the ties to the center of the girder was 9 ft. 6 in.

With 154,800 lbs. uniform load on the main panel and 50,000 lbs. uniform load on the false work, making the actual load on the girder 102,300 lbs., fine cracks appeared in the middle of the girder on each side of the center extending about one-half the distance to the bottom of the slab, the deflection being 1/8 in. On the failure of the center beam as previously noted, the inside edge of the girder was broken off at the center, exposing the bars, and a horizontal crack was formed in the outside face about 12 in. from the bottom and about 3 ft. long.

Approximately 219,200 lbs. were then placed directly over the girder, none of the load being outside of the center of the spans of the false work and the main panel, and a space being left across the middle of the girder to prevent arching. This load caused a 1/2 in. deflection in the girder, but no further cracks appeared. Estimating three-fourths of the total load as carried by the girder under test, the load on the girder represented a panel of 360 sq. ft. loaded 620 lbs. per square foot, and the total moment in the girder was approximately 5,740,000 inch pounds, using the formula 1-10 wl, in which w is the weight and l the length. This load was allowed to remain on the girder over the next day, or about 40 hours. The deflection was then found to have increased to 3/4 in. and the cracks to have increased to about 1-16 in. at the widest point. The foundation had settled at one corner about 10 in. and at the other corners about 7 in., making any further loading impracticable.

It may be worthy of note that the floor slab and beam were designed to carry 600 lbs. per square foot ultimate load, and the girder about 85 per cent. of this load. These loads include the weight of the structure. On this basis, the slab carried more than 50 per cent., the beam 23 per cent., and the girder, at the time the test was discontinued, 13 per cent. above the computed breaking load.

One or two points seem evident from the foregoing—that formulas frequently prescribed in building laws, such as 1-8 wl, 1-10 wl, or even 1-12 wl, do not even approximately represent the carrying capacity of floor slabs. This also applies to the formulas in which strips are assumed to carry loads in two directions at right angles to each other, because such formulas will show that about 90 per cent. of the load is carried in the short direction when one side is twice as long as the other. The assumption that a floor panel is an arch—a groined arch, perhaps seems unsound in view of the small rise that is possible in a 4-in. slab with a 10-ft. span, as well as the decidedly large deflection noted in the center. The opinion has frequently been expressed that little if any reinforcement is required in a floor panel, because of the restrained condition of the edges. While future investigation may reveal the desirability of radical changes in the method now employed in reinforcing floor panels, the writers wish to state most emphatically that a large portion of the under side of the panel tested was under very heavy tensile stress, made evident by the number of small cracks that appeared at right angles to bars, and the flaking of the concrete as the load approached the ultimate. Beams and girders, when incorporated in floor construction, agree very well with computed strength if computations are based on 1-12 wl—in fact there seems to be a comfortable margin of strength above this, which to a certain extent will take care of uncertainties in workmanship. Beams in end panels, where incorporated and made monolithic with exterior girders, have nearly the same strength as in interior panels. Floor slabs, while stronger than computed by the ordinary beam formulas, cannot be loaded indefinitely with "no appreciable deflection."

The Upper Grays Dam, Consolidated Water Co., Utica, N. Y.

The following notes refer to a dam built under somewhat unusual conditions as to foundation and equally unusual requirements as to future extension. It is owned by the Consolidated Water Co., of Utica, N. Y., and is to provide additional storage for the water supply of that city. Investigation on the part of the company developed a good storage reservoir but with the severe drawback that the only available site for a dam was underlaid with foundations of clay, without either hardpan, gravel or ledge in sight. The clay was of a good quality and fairly tempered with sand. The difficulties of building on this foundation, however, were so great that it was tentatively abandoned and a new site selected where the foundations were adequate, but at a sacrifice of a large portion of the reservoir capacity.

At this stage the owners invited the Ambursen Hydraulic Construction Co., of Boston, Mass., to consider with them the situation and submit a design for a dam to be built on the clay foundation. They furthermore stipulated that the present height of the dam must be 30 ft. but with provision for future extension to a height of 40 ft., when additional storage should be required. This latter condition by itself was fatal to a solid dam on account of the cost of the 30-ft. dam being practically equal to the full cost of the 40-ft. dam when completed, assuming it was built at one time.

The borings indicated that the foundations could safely be trusted to support a working load of 1¼ tons per square foot with the clay confined against spreading. A broad floor was therefore laid out of such dimensions that the total load of the full-height dam under flood would be represented by a distributed pressure of 1.2 tons per square foot. The floor of course was amply reinforced in all directions and was pierced with a number of weep holes to relieve any upward pressure which might occur from accidental seepage and hillside springs.

Cut-off walls of reinforced-concrete were sunk in trenches at both the upper and lower edges of the dam, the former one being carried down 8 to 10 ft. until they intersected a bed of fairly good hardpan. The general arrangement is shown in the cross-section.

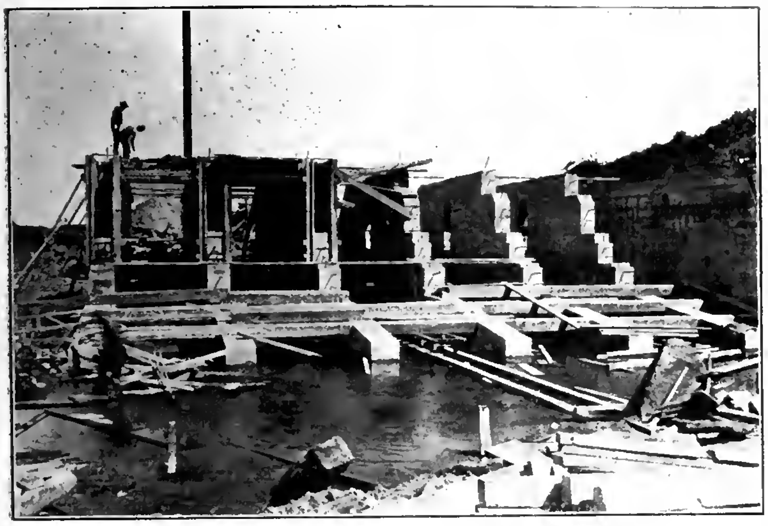
On this floor heavy buttresses were carried up, the downstream edges of which were stepped off as shown, with corrugated steel rolls left projecting from the vertical face of the steps so as to secure an ultimate bond with the extension when finally built.

The deck was carried up of a thickness proportioned, of course, to the ultimate height of 40 ft. plus flood, and finished with a temporary crest at the 30-ft. grade. Purlin timbers were then bolted to the nosings of the steps and on them was spiked a temporary apron of plank which served to carry over the ice and logs and at the same time protect the projecting rods from injury.

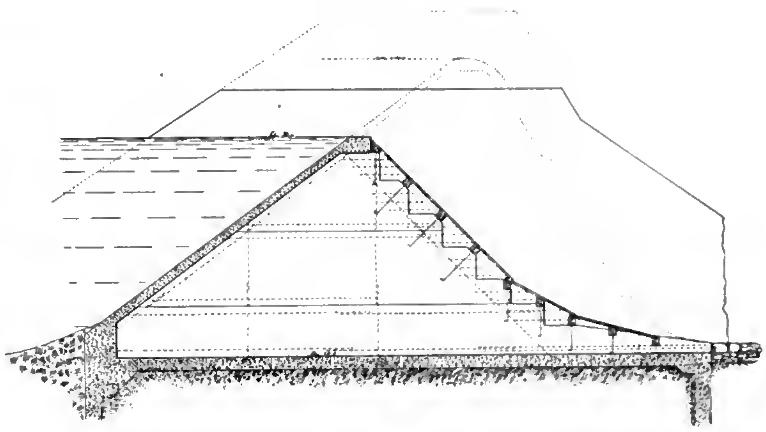
The bed of the river below the dam was paved for 30 ft. with a heavy body of boulders grouted together and finished to a cement surface.

The interior of the dam between the buttresses was fitted up for three measuring weirs, which enables the water supply to be carefully gauged and controlled.

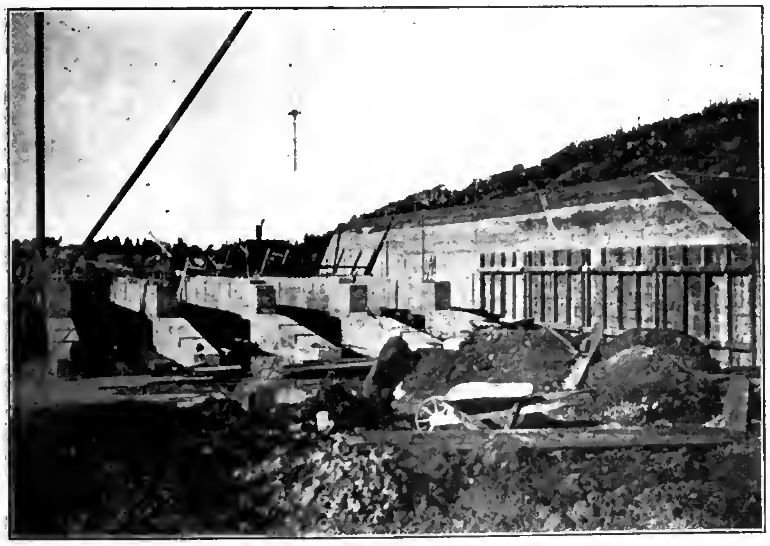
When the dam is raised to the full height of 40 ft., the temporary plank apron will be removed and used as forms. The latter will then be bolted up to each side of the present buttresses and filled with concrete, with a bond secured by means of the projecting rods. The final deck and full apron will then be laid in concrete, as shown by the dotted lines, which represent the dam as finally completed. It should be noted, however, that the additional 10 ft. section is self-stable and would be permanent even if there were no mechanical connection between it and the lower section. The use of the junction rods is obvious and cheap and is at least a satisfaction to the mind if of no very marked utility.



Buttresses of Dam.



Section of Upper Grays Dam.



First Lift of Buttresses.

Part of Deck in Place.

The dam was finished last fall and has been in successful service for some six months. This construction opens up new possibilities both in respect to dams on soft foundations and in respect to providing for future increase of height.

Two Building Collapses recently occurred in Philadelphia which were probably due to careless or negligent building methods. On July 13, while a gang of Italian and negro workmen were tearing down an old brick building four stories high, the floors collapsed and a number of men were injured, some fatally. The collapse was caused by overloading the second floor with brick from the third and fourth stories. The other accident occurred on July 10, and was the collapse of an incomplete reinforced concrete building on account of the premature removal of the forms, before the concrete had hardened. Several lives were lost.

Completion of Grade Rectification in the Battery Tunnel, New York.

The rectification of the minor irregularities in the alignment of the twin tubes of the Battery tunnel has now been completed. As described in several previous articles, these irregularities were of a secondary nature, due to divergencies in the movement of the heavy tunnel shield through soft material and were corrected by comparatively small elevations or depressions of the roof and invert so as to cut out the summits of the line of divergence and distribute the deviation over a longer grade, providing for smooth track and preserving the minimum clearance of 8 in. for the cars.

All of the work has been done in soft, wet sand or quicksand and has substantially consisted of removing some of the original arch or invert segments and replacing them with concrete or cast-iron construction, changing the cross-section of the tunnel from a circle to an egg shape. Only a small part of the work was done under atmospheric pressure but for nearly all of it pneumatic pressure was necessary, which of course added to the delay and expense involved. The depression of the invert consisted simply of removing the old segments and rebuilding the lining to the required new dimensions and was done piecemeal with little difficulty.

Where it was necessary to raise the roof, it was at first intended merely to cut through the old lining at about the springing line and replace the upper portion of it with new cast-iron segments providing for an elongated vertical axis and giving the required additional headroom. This did not involve any change of the invert in these parts of the tunnel, and operations were commenced as described in The Engineering Record of March 2, 1905, by the construction of interior timbering which afforded a jacking platform over a clear roadway in the lower part of the tunnel. Special powerful hydraulic jacks were inserted between horizontal distributing and reaction beams on the falsework and fillers fitted to the arch segments. After unbolting and disconnecting the segments on longitudinal horizontal lines, they were jacked 2 or 3 ft. vertically upward into the sand above the tunnel roof, the sand being partly removed to facilitate their displacement by "bleeding" through holes cut for that purpose in the segment webs.

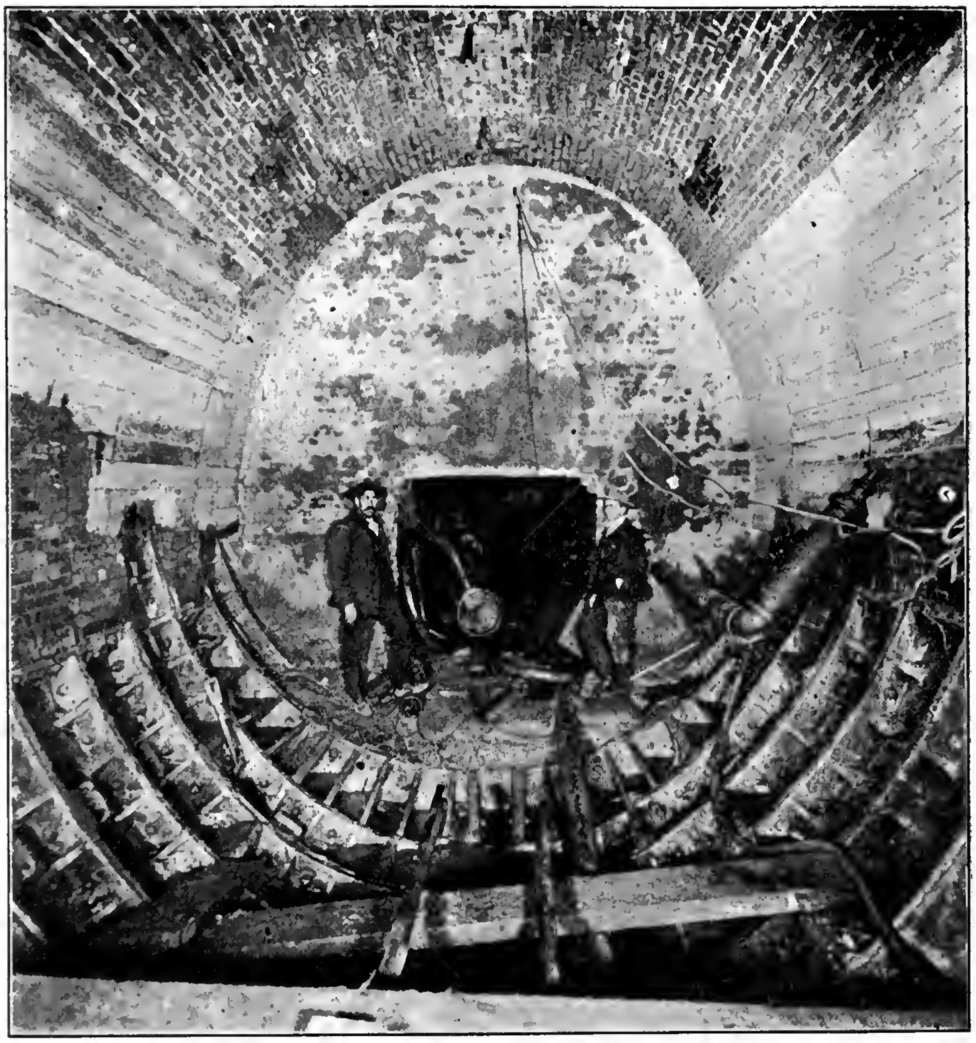
The jacks were removed and the segments temporarily supported by radial shores seated on transverse timber arches inside the tunnel and affording clearance for passage and operations there. On each side of the roof segments thus elevated, lines of thin vertical steel sheeting were driven to exclude the sand and retain the surface exposed between the separated portions of the lining. As the ground water line approached nearly to the lower edge of the sheeting and as that point was considerably above the bottom of the new tunnel lining, the question of removing the remaining segments on the sides of the tunnel and retaining the sand there while the new structure was built, became a very serious one.

It was at first proposed to drive poling boards nearly vertical on both sides of the excavation and as far as practicable from the tunnel axis, so as to enclose the new work, and then endeavor to drain the space between them and the tunnel lining by pumping so as to make it possible to remove the reamining sections of the old segments and construct the new work under atmospheric pressure, being prepared, however, to furnish pneumatic pressure if necessary.

Eventually, this plan was somewhat modified and the work was finally executed, as indicated in the accompanying cross-section, by jacking out the segments on both sides of the tunnel in exactly the same manner as the roof segments had been jacked out; before this was done, however, poling boards inclined somewhat from the horizontal were driven under the lower edges of the roof segments to support the earth there and the vertical sheeting was removed. The segments were then jacked out until their upper ends were nearly in contact with the lower ends of the poling boards, where they were maintained in position by radial shores wedged against the segments and reacting against the arch timbering or bracing in the tunnels. The surface of the earth exposed at the lower ends of the side segments was nearly horizontal, so that no difficulty was experienced in making it stable. During this operation the ground water level was lowered by drawing the water into the lower portion of the tube through several well points, so that it was not found necessary to provide a pneumatic pressure to exclude the water.

A new lining about up to the haunches was then built with concrete, reinforced by three curved 1-in. square bars for every 22-in. ring. This concrete enclosed the upper segments of the old lining and extended about 1½ ft. above them or 4 ft. above the springing line, where it was finished with a radial surface acting as a skewback to receive the 4-ring brick arch roof, which was built on it in preference to continuing the construction with concrete, because the brickwork could be more easily handled in the tunnel and required less time for setting after it was laid, thus considrably expediting the work. The space between the adjacent ends of the displaced segments and those which remained undisturbed in the lower part of the lining was carefully filled with concrete, sealing it against the earth and water pressure, and the remainder of the space between the displaced old segments and the new lining was carefully backfilled with solid brickwork. Care was taken to have the upper ends of the reinforcement rods project about 6 in. beyond the surface of the concrete lining to bond the latter thoroughly with the brick roof arch. The work progressed rapidly and steadily and when completed presented a very neat and satisfactory appearance.

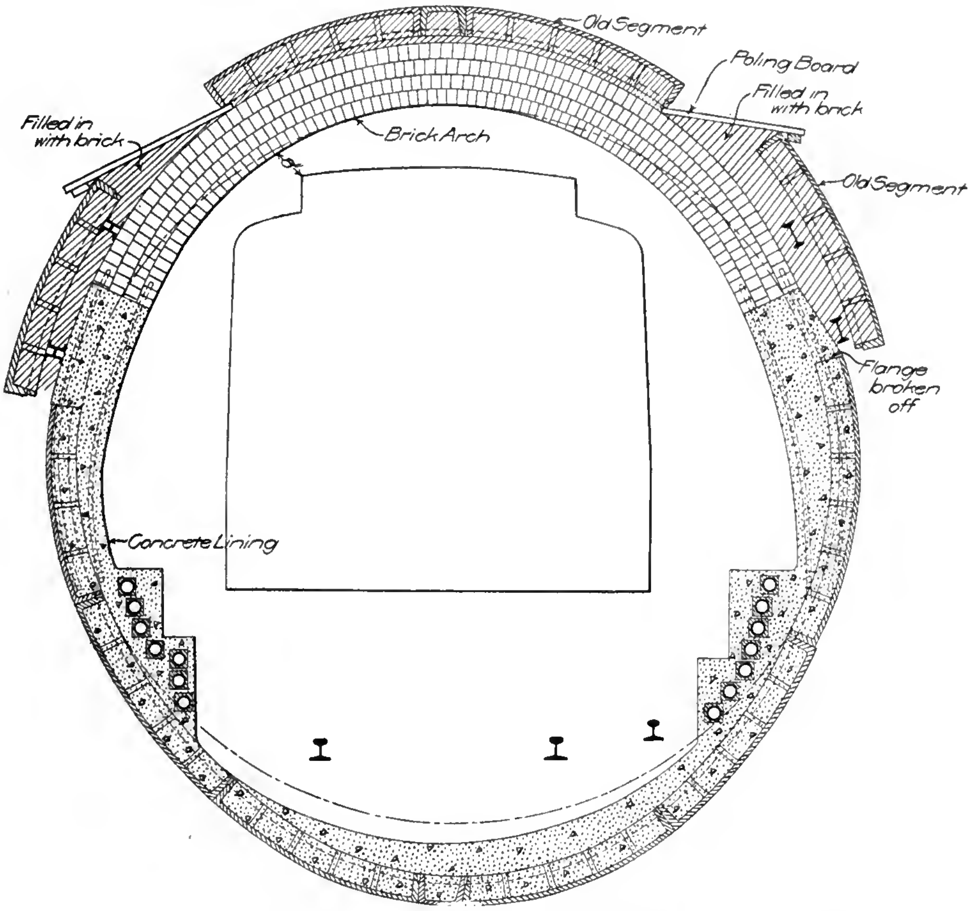
The reconstruction of about 210 lin. ft. of roof arch and 2,676 ft. of invert in both tubes was commenced in April, 1906, and was completed in June, 1907, with an average daily force of about sixteen men for each tube at a fraction of the outlay which it was conservatively estimated would be required for doing the same work by means of a shield built around the old tunnel. The latter method was considered to involve great difficulties in the construction and operation of the shield and serious doubts were entertained as to its practicability. Its control was believed to be a difficult and delicate matter, subject to the same difficulties encountered in the original construction which would, it was expected, be considerably augmented under the new conditions. That the work has been carried on so rapidly and successfully and at such a small comparative cost demonstrate a high degree of skill and ability in the engineers and contractors and must be a source of great satisfaction to all concerned. The work was designed and executed under the approval of the Rapid Transit Railway Commissioners, Mr. Geo. S. Rice, chief engineer, and Mr. Frederick Noble, division engineer. The general contractor was the Rapid Transit Subway Construction Co., Mr. Geo. H. Pegram, chief engineer, the details being designed and executed by Cranford & McNamee, Mr. J. C. Meem, chief engineer, and Mr. W. I. Aims, consulting engineer.



View of Portion of Rectified Tunnel.

Cold Twisted Steel Rods for Concrete Reinforcement.

Although a great deal has been written concerning reinforced concrete comparatively little has been published regarding the steel used as



One Method of Rectifying Battery Tunnel.

reinforcement. The subject was brought up at the recent meeting of the American Society for Testing Materials by Mr. Jesse J. Shuman, chief inspector of the testing department of the Jones & Laughlin Steel Co., in a paper that called forth considerable discussion in which diametrically opposite opinions were expressed by reinforced concrete specialists. Mr. Shuman's paper read as follows:

When a bar is twisted by a machine of the usual type it does not change in length; in fact one end is inserted loosely into the revolving die and there is no tendency to pull out. Hence the central fiber alone is unchanged in length and strength, and the great increase in the strength of the bar is an average of values that are widely different. Moreover, the size of the square has a direct bearing on this average; a point that is commonly neglected in specifications.

If square bars of any size be twisted until they have made one complete turn in 9 times the dimension of a side (pitch = 9), the metal on the corners is stretched about 11.5 per cent. as determined by formulas for helices. The areas of squares, however, vary with the squares of their sides, so that in a small bar the average stretch is greater than in a large bar, and the increase in strength is correspondingly greater. This is amply illustrated by laboratory results in any series of tests in which the size varies, and it should be recognized as a normal manifestation.

The moment the twisting machine has created a permanent set in the fiber, the steel has begun to increase in strength, in the same manner as higher yield-point and ultimate strength are set up in a bar when it is slightly stretched in a testing machine. As the twisting proceeds the yield-point ascends more rapidly than the ultimate strength. There is a point, however, at which the maximum strength of the bar is reached, and beyond which it is reduced somewhat before the bar twists apart.

The interesting behavior of half-inch squares of three widely different grades is shown in Table 1. It would clearly be a mistake to specify a number of turns approaching the maximum strength of the steel, for the internal strains in such a bar are already nearly enough to destroy it; yet it is not uncommon for engineers to do this very thing. In Mr. Shuman's opinion the number of turns should be about half the number at which the steel is at its maximum strength, and in the ordinary soft Bessemer product this means one complete twist in 8 to 10 times the size of the bar; in other words, the pitch of the twist should be 8 to 10 for Bessemer steel of about 60,000 lb. tensile strength. Basic open-hearth squares of similar grade should have a pitch of 5 to 7 in order to have their best properties developed. If carbons higher than ordinary structural grades are insisted upon, a proportionate concession must be made in the number of twists.

Excellent results have been obtained with both Bessemer and open-hearth steels of a wide range of carbons. It seems reasonable, however, that the grades that have been found to be best adapted to structural work would also be most reliable for reinforced concrete. Bessemer steels containing carbons up to 0.30 or 0.40 per cent. can be twisted successfully, and are very high in tensile properties, but they have the same brittlenes that constitutes the strongest argument against the various hot-rolled and hot-twisted concrete bars. The latter must be high in carbon in order to yield an elastic limit that even approaches that of the soft steel cold-twisted square rods. Surely the lowest yield-point in Table 2, in which are shown results on soft Bessemer bars, is high enough to suit the most exacting requirements.

On low-phosphorous steel the effect of twisting is not as marked as on Bessemer steel, the behavior in this respect being quite similar to that of the same steel when cold-rolled or cold-drawn. The lower results are readily raised, however, by carrying the twisting process further. Table 3 shows what can be expected of basic open-hearth bars of 55,000 to 65,000 lb. tensile strength twisted an appropriate number of turns.

Manifestly it would be a poor plan to use open-hearth steel softer than the tests shown in this table, but it would be both safe and advantageous to use steel up to about 0.35 per cent. carbon, with phosphorus under 0.04 per cent.

Inasmuch as the function of a reinforcing bar

View of Jacking Platform, Battery Tunnel.

is performed inside the elastic limit, the elastic limit is the feature of highest importance from the engineer's standpoint. It is here that the cold-twisted square excels all hot-finished sections, in Mr. Shuman's opinion, and must always continue to do so, for its elastic limit of 60, 70, and even 80 thousand pounds permits the use of less steel for the same service than can be guaranteed by its competitors.

In the testing laboratory it is necessary to take unusual pains to observe the yield-point, commonly called elastic limit, for the reason that the beam of the machine does not always drop when the point is reached at which permanent deformation begins. The machine should be run not faster than 5/8 in. per minute, and in the absence of an autographic device a pair of dividers should be held on the specimen until the yield-point is observed.

Specifications for cold-twisted bars should be consistent with the behavior of steel of known quality, and should recognize the empirical laws peculiar to the material. Thus, to summarize and add to points made in this paper, the following suggestions are offered by Mr. Shuman as a broad foundation for specifications.

1. Process. Specify whether open-hearth or Bessemer steel is to be used, or either. Open-hearth steel should contain less than 0.04 per cent phosphorus for basic and 0.06 per cent. for acid steel.

2. Carbon. This should usually be left to the discretion of the manufacturer, who insists that when carbon limits are named the tensile requirements should be left open.

3. Elastic Limit. For squares ½ in. and smaller, this should be at least 65,000 lb.; for squares ⅝ in. to 1 in. at least 60,000 lb., and for squares 1⅛ in. and larger at least 55,000 lb. Manufacturers can generally guarantee minima values somewhat higher than these, but the above would be a reasonable specification.

4. Ultimate Strength. To be recorded.

5. Elongation. At least 5 per cent. in 8 inches, or 12 per cent in 2 inches.

6. Reduction of Area. To be recorded.

7. Bend. Bars to bend cold around a pin twice their size without distress.

8. Number of Turns. For Bessemer steel, one complete turn in 8 to 10 times the size of the square; for open-hearth steel, in 5 to 7 times the size.

9. Number of Test Pieces. One tension test specimen and one for bending test for each melt used in each size.

10. Inspection. All tests governing the acceptance of material to be made at manufacturer's works. Inspector to have access to the bars prior to shipment, but the manufacturer is not relieved thereby from responsibility for unsatisfactory material. In this connection it may be stated that each bar is thoroughly cleaned by the twisting process, and that each piece is in a large measure tested at the same time, as no imperfect bar will stand the cold-twisting process.

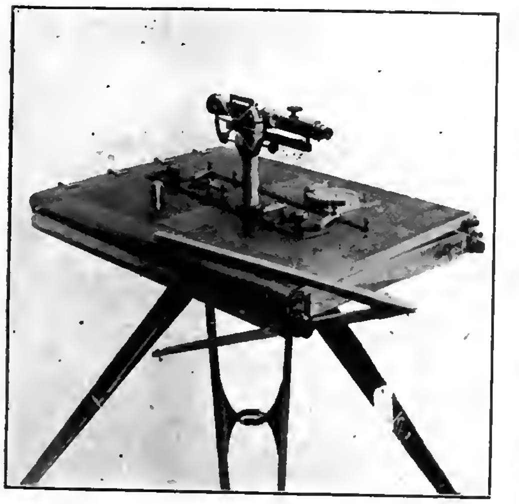
In the discussion of the paper, some of those taking part urged that no distinction should be allowed between specifications for structural steel and those for reinforcement steel. Mr. H. H. Quimby stated that all the steel for reinforced concrete work done under the direction of the Bureau of Surveys of Philadelphia was purchased under the same requirements as governed the steel for bridges and buildings. He was strongly of the opinion, however, that it was not advisable to specify properties of steel bars both straight and twisted, for it was enough to test them in one or the other form. Other engineers stated that there was every reason for departing from the requirements for structural steel in purchasing reinforcing steel. The properties required in structural steel are largely necessary on account of the hard treatment received by the steel during its fabrication into the members used in bridges and buildings. Reinforcement steel is not subject to any such severe treatment and on that account, it is claimed, the specifications governing it need not be the same as for structural steel. Mr. T. L. Condon, who was among those who expressed such opinions, stated that for many years he was an advocate of strich requirements for structural steel. When he first employed reinforced concrete he held that the same grade of metal should be employed in that work. After a longer experience in the design and execution of reinforced concrete he became convinced that the treatment of steel for reinforcement and the work required of it varied so widely from steel structural work that the differences should be recognized in specifications.

SUBMERGED ROCK BREAKING with a Lobnitz chiseling machine is now in progress at the harbor works of Blyth. About 150,000 cu. yd. of rock were taken out by drilling and blasting before two of these machines and two 700-ton hopper dredges were put in service, and on this account a comparison of the cost of the two methods of working is possible. At the recent engineering conference of the Institution of Civil Engineers Mr. J. W. Sandeman stated that each chiseler consists of a steel barge carrying shear-legs from which is suspended a steel ram weighing 15 tons. It is about 45 ft. long and 17 to 18 in. in diameter, and its conical point can be renewed. The latter is tempered so as to have a hard center with a soft exterior, which enables a sharp point to be preserved. The ram falls from a height of 8 ft. and an average of 8 or 9 blows is sufficient to penetrate the sandstone rock, which is of variable character, about 3 ft., sufficient to permit it being dredged to a depth of 2½ ft. One machine working day and night and allowing for all stoppages averages about 900 cu yd. of rock broken per week at a cost of 8.8d. per cubic yard. Adding various contingencies and expenses for repairs not included in the figure mentioned, the total cost is about 14.5d. Drilling and blasting the rock cost about 3s. per cubic yard and left it in a somewhat less favorable shape for removal than the rock broken by a chiseling machine. The blasted rock cost 3s. 2.2d. per cubic yard to dredge, while the broken rock left by a Lobnitz machine cost but 2s. 9.1d. to dredge. Summarizing all the figures it was found that the rock breaker made a saving of 2s, 2.6d per cubic yard.

The Topographical Survey of Staten Island.

The preparation of a topographical map of each borough of New York is required by the city charter. The work of preparing such a map of the Borough of Richmond was begun in August, 1902, five men being put in the field at that time. Since then the working force has been steadily increased until there are now about 120 men employed. This Borough, otherwise known as Staten Island, is triangular in general form, its area being 57¼ square miles. It has a maximum width and length of 7 and 14 miles, respectively. The island is very hilly, the highest points being about 400 ft. above sea level. Trees and brush cover a great part of the surface and numerous small streams divide it into a large number of small watersheds. Though some portions are thickly settled, the total population is only about 77,000, or 1,350 per square mile. The unusual conditions existing in the Borough have resulted in the adoption of methods which differ from those ordinarily employed for topographical surveys.

The primary purpose of the topographical survey is to secure data for planning a street system, but the information is also valuable in planning drainage and sewerage systems and most other public improvements. As in the other New York boroughs, the work of primary triangulation is to be done by the United States Coast and Geodetic Survey. As a preliminary measure a reconnaissance of the island was made by the topographical division of the engineer corps of the Borough and 43 stations have been selected and a map prepared showing their intervisibility. The stations include sixteen towers, four lighthouses, twelve public buildings and eleven other buildings, mostly residences. The base line is about 1¾ miles long.



Improved Plane Table.

Portable Tower.

As it was necessary to carry on the survey before points of control could be determined by tringulation, it was important to measure the primary traverses very carefully. It was soon found that the common 50-ft. spring-balance chain used horizontally was not satisfactory, because of the many steep grades and the extreme care necessary to secure accurate results. A system of measurement along the slope was therefore devised which depends on the plumb bob only at the ends of a measured line. A standardized 100-ft. steel tape is used, a 16-lb. pull being applied with a spring balance and the temperature taken as usual. Solid steel tripods, with a spread of about 2½ ft. and a height of about 2 ft., are used, on which to mark successive tape lengths, the elevation of the tripod heads being obtained with a wye level and proper corrections made for inclination and temperature. The tape is suspended between the end marks without intermediate support. Duplicate measurements are made, which must agree within 0.01 ft. × (0.00003 × the distance in feet), or the line is remeasured, which is rarely necessary. With a party of six a line can be run in this manner faster than with the 50-ft. spring-balance chain and the cost is about the same.

The traverses, which are limited to about 10,000 ft. in perimeter, are made as nearly square as practicable and usually close within about 1 in 30,000. The ten or more traverses in a section are adjusted together, commencing with the one having the largest error of closure, so that the maximum error in a section is made as small as possible. The sections are adjusted systematically one to another so that all errors are limited in amount and properly distributed. A single system of co-ordinates is thus obtained. The traverse work is built up in a compact body extending outward from the first adjusted section and is kept in advance of the work of filling in the detailed topography. Marble monuments, 4 in. square and 30 to 40 in. long, are generally used to mark important traverse points.

Level circuits for establishing bench marks are run with wye levels, forward and backward in closed circuits of about the same size as the primary traverses. A number of level circuits are adjusted together in the same manner as the traverse circuits. Bench marks are selected in pairs so that the elevation of any bench mark may be checked by another nearby. The bench leveling is kept in advance of the work of detailed topography and both field work and adjustments are carried forward as the survey proceeds.

In thickly settled districts the work of filling in detailed topography is done with the transit and the contours are traced by the wye level and located with the tape. Outside the thickly built-up districts the location of all instrument stations, monuments, property lines, buildings, and the like, is determined by the transit in advance of the contour work. The contours, which are traced with a wye level, and the other topographical details are then located by the stadia, using either the plane table or transit.

When the survey was begun, the transit and stadia method was generally used, the computations and mapping being done in the office, and the maps then taken into the field and checked. So many of the stadia traverses had to be rerun to close within the assigned limit of error, that it was soon found more economical to tape and level over all instrument stations and depend on the stadia method only for determining points about a station fixed by the transit, tape and wye level. A fault of this method is that too much depends on the judgment of the rodman in selecting points and when errors of reading occur, it is difficult to detect them.

The unsatisfactory results secured by the transit and stadia method and the fact that draftsmen could not be obtained to plot the survey promptly, led to the design of a special plane table shown in an accompanying illustration. This instrument is designed to accommodate the 27 x 40-in. Whatman's "Double Elephant" sheets on which the survey is plotted. Under each of the longer edges of the 22 x 28-in. board is a 2-in. roller with a ratchet with which the sheet can be drawn tight, a special clamp being used to hold the entire edge of the sheet to the rollers. The alidade is equipped with a 20-in. parallel ruler, which makes it unnecessary to give attention to the position of the ruler edge in taking a shot. The under side of the ruler and base plate is covered with white celluloid, which does not soil the paper like a brass surface. The telescope is of the inverting type, as are all those used on the work. It can be turned completely through a vertical circle and the vertical scale is equipped with a floating vernier. The sector-shaped swinging drawer turns on a pivot and can be opened and closed with little risk of disturbing the instrument.

The contours are traced with a wye level and plotted at once on the plane table sheet, the distances being determined by the stadia. Rods 12 to 18 ft. long are used and the telescope is kept in a practically level position. The contours are traced across all streets and streams and all features of any importance are shown. The map is thus available for use as soon as taken off the table. The traced contours represent the topography much more accurately than those drawn by interpolation and are much superior for grade studies. The instrumentman can at any time compare the map and the ground and errors or omissions are almost impossible. While tracing contours is somewhat more expensive than taking isolated elevations by the stadia, when the cost of computations and the inaccuracy of interpolation are considered the balance is largely in favor of the tracing method. The location of contours, on ground of average slope, requires a more accurate determination of the elevation of the selected points than of their horizontal position. The tracing method thus gives increased precision where it is most needed, while the reverse may be said of the transit and stadia method.

In open country, where the maximum slopes do not in general exceed 5 per cent., a party consisting of a plane table man, levelman and two rodmen can cover about 8 acres per day. When the country is rougher or wooded the area covered is less, about 5 acres being the minimum. In wooded country 2,600 ft. of contour line per day is considered good progress, and in open country a mile per day is about the average.

The field parties work every clear day during the year. During the winter they are kept in the wooded districts as much as possible and in the summer when the foliage is heavy they work in the open. To facilitate the work where brush is thick, a portable tower has been devised on which both plane table and level may be set up. With the tower a very long rod is used and the contours can thus be traced without clearing off the brush. The platform is 8 ft. above the ground and is 9x6 ft. It is made in two sections, each 3x9 ft., so that it may be more readily carried about. The posts are 4x4 in., the braces 2x1 in., the platform stringers 2x4 in., and the floor 1-in. matched flooring. Bolts with thumb nuts are used to fasten the various parts together.

In connection with the transit and stadia work two portable field offices have been used in which the plotting can be comfortably done in all weathers, close to the field party. These offices, which were described and illustrated in The Engineering Record of Dec. 19, 1903, are sub-

stantially built of wood, with glass windows and awnings and are mounted on a spring wagon gear. The climate of Staten Island, while it is seldom too severe for field work, is so changeable that such shelters are very valuable.

The survey is plotted 27x40-in. sheets to a scale of 50 ft. to the inch. The contours are shown at intervals of 2 ft. below El. 50 and at 5-ft. intervals above. All important topographical features are shown and all transit lines and measurements to locate buildings, monuments, and property lines are given. This scale, while somewhat larger than that usually employed on such work, has proved very satisfactory for mapping thickly built-up districts. The plotting can be done with less strain on the eyes than with a smaller scale, and any errors due to inaccuracy or shrinkage of paper are diminished in magnitude. The cost of the survey depends mainly on the accuracy and amount of detail obtained, and when these remain the same the cost is not increased materially by the use of the larger scale. The least accurate part of the survey is the location of contours and topographical details by stadia measurements. With the telescopes used, which were specially designed for stadia determinations, these measurements are correct to within about 1 ft. in 400, and as the longest sights are not over 600 ft. the maximum error of location of a contour does not exceed 1½ ft. If the map is to represent the contours as accurately as the survey warrants, a scale large enough to show errors of this magnitude is required. These maps have proved very satisfactory in preparing detailed plans for streets, drains and sewers.

Though the field sheets are well adapted for the study of details they are on too large a scale for many purposes, particularly for the study of a general street system involving the consideration of a large area at one time. It was decided that for such purposes a scale of 150 ft. to an inch would be most satisfactory, since a large area could thus be shown on a sheet of practicable size, which is necessary in comprehensive planning, and at the same time the topography could be represented with proper accuracy. At first the usual method of reduction with the precision pantagraph was used, but this proved so inaccurate and expensive, particularly when much detail was required, that resort was had to photography. Photographic prints of topographical sheets can be copied by means of a stylus and carbon paper if only one copy is needed, but when a number of copies of each large-scale map are required they can be obtained best by photolithography, by which all the details of the original field sheets are reproduced accurately and economically.

The lithographic sheets are made the same size as the field sheets and nine of the latter are required to make one of the former. The field sheets have to be carefully matched in order that the junction of the separate sheets will not be apparent, and lines and letters have to be made of proper strength. Negatives, 8⅓x12⅔ in., are first taken of each field sheet. Prints from these negatives are then made on photolithographic transfer paper and these prints are then carefully trimmed, mounted, matched and pasted together upon a large sheet of paper. This built-up transfer is then put down in the usual manner on the lithographic stone, from which as many copies are printed as are desired. The maps of the Borough of Richmond have been printed in editions of 400. On account of the number of processes involved and wetting and stretching of the paper, care is required to preserve the accuracy of the scale, but the error need not exceed 1 in 500. These lithographs fully meet the requirements for maps on which to project street layouts and similar studies, as they contain all the data on the field sheets.

About 764 27x40-in. topographical sheets will be required to map the entire borough. Of these, 245, covering much of the most thickly settled portions, are either completed or in progress. Since the survey was begun the work has been done under the direction of Mr. George W. Tuttle, engineer in charge, and Mr. Louis L. Tribus, consulting engineer and Commissioner of Public Works. The improved plane table was designed by Mr. Edward M. Law, assistant engineer. Nine of these instruments are now in use, all of which were supplied by the Keuffel & Esser Co., New York.

MAINTENANCE-OF-WAY WORK has a direct influence on the cost of repairs to electric railway equipment, according to Mr. W. R. W. Griffin, of the Rochester & Eastern Rapid Ry. In 1905, the second year of operation of that road, $11.20 per thousand car-miles was spent for maintenance of way, $14.52 for maintenance of cars and $5.20 for maintenance of electrical equipment. In 1906, $15 per thousand car-miles was spent on maintenance of way, $10.77 for maintenance of cars and $5.42 for maintenance of electrical equipment. This saving of $1.01 per thousand car-miles in the total maintenance charge (after eliminating expenses for painting and damaged car bodies) is attributed to the better condition of the track during 1906.

The White-Souther Endurance-Test Specimen.

A paper read before the convention of the American Society for Testing Materials by Henry Souther.

For certain classes of work, I believe that an endurance test is the best measure of the value of any given material for any given purpose.

Back in the days when the bicycle was most popular this fact was forced upon me, and I rigged up in my laboratory many forms of endurance test. I not only used test specimens as such, but I tested by endurance methods many structures, as, for example, assembled wheels, assembled bicycle frames and forks, and bicycle cranks. All of these tests answered the problems for which they were contrived with the greatest finality. I did not hesitate to make recommendations based upon the results obtained; they were conclusive.

The one possible exception to this statement refers to the endurance-testing machine for test specimens. I took for my model the kind of machine used at the Watertown Arsenal, with which I was familiar. Much experience has been gained with that machine, and a great many results were available in the government records; so I hoped it would answer every purpose. The results obtained with it were not as consistent as they should have been, although, as I have already stated, much good work was done and definite results obtained, upon which to base recommendations.

Mechanical difficulties developed with it, due to its construction. The construction consisted of what amounts to a lathe bed with head and tail stocks 33 in. apart, and provided with universal joints, so as to permit the bending of the specimen, the load being applied at the middle supported upon some form of bearing, either roller or plain journal.

The specimen was objectionable, it being very difficult and expensive to make so long a one and get it exactly right. Owing to its length, it vibrated to a greater or less degree; the vibration, differing in different tests, put upon the specimen different, and immeasurable stresses Also, at the point of application of the load, more or less heat developed and to a greater or less extent must have influenced the test, because the heating came at the point of greatest bending moment. High speeds with this form of specimen were out of the question, because of the heating, and something like five or six hundred revolutions per minute seemed to be the upper limit. All this criticism is not with the idea of detracting from the value of the work

done at Watertown, because I believe it has been very valuable, but simply to show my starting point in the evolution of an endurance machine.

With all these facts in mind, Mr. Maunsel White and myself devised a test specimen which seems to do away with all the objections mentioned without introducing others of serious moment.

This specimen, measuring about 13 in. over all, is a comparatively cheap one to prepare; also, as it is large at its center, there is little trouble in the lathe due to bending. It is, therefore, quite easy to make accurate to size and straight. It is a double-ended specimen, which makes it possible to obtain definite results, even though there may be a flaw or other defect in one end. This double-ended specimen also gives check results in case both ends are sound. I feel that the higher of the two results is the proper one to accept, inasmuch as it is the highest measure of the efficiency of the material under test, and no material can endure beyond its capacity.

The specimen is supported at the center portion on large ball bearings, and may be rotated at very high speeds. No heat is produced, at least no great amount of heat, and, even if it were, the center portion being larger than the ends, it would matter little. There is no wear of any kind on the specimen, the loads being applied at the ends, not at the point of greatest bending moment. The critical points of the specimen are, of course, the fillets, coming at the point of greatest bending moment. These must be accurate to shape and perfectly machined; slight flaws or defects at this point are serious.

I append herewith a table of characteristic results obtained without going into exact details. This series of tests was undertaken to get a ground work for suitable comparison. For example, the first specimen may be classed as high grade machine steel. It will be noted that the elastic limit was about 60,000 lb. per square inch, as shown by the tensile test. My idea was to break this quickly, and I therefore loaded it with a fiber stress of 53,600 lb. per square inch and quick results were obtained, as expected. I then went forward with high grade material, one after another, variously treated, the heating being carefully done in an electric furnace in connection with a pyrometer. There are some exceptions to this, in that some of the specimens were tested as received.

The results obtained show the tremendous possibility in the use and adoption of high grade materials. The tests also show that in order that the endurance test may not be too prolonged and therefore not practicable, it must be conducted in such a way as to give quicker results than some of those given. For example, it is practically out of the question for a manufacturer to wait for a machine to run one hundred million revolutions, or probably ten weeks, running night and day at 1,300 r. p. m. Consequently, I have adopted lately an increasing fiber stress; for example, starting the test at 50,000 lb. fiber stress, and, if the specimen endures for ten million revolutions, increase it to 60,000 lb.; and after the next ten million increase it to 70,000 lb., and so on until rupture occurs. It is still possible to compare the behavior of various steels and to show the results graphically. The test is, consequently, more useful because more valuable.

A higher number of revolutions than adopted for our tests may be used with this machine, if considered desirable, but I feel that 1,300 r. p. m., more or less, is a practical number. For example, the crank shaft of an automobile rotates at that speed, and there are many rotating parts in the manufacturing industries that are near that speed. Were a very much higher number to be adopted certain unknown elements might be introduced into the test that would render the results questionable, as being a test carried on under abnormal conditions.

For any manufacturer whose product goes into machinery subjected to dynamic loads, such a test ought to be extremely valuable. Further, the heat treatment of steel and the great benefits derived from it are rapidly being appreciated and increasingly used by all manufacturers. Such a test is a measure of the benefit due to heat treatment. Moreover, I have found that certain clients in talking about the increased strength of new alloys and heat treating in general, have said—Oh! yes; of course there is a great increase in strength and apparent toughness and good qualities in general, but how about the capacity of the metals in such a condition to resist shock?" I believe that this test does show the capacity of metals to resist shock, whether of impact nature or alternate stress.

In the table of results given will be found a number of aluminum and bronze specimens which are very instructive.

*Estimated from other specimens.

We are just beginning to get at the results of tests on vanadium steels. The few we have that are trustworthy show a considerable benefit under the endurance test, but I do not like to put them on record, for there are certain features of the treatment unknown to me. We also had the misfortune to have our pyrometer go wrong in connection with the treatment of several specimens, and the results are, therefore, worthless. To generalize, however, it is my impression that vanadium will add to the endurance of any given steel if present in quantities aproximating 0.25 per cent. The increased endurance seems to be at least four to one, but in view of the above lack of knowledge on my part as to all the conditions, I do not wish to commit myself fully.

A Pile Pointing Machine.

A pile pointing machine has recently been built in England for the use of Messrs. E. Robinson & Sons, contractors for the Rotterdam harbor works. Its purpose is to taper the end of fir piles 20 in. square, leaving them 5 in. in diameter at the point and extending the taper back about 4 ft. Illustrations of the machine in "Engineering" show that the pile is clamped rigidly in a horizontal position, and a conical shaving head, with a knife on its inner surface like the old-fashioned pencil-pointing device, is then pushed against the end of the pile. The cone containing the knife is driven by a belt and the whole cutting head is gradually forced forward by a screw in the same way that the tool-holder of a lathe is traversed. The machine is stated to point a pile in about 15 min., leaving it in a condition ready to receive the iron shoe used at these works.

THE FIRST RAILROAD IN MOROCCO, Africa, was opened some months ago. It was built by a German company to haul stone from a quarry to tide-water and is only about 1¼ miles long.

Book Notes.

The Bureau of the Census, of the Department of Commerce and Labor, has issued a bulletin containing some instructive figures of the condition of the electrical industry in 1905. The author, Mr. T. Commerford Martin, has succeeded in investing the dry statistical data of an ordinary census report with deep interest by his explanation of the changes in the electrical art which are the underlying cause of the numerical developments in the classes of apparatus for which figures are given. The report is, in fact, a well-written and authoritative summary of progress in electrical engineering during the five years ending Dec. 31, 1904.

It is pretty well recognized now that in preparing a textbook on certain engineering subjects for class room use it is advisable to abandon some of the conditions which would govern the writing of a treatise for specialists. The requirements of teaching and the knowledge possessed by students when they take up a subject must be considered in determining the sequence of the topics in a school book, and the author's ability as an instructor is often revealed by the departures he makes in a text-book from the order of presentation of topics which would be followed in a treatise. These reflections are suggested by the excellent "Steam-Engine and other Heat Motors" by Prof. W. H. P. Creighton, which is a model text-book. It is highly gratifying to observe that the author has had the courage to compress the subject of thermodynamics into the space it really should occupy in an engineering text-book, and has taken into account the desirability of assuming that, by the time the student is able to take up the steam engine, he has already acquired in other classes and by association with upper classmen enough knowledge to warrant introducing the vital subject of indicator cards before the principles of thermodynamics are discussed. This is one of the many indications in the book of the author's knowledge of the needs of students as well as his thorough acquaintance with his subject. The latter is shown on every page in the concise yet clear manner in which the matter is presented and in the excellent choice of numerical examples, selected so as to make the student grasp all aspects of a topic instead of very limited portions of it, like most exercises in text-books. It is also shown in the presentation of a subject in all its complexity at the outset, and the deduction of the more simple cases from the general case, a procedure that is far better from a teaching point of view than the reverse one. In short, the book is one calculated to make the student think logically, to interest him in his work, and to respect what knowledge he possesses at the outset of his study. The contents of the volume are well indicated by the chapter headings: Review of elementary principles and general view of steam engine plant; Steam engine indicator and its calibration; Curves and the work of expansion; Zeuner and Bilgram valve diagrams and design of plain slide valves; Measuring the effects of heat; Measuring the effects of heat on water and steam; Measurements of heat losses; Entropy; Condensers and air pumps; Small auxiliaries; Multiple-expansion engines; Revolution control; Steam variation control; Steam engine tests; Superheated steam and steam turbines; Gas engines and gas producers; Boiling in a vacuum; Refrigeration; Appendix of useful tables and physical data. These subjects are presented with a nice appreciation of their relative importance and of the distinction between what is appropriate for a class in engineering and one in physics, and the volume as a whole is a particularly important contribution to our list of engineering text-books. (New York, John Wiley & Sons, $5.00).

Letters to the Editor.

EJECTOR PRACTICE.

SIR:—Regarding the inquiry in your issue of June 15 concerning the use of ejectors for delivering water against pressure, I think it is worth while to notice that in this year's "La Technique Sanitaire" there was a description of a successful arrangement of this kind made by Koerting Bros., of Hanover, Germany. The purpose of this arrangement was to force the water from a low-service reservoir into a pipe system when the latter is operating under the high fire pressure furnished directly by the pumps. The accompanying diagrams indicate the position of the apparatus. In the first diagram, for everyday service, the low pressure is directly from the reservoir, as shown. In the second diagram, showing the conditions during fire service, the high pressure from the fire pumps passes directly to the mains, the low-pressure reservoir being cut off by the valve, as indicated. Water from this reservoir is taken into the pipe line, however, through the ejector, which is thus in use under the conditions mentioned by your correspondent.

Yours truly, BORIS N. SIMIN.
Moscow, Russia.

ANCHORING BRIDGE SPANS.

SIR: May I put a few words in your columns about the anchoring of bridges against a vertical lift. Nearly all standard specifications provide that "all spans shall be anchored against moving sideways or lifting vertically" but how many of our modern bridges are securely held against a vertical pull is problematical. I do not refer to the design but to the setting of the anchor bolts at the time of erection.

Is the hole in the masonry drilled large enough to allow the cement fronting to find its way to the bottom to surround the anchor bolt thoroughly and efficiently and provide for the performance of its full duty? Of what use to drill a hole and stick a bolt 16 in. into the masonry and so small the fronting can penetrate but 4 or 5 in. and even then perhaps does not surround the bolt? Such a bolt may be good for moving sideways, but what about the emergency when the uplift comes?

In the ordinary proceedings for erecting a bridge the anchor bolts are put in last or any old time on the fixed end and the expansion end must be left till the span is swung. On both ends, therefore, the holes are drilled through the bed plate castings and their size is governed by the holes in these castings. When these holes are barely large enough to admit the bolts, which is often the case, we get the same condition down into the masonry.

If the bolts cannot be set before the span is erected, the writer's experience for best results has been as follows: Drill the hole as large as the casting will permit and at least an inch deeper than the bottom of the fixed bolt, unless it be with a split wedge end. Mix the fronting of neat cement or cement and sand to a good flowing consistency and fill the empty hole about one half full. Now let or drive in the bolt to its proper depth and if sufficient grouting has been poured into the hole it will overflow at the top.

The hole is now entirely filled, the anchor bolt is entirely surrounded and, when set, the writer believes, a better and more efficient anchorage can be secured than by the usual method of pouring in the grouting after the bolt is driven.

The co-operation of the masonry can then in emergency be depended upon and the bolt can perform the duty for which it was designed.

Very truly yours, H. N. PECK.
TUXPAN, JALISCO, MEX.

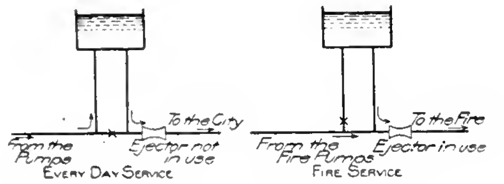
CHROMIC ACID AS A RUST INHIBITOR.

SIR:—I notice in your article on "New views of the cause of the corrision of iron" in yours of July 6th that you state as follows:

"The fact that chromic acid and its salts act as inhibitors of rusting has been known for some time, but no explanation of the curious phenomenon has ever been offered heretofore nor has its application to practice ever been suggested. Dr. Cushman has made a special study of this problem, and although it remains to be seen what practical benefits may develop out of these new ideas, it is most gratifying to be able to state that if any patents are granted covering rust inhibitors they will be taken out in accordance with the practice of the Department of Agriculture, so that they will be free for all American citizens."

From this it is evident that you have not seen the report made by the Committee of Tests of the Master Car and Locomotive Painters' Association, submitted by them at their last annual meeting in 1906 in which they state as follows:

"Steel Plate Exhibit No. 269 represents a small plate of steel exposed to the weather for twenty-



A French Ejector Application.

eight months, after having been treated with an exploited chromic acid rust-neutralizing process, the powerful black staining chromic acid preparation being knife applied over the entire surface, half of which was then coated with an especially furnished graphite and oil mixed paint.

"The Committee suggests a critical examination of this exhibit, which, it judges, shows that all up-to-date attempts at chemically oxidizing a steel surface against future corrosion have been attended with failure, such as is indicated by this badly under corroded plate so treated, but you will also please note that the single coat of honest graphite paint is still a protective coating, notwithstanding the hard task of holding its ground against this most powerful acid, said to be soluble only in water, which if true, would fully account for its apparent failure as a corrosive preventative."

Judging from the above and from our own researches, I do not believe that chromic acid can be used with any success as a protection against corrosion in metal surfaces.

Yours truly, FRANK P. CHEESMAN.

CABLE AND HOLLOW ROD DRILLS FOR BLAST HOLES.

SIR:—With reference to a letter from Mr. W. T. Kershner, of Hell Gate, Montana, published in your issue of June 1, 1907 (page 665), describing "a competitive test" of a Keystone cable drill and a Cyclone hollow-rod drill on a blast hole proposition of the Winston Bros. Co. at Hell Gate, we have the following correction to make:

The statement that "the drills were operated by the makers" is at least partly in error, as the Keystone Driller Co. had no representative or employe at the scene of operations either before or during the "test." Mr. R. H. Horrell, who operated the cable drill, is a competent driller but has been in no way connected with the Keystone Driller Co. Mr. Horrell was favorably impressed however, with the work of the cable drill, and we have the following report from him under date of May 16, on this subject:

"On April 8 I arrived at Missoula, Mont., being to report to Winston Bros. Co., to set up and operate the machines that were shipped there along in January, which were a long time on the road, on account of the heavy traffic west of St. Paul.

"Upon arriving there, I found that they had also ordered a Cyclone machine, which arrived a couple of days afterward, being put in competition with the Keystone machine. Only one machine was set up and operated for the time being. We commenced practically at the same time with both machines, the Cyclone people having a practical driller on the ground to operate the machine in drilling blast holes for the cut, which is to be 150 ft. wide and 125 ft. in depth.

"The material is taken out 20 ft. at a time, and hence the holes do not run over about 20 ft. in depth, the rock in most cases being exceedingly hard.

"During the time of being there we operated one machine, and in nineteen days we drilled 1,200 ft., which included the moves from place to place, while the Cyclone in the same length of time drilled 800 ft. In part of the time at this work, the work was in cleaning out holes that were sprung, and on this class of work we were set side by side with the Cyclone machine, starting at the same time. The Keystone succeeded in cleaning out fourteen holes to the Cyclone's six, in one day. This will give you an idea of the work being done by the two machines. The Cyclone people had an A No. 1 practical man on their outfit and it was pushed to the limit.

"In the amount of drilling that was done their rope was entirely worn off in drilling 800 ft., while in the amount of drilling that was done with the Keystone machine, there was no change made in the rope and the part that was used is still good for a number of feet yet. The superintendent and also Winston Bros. seem very well pleased and satisfied that the Keystone is far ahead of the Cyclone machine."

Yours truly, R. H. HORRELL.

Parts of Mr. Kershner's letter, such as this, "the best day's work for each drill was 73 ft. in 10 hours for the rod machine and 71 ft. in 12 hours for the cable machine" cannot but be misleading. Referring to a letter from Mr. W. O. Winston, of Winston Bros., to Mr. Horrell, on the subject of this test, the fact is found to be that the Keystone cable drill averaged 51 ft. per day, whereas the Cyclone rod machine averaged but 46½ ft. per day. Furthermore, the 5-in. cable drill hole was made at a cost of 23 cents per foot, while the 3-in. hole cost 23¼ cents per foot.

We append Mr. Winston's letter, which may be regarded as an unbiased report of the "test."

"Your letter to Mr. Young at Hell Gate has been referred to us for reply.

"As you are aware, we were not personally on the ground, and therefore do not feel that we can accurately gauge the merits of the two machines, Keystone and Cyclone. Our records show that the holes drilled by the Cyclone cost 23¼ cents per foot, and those drilled by the Keystone cost 23 cents per foot. The Cyclone averaged 46½ ft. per day, and the Keystone 51 ft. per day. The holes drilled by the Keystone were 5 in. in diameter and those by the Cyclone 3 in. in diameter.

"We are very well satisfied with both machines, and can say that we consider the Keystone certainly as good a machine for contractor's use as the Cyclone. In some cases the Cyclone, being light, might have some advantage. In other cases, the Keystone will be the better machine to have."

Yours very truly, KEYSTONE DRILLER CO.
New York, July 8.

THE ENGINEERING RECOR

PUBLISHED WEEKLY BY THE

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

114 LIBERTY STREET, NEW YORK.

BRANCH OFFICES:

CHICAGO: Old Colony Building.

PHILADELPHIA: Real Estate Trust Building.

CLEVELAND: Schofield Building.

SAN FRANCISCO: Atlas Building.

LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico	$3.00 a year
Canada	$4.50 a year
Foreign subscription	$6.00 a year

25 shillings 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGES OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1905, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,250 copies are printed. Total circulation for 1907 to date 434,750 copies, an average of 14,492 copies per week.

TABLE OF LEADING ARTICLES.

A New Code of Reinforced Concrete Rules.

Elsewhere in this issue will be found the full report of the joint committee of British architectural and building associations and government bureaus, which has been working for many months to adopt a code of rules for the design and construction of reinforced concrete works. This report is both interesting and important as emanating, primarily, from an institution of architects since it indicates that the Royal Institute of British Architects, the prime mover in the organization of the committee, is of opinion that reinforced concrete is to be recognized as an accepted material for general structural purposes. The report embodies a fairly complete set of general rules to govern the use of reinforced concrete without limitation in regard to the classes of buildings to which it may be applied. In other words, if there is any such limitation in the mind of this body of architects and builders, the limitation is neither set forth nor even mentioned in the report. It is fair to assume, therefore, that the committee intended no such limitation, especially in view of the fact that some of the regulations recommended for the design of reinforced columns apply to buildings of any number of stories in height. This is of interest, for the reason that some American architects are still averse to more than a limited application of reinforced concrete to building construction.

The report sets forth certain provisions which govern the design and construction of this class of work in substantial accord with similar provisions in force in the larger cities of this country, although some features are perhaps less extended and vary to some extent from corresponding provisions of American practice. The opening paragraph, however, is one which every engineer or other interested agent will indorse without qualification, viz: That the use of reinforced concrete has now become so general "in building and engineering construction, that a general agreement on the essential requirements of good work is desirable." If there is any one feature of reinforced concrete work imperatively needed at present in this country it is a body of uniform regulations designed to secure an excellent quality of well-built structures and so avoid the accidents which have been due to ignorance and indifference to suitable structural procedures. Reinforced concrete work needs, first, competent engineering design, and then intelligence and effective supervision to secure good materials and well considered structural processes. The accidents in reinforced concrete work which have taken place during the past two or three years in the United States and have thrown doubt upon the attainable excellence of this class of work are without any other cause than ignorance, incompetence or some sinister reason. Reinforced concrete is precisely like any other excellent building material in that it must be made and put in place under suitable specifications supplemented by competent design and supervision. One of the most commendable characteristics of the report of the committee is the recognition of these simple fundamental principles.

The proposals and specifications as to materials, as well as the practical instructions for actual fabrication of work, are all, in the main, well considered and adapted to secure the ends desired, although a few minor matters will, it is probable, be modified, by more extended experience. In this category is the provision that "work should not be carried on when the temperature is below 34 degrees Fahr." Experience during the unusually severe weather of last winter in New York city in constructing some of the heaviest and best reinforced concrete work ever built demonstrated conclusively that simple and effective measures for the protection of reinforced concrete during fabrication, including the use of enclosing canvas and salamanders, make it perfectly practicable to carry on this class of construction with the best results, with little or no interruption during the severest weather of a New York winter. It is also probable that further directions and provisions for the centers, or forms, and for their use will be set forth after more extended experience; to secure reduced expense, ease of removal and re erection and general efficiency in this part of the work.

That division of the report relating to methods of calculation is especially worthy of commendation, although here also there seems to be some lack of recognition of what has been done in the United States in reinforced concrete construction. Within the past year the ratio of the coefficients of elasticity of steel and concrete has often been taken as fifteen rather than twelve, which is frequently employed here. The usual neglect of the tensile resistance of concrete is recommended and the straight-line law of the variation of intensity of stress in the concrete beam is adopted rather than any law, such as the parabolic represented by a curve. While the curved relation is used by a good many engineers, the general belief seems to be that the straight-line relation is as good for all practical purposes as the other, and is more easy to use. It is an open question, however, which can be definitely settled only when more experimental results are available than we now have, and even then the choice will probably be governed largely by the temperament of the individual engineer, as is the case to-day with the Gordon and straight-line column formulas.

The methods of calculation, relating to columns, appear to be set forth without knowledge of the most advanced reinforced concrete column design. The Considère type of column alone is considered, with its extremely light longitudinal rods which are considered by some engineers to be actual elements of weakness, although this weakness is supposed to be cured, by the wire or other banding. This column can never be satisfactory for use in the highest buildings. The type of column used in the McGraw building in New York, with its self-supporting steel column enveloping the concrete, is admirably adapted to any height of building whatever, and to the strongest and best possible connections for floor beams and girders. Such a column fully justifies 750 pounds per square inch on the concrete instead of 500 pounds stated in the report.

In spite of a few secondary considerations of this character, the report as a whole is well calculated to secure satisfactory results in this field of construction, wherever its recommendations are efficiently enforced.

State Ownership of Water Powers.

The Fuller bill recently signed by Gov. Hughes is likely to have an important bearing on the great unused water-powers of the Adirondack regions, for under this measure the State Water Supply Commission is empowered to collect full information regarding the water powers of the State and to devise plans for their development under State ownership and control.

The Adirondack region has many possibilities in the way of hydraulic development, and already several projects have been put on foot for the construction of power transmission plants in that region. Were these simply projects relating merely to the utilization of the streams in the ordinary way, probably they would have attracted little attention and would not have aroused any sentiment in favor of State control. In point of fact, the greatest possibilities in the Adirondacks are believed to lie in large developments with elaborate storage systems requiring very extensive hydraulic works and, possibly the diversion of considerable streams. Under these circumstances, the public may be deeply concerned in the projects and a safeguarding of the public interest becomes doubly necessary. It is certainly necessary to develop the hydraulic

resources of the State to the fullest and so develop them that the best result possible shall be produced. To this end the proposed critical examination of the resources of the Adirondacks is a necessary preliminary. With the data once fully in hand it will be possible to carry out the utilization of the powers on a consistent plan and to the fullest extent.

Just how far actual development by the State will prove practicable or desirable it is impossible now to tell. It is possible that the State could successfully carry out the hydraulic work and lease the developed powers to transmission companies which would undertake the work of distribution, or the powers might be leased in their crude state with a provision by which the lessee should carry out the development in accordance with the lines laid out by the State. It is unlikely that the State would wish to undertake the full development and distribution, or that it would be desirable for it so to do. That these vast water powers are steadily assuming greater and greater importance is true, and the increasing cost of fuel will make them even more necessary in the future, so it is highly desirable that those which now remain unutilized should be developed in a systematic way. The aggregate result under a state power that can obtain from any system of water-courses depends in a large measure upon the skill with which the hydraulic work is planned, and if planned on a large scale after thorough investigation the final result will be vastly more satisfactory than if the development is carried on piece-meal by independent organizations.

The Engineering Record therefore believes that the fundamental principle of the Fuller bill is a thoroughly good one, and while it would dislike to see the State embark on public enterprises of an intricate character, it is certain that the State and its people will profit from a careful and intelligent exploitation of these water privileges. If it proceeds somewhat slowly, so much the better, for each year increases the resources of power transmission and renders development on a large scale and with a broad view of the future, the easier.

The Subjugation of the Ludlow Reservoir.

For many years the water of the Ludlow reservoir at Springfield, Mass., has had a most notorious reputation. It has been the subject of many investigations and its evil character has been laid bare in all American books on water supply which make any claim to thoroughness. The reservoir has stood forth from others as an unequaled cultivator of odors that rival the aroma of a fertilizer plant on a hot, moist day. The Water Board of Springfield has never enjoyed the distinction which ownership of this famous basin thrust upon them, and so, from time to time, they have asked various engineers and biologists how to make the reservoir behave as it was intended to. The Board has been accumulating this advice for many years, and has received all kinds of suggestions, ranking from physicking the water with germicides to treatment by repeated filtration. In the counsel of many lies wisdom, we are told, but the counsel in this case was too varied for the Board to sift, and so it eventually placed the burden on Messrs. Hazen and Whipple, the New York consulting engineering firm, which was engaged in preparing plans for an additional water supply for the city. A temporary additional supply was greatly needed pending the completion of the new works, which would not occur for several years, and the engineers naturally turned at once to the Ludlow supply, which is objectionable only on account of its offensive character at certain seasons. They have fortunately been able to construct works which have rendered this water suitable for city uses, and their success is a real engineering achievement.

The Ludlow reservoir was made by building two dams across valleys, thereby flooding a peat swamp with water to an average depth of perhaps 12 ft. A considerable proportion of the watershed is swampy. Ever since it was put in service thirty years ago the water has suffered during the summer from growths of micro-organisms. Anabæna has been the most abundant and best known of these, but probably many others have contributed to the tastes and odors, which have made this reservoir the most notorious in this respect of any reservoir in the United States. Possibly some reservoirs are occasionally more malodorous, but they are by no means so well known as this, which has generally been considered as the worst chronic offender in the country. The experiments that had been made on the purification of this water were all based on the use of continuous filtration, with aeration at different stages of the process. Two such filtrations in the experiments had sufficed entirely to remove the tastes and odors. One filtration with suitable aeration had usually sufficed to do this, but had proved wholly incapable of treating the water when the growths of organisms were at their height.

The idea suggested itself that, as the organic matter in the water was in a readily decomposable state and chemically was much like the organic matter in sewage, the system of purification which had given the best results in purifying sewage in Massachusetts might also be applicable to this water. The temporary plant designed was, therefore, in all its essential features, a sewage purification plant, in other words, intermittent filtration through coarse sand was used. By this method of filtration the water is aerated, not only before and after filtration, but during the whole process. The whole filtering material is drained once each day and its pores become filled with air, and this air, which is only partially displaced when the water is applied to the sand, serves to effect an additional aeration in the sand itself while the filtration is taking place.

It was expected when the plant was built that the quality of the water would be materially improved by it. It was not expected that complete removal of tastes and odors would be secured when the growths in the reservoir were strongest. At the same time it was recognized that the results to be obtained were more or less uncertain, for the process had never been adequately tested in treating a water of this character. The plant was put in service July 6, 1906, and served to remove the tastes and odors fully during that summer, although the growths in the raw water, for some reason, were not as great during this period as they had frequently been in previous years. The season of 1907 opened with a growth of uroglena as strong as had been previously observed in the reservoir, and this was immediately followed by a strong growth of anabæna, the most troublesome of all the organisms that have grown in this reservoir. Up to the present time the tastes and odors have been removed in an entirely satisfactory manner. The accomplishment of this result is probably due fully as much to the care and intelligence with which the filter has been operated by Mr. E. E. Lochridge, engineer of the Water Board, as to its design. Certainly the remarkable results that have been obtained could not have been secured with anything but the most skillful supervision. In connection with the removal of the tastes and odors there is a striking reduction of color which is most interesting. This reduction in color seems to be due to the coagulating effect of the iron, which is present in the ferrous state in the reservoir water at the times of growths and is precipitated by the aeration and filtration of the water, thereby accomplishing results which certainly could not be reached were it not for the iron.

The cost of the filter complete was about $50,000. It should be stated, however, that many parts were built in a temporary way and without reserve, and that it would not be possible to build a permanent plant of this type, with duplicate parts, for this sum. The quantity of water treated is 10,000,000 or 12,000,000 gal. per day. The Ludlow reservoir is able to supply this amount in a wet year or an average year, but would be quite incapable of maintaining the present rate of draft in a dry year; and for this reason the additional works now authorized would be necessary, even though the treatment of the Ludlow reservoir should prove in all respects to be feasible.

This experience teaches an important lesson, for it shows very clearly the practical value of the knowledge of the characteristics of water and the methods of purifying it which have been acquired by those who have been makilng a specialty of the subject. The progress of late has been extraordinary, and uncertainty concerning the nature and cause of many phenomena has given way to reasonably complete knowledge. But it is important to bear in mind that this increasing knowledge brings complications with it and is difficult to apply. The Water Board that attempts to determine how to improve the quality of a supply from what information it can gather from books will be very sorry that it assumed the role of a specialist, while the superintendent who carries out works for water purification without securing the advice of competent experts is not likely to obtain the best possible results at the minimum of expense. The purification of water and sewage are not simple problems, but are complicated by many conditions of different degrees of importance, which only specialists can appraise accurately.

Notes and Comments.

The Architectoral Development of Suburban Property will be investigated by a committee of the Royal Institute of British Architects consisting of Mr. T. E. Collcutt, president, Sir Aston Webb and Messrs. John Belcher, Paul Waterhouse, John W. Simpson, W. E. Riley, Leonard Stokes, Reginald Bromfield, and Prof. Beresford Pike. The purpose of the committee is to suggest lines on which a scheme can be prepared for the expansion of suburbs of large towns on a rational plan. This is a topic of much importance in the neighborhood of many large American cities, where the rate of growth is even faster than it is in the vicinity of European cities. Many suburbs suffer from a lack of proper planning when they were first started or before they began to develop rapidly. It is often considered that the control of the growth of a suburb is impracticable, but experience indicates that where attention is paid to the prospective development of transportation facilities and to the fitness of a locality for the homes of people of different classes, it is possible to guide the development quite closely. Just what lines the committee of the Royal Institute will follow is now unknown, but it goes without saying that all suggestions from a body of such eminent architects will prove valuable, although they may be impracticable for many suburbs. Too many committees of a somewhat similar nature have seen fit to recommend schemes of development which cannot be adopted on account of their costly nature or lack of fitness for the community for which they were intended.

AN ANOMALOUS ROAD SITUATION exists between Newark and Jersey City, respectively, the sixteenth and seventeenth cities of the United States in population, which are about 7 miles apart. Newark is noted for the great variety of its manufactures and has a heavy trade with most places in the vicinity. Jersey City, on the Hudson River water front, is also a manufacturing place, and the relations between the two cities would naturally be quite close. They are separated, however, by a stretch of marsh, and although several railways have been built across it, there are but two roads connecting the two cities, and both are in such a condition that travel over them is an unpleasant task. One of these roads is a plank affair, which may have been in fair condition years ago but now has its planks so loose that they are positively dangerous. A line of trolley cars runs along this road and their presence does not by any means improve the character of the highway. The other road is an alleged macadam affair, but its condition is such that nobody uses it who can avoid doing so. The importance of the lack of good roads in this district is so great that before long their improvement will undoubtedly be undertaken. At the present time the meadow land is regarded as the future site of many large industrial establishments, and a number of them have already been erected on its borders, notably the large plant of the International Pump Co. Many people are interested in developing this territory, in a general way, but it seems to be overlooked by most of them that until roads are constructed across it which are fit for use by both light and heavy teams, it will hardly be practical to get many industries to settle in the vicinity. But with good roads connecting Newark and Jersey City, and with water front facilities such as can be readily furnished, it does not seem improbable that the dreams of a great industrial center on the Jersey meadows will be at least partially fulfilled.

THE PHILADELPHIA FILTRATION CONTRACTS held by the McNichol firm have probably attracted more attention than any contracts for public work in this country for some time, owing to the attempt of the authorities of Philadelphia to have them annulled on the ground of fraud. A few years ago all sorts of assertions were made concerning the character of the work and the favoritism shown to this firm. When work was stopped a large sum was due the contractors as deferred payments, and after heated controversy and an unsuccessful attempt to show that a former chief of the bureau of filtration was negligent in the discharge of his duties, or worse, the whole matter was finally left to an arbitrator. On July 22 the latter decided that the city was indebted to the firm for more than $2,000,000 and the sum awarded was immediately paid over by the city to the contractors. The arbitrator also found that while one of the members of the firm was a member of the city councils he received about $51,000 as his part of the profit on the contracts, and this sum the arbitrator has directed him to return to the city. It is fortunate that the matter has at last been settled, for the controversy has resulted in great delay in the completion of much needed works for the purification and extension of the Philadelphia water supply. During the progress of the construction, the work was visited by many engineers, and this journal has yet to learn from any of them that the character of the work was not fully up to the average of good municipal construction. It is true, however, that the contracts were generally taken at a very high figure, as such work goes, and it is possible that better prices might have been attained had some of the conditions attending the award of the contract been different. So far as the engineering work and the actual construction are concerned, however, it is hardly probable that were the work to be placed under contract to-day, with all the knowledge gained in the interim, the workmanship would have been much different or the prices much lower.

THE SMOKE NUISANCE was the subject of a very important recent decision by the New York Court of Appeals in McCarty *v.* Natural Carbonic Gas Co., 81 N. E. Rep., 549. The question the court has to decide was: in a country district suitable for country homes, does the use of soft coal in a factory so situated that thick black smoke therefrom, great in volume and dense in quality, envelops and discolors a neighboring dwelling house, causing much discomfort and some financial loss to the occupants, constitute a nuisance, when such use of soft coal is not necessary for the practical running of the plant and is not a reasonable use of the manufacturer's property? The court decided that while the defendant's business was lawful and not of itself a nuisance, it was a nuisance as conducted, although a neighboring plant where anthracite coal was burned was not one. It was therefore ordered that the company must either burn hard coal or make such alterations in its plant that soft coal can be burned without causing offense. This opinion is particularly important because it does not refer to a smoky plant in a city, but to one in the country, where the house of the plaintiff is 840 ft. distant. It therefore establishes the rule throughout the entire State that no boiler plant may be so conducted as to be a nuisance without being subject to a permanent injunction until it is rendered practically smokeless. Whether it is a nuisance or not must be determined from all the facts in each case, and this is likely to cause considerable controversy, but the decision as a whole is nevertheless of much technical importance. It is fortunate that the upper court did not uphold the decision of the trial court, which forbade the use of soft coal under all conditions. The time is at hand when soft coal must be used far more extensively than at present, for the supplies of anthracite are running short except from collieries which it is expensive to work. There is no reason why soft coal should not be used except the practically universal lack of knowledge of American people concerning the way to burn it without producing dense smoke. It is sometimes said that smoke is inevitable where soft coal is used; the complete ignorance shown by those who make such a statement can be readily demonstrated by a visit to any large European city, where soft coal will be found in general use but without causing any greater obscurity of the atmosphere than in New York City to-day.

A WHOLLY UNJUST REQUIREMENT is contained in the proposed terms of the contracts for some of the New York Barge Canal improvements, which, it is safe to say, the eminent lawyer who is now Governor of the State would alter immediately if it were brought to his attention. Section 29 of the proposed contract for some improvements now being advertised reads as follows: "The State Engineer shall between the first and fifteenth days of each month make and file with the Superintendent of Public Works an estimate of the amount, character and quality of the work done and of material which has been actually put in place in accordance with the terms and conditions of this contract during the preceding month and compute the value thereof. The Superintendent of Public Works *may* within fifteen days thereafter, at his office in the City of Albany, N. Y., pay to the contractor from the money which shall have been appropriated for that purpose a sum not to exceed ninety per cent. of the value of the work performed and material furnished as so certified by the Engineer—retaining not less than ten per cent thereof until the contract shall have been completed and approved by the State Engineer and Superintendent of Public Works." Attention is called to the use of the word "may," as it makes the contract a mere gamble and possibly destroys its legality for want of consideration. As the clause now stands, whether or not the contractor gets his money depends on the whim of the Superintendent of Public Works, as there is no law to compel him to pay, nor any contract provision, and only a suit in equity, assuming one to be possible, would give the contractor relief from an official who was disposed to withhold money from a contractor until the latter had seen the right people. This journal does not believe that any of the people now in office would make any improper use of this peculiar wording of Section 29, but it is very strongly of the opinion that no contractor is justified in signing a contract involving large sums of money which does not protect him in the very vital matter of payments in a better manner than that above quoted. There has been so much scandal and so much wrangling over canal work in New York, that such a palpable opportunity for graft as this clause offers should be immediately done away with.

THE STRENGTH OF A DUMP CART is something few people have ever had an occasion to determine carefully, and for this reason some tests made by Prof. W. K. Hatt, in the laboratory of Purdue University are decidedly interesting. They were made on a stock cart built by the Troy Wagon Works Co., and rated at a safe capacity of 4½ tons. The purpose of the tests was to show just what resistance could be expected from such a cart under the most adverse conditions of loading. The first test was made by filling the body with sand and applying a heavy load on top of it with a testing machine. Failure did not occur until 36¼ tons had been applied, at which point the body gave way, but the running gear was uninjured; this is equivalent to a factor of safety of about 8½. The second test was to show the resistance of the rear wheels to the strain brought on them when the wagon rests on a side hill parallel to the slope, the latter being just below the inclination, 31 deg., which will cause the fully loaded cart to overturn. The theoretical force acting at right angles to the wheel rim under such conditions is 2,680 lb., while the test showed that the wheel had a resistance of 5,500 lb. to such a load, equivalent to a factor of safety of a little over 2. Inasmuch as no teamster ever drives a loaded wagon on a side slope as steep as this, it is evident that the actual factor of safety is largely in excess of that mentioned. The third test was to ascertain the resistance of the rear wheels to the strain that occurs when the wheel is caught in a rut and the horses attempt to turn it out of this rut. Prof. Hatt figured that theoretically the maximum strain which would be produced under such conditions was about 7,600 ft.-lb., while the wheel which was tested developed a resistance equivalent to 13,080 ft.-lb. This gives a factor of safety of 1¾, but as it will rarely happen that a single wheel is caught in a rut and has to withstand the whole wrenching of turning out, it seems likely that the actual factor is considerably higher. The fourth test was to determine the strength of the rear axles under actual load conditions, which was found to be 31,000 lb. Full details of the tests and results are given in a little pamphlet issued by the builders of the carts, and are instructive as showing the real strength of such wagons. They also show how the modern testing laboratory can be utilized to furnish definite information concerning appliances that, until recently, were considered to be beyond the range of experimental examination.

THE KINNICKINNIC RIVER FLUSHING TUNNEL AND PUMPING STATION, MILWAUKEE, WIS.

The Kinnickinnic River in Milwaukee, Wis., rises about 10 miles southwest of the central part of the city and empties into the Milwaukee River at a point half a mile from the mouth of that stream in Lake Michigan. The mouth of the Milwaukee River is a little to the south of the central business district of the city, the river running northwesterly for nearly half a mile from its mouth, and then turning to the north, which general direction it follows to beyond the outskirts of the city. The original portion of the city, and what is now its most congested sections, lies between the lake and the Milwaukee River, and to the west of the latter. The area along the Kinnickinnic River just south of the central business district is largely covered with factories, while farther out are residence sections, which are comparatively new. The Menominee River flows east and west through the city and also joins the Milwaukee River at the point where the latter turns to the north. The land on both sides of the Menominee River is fully occupied from its junction with the Milwaukee River to the city limits, a distance of about two miles, with factories and coal and steamship docks.

The sewerage system of Milwaukee is on the combined plan, practically all the sewers having their outlets in one of the three rivers. All three streams have comparatively small watersheds, which are of such nature that during dry weather the flow in them is slight. The Milwaukee River has an average width of 200 ft. and a depth of 20 ft. for about 3 miles from its mouth; the Kinnickinnic River is also 200 ft. wide and 20 ft. deep for nearly 2 miles from its mouth, and its channel is being dredged to that cross-section for one-half mile farther. The large cross-section of the Milwaukee River, the small volume of water flowing in it during eight to ten months of the year and the great amount of sewage tributary to it, long ago rendered the stream very offensive for all but two or three months in the year. In order to relieve the situation, a 12-ft. tunnel, 2,500 ft. long, was built in 1888 from an intake on the shore of Lake Michigan to the river at a point just downstream from a dam which is about 1½ miles south of the northern limits of the city. All of the sewage above the dam is intercepted and carried below the mouth of the tunnel. A 14-ft. screw-pump, placed in this tunnel near the lake, gives a head of 3 ft. to the water in the tunnel, which is sufficient to cause a large enough flow through the tunnel from the lake to flush the river. This pump is driven by a vertical tandem-compound steam engine in a pumping staiton near the lake. The water supplied through this flushing tunnel has kept the river in good condition at all times since it was placed in service over 19 years ago.

When the Milwaukee River flushing tunnel and pumping station were built, the areas along the Kinnickinnic River were sparsely covered with buildings, and the old channel of the latter river had not been dredged to its present cross-section. Since then these areas have become quite congested and the river has been widened, with the result that the pollution of the stream has been greatly increased and the nuisance caused by this pollution has been correspondingly aggravated, until in the last few years some means of relieving the situation became an imperative necessity. A flushing tunnel, 12 ft. in diameter and 7,182 ft. long has accordingly been built from Lake Michigan to a point on the river, 2½ miles from the mouth of the latter. A pump similar to the one in the Milwaukee River tunnel was placed in this tunnel at the river, and is driven by an engine in a pumping station built over the outlet end of the tunnel. The river will be dredged to the standard width of 200 ft. and depth of 20 ft. from the lake to this pumping station, and as it is only 20 to 30 ft. wide above the station no trouble from pollution in this portion of it is anticipated.

The intake at the lake, from which the tunnel starts, consists of two parallel, rock-filled pile piers which are 60 ft. apart and extend 385 ft. into the lake from the shore line, the channel between the piers having been dredged to a depth of 16 ft. As practically all heavy storms on the lake and most of the floating ice come from the northeast the intake has been built to provide against any difficulties which may arise from this condition. The pier on the south side extends 300 ft. from the shore line, an opening 75 ft. wide being left between it and the end of the intake; the pier on the north side is carried 75 ft. farther out, and has a section, 80 ft. long, at right angles to it at the end, which section is across the end of the intake channel and protects the opening along the south side of the intake. The corner between the end and north side piers is reinforced with a diagonal pier on the inside and is riprapped on the outside with heavy stone for a width of 32 ft. along the end and for 50 ft. from the corner along the side. The two parallel side piers converge at the inshore end, and in a distance of 85 ft. from the shore line the space between them is reduced to a width of 12 ft. A short length of concrete conduit connects the end of the intake with the tunnel proper, the cross-section of this concrete conduit being changed from square to circular from the outer to the inner end fo it.

The piers of the intake consist of two rows of round piles which are 10 ft. apart, outside to outside of rows. The piles in the outer row of each pier are 18 in., and those in the inner row 36 in. apart on centers. The two rows of piles in each pier are tied together at the water line by 1¼-in. rods spaced 3 ft. apart, these rods being anchored to 8x12-in. waling timbers. A row of 2x12-in. triple-lap sheeting is driven along the inside of each row of piling to hold the stone filling in place. The piers are also floored over 5 ft. above the water level.

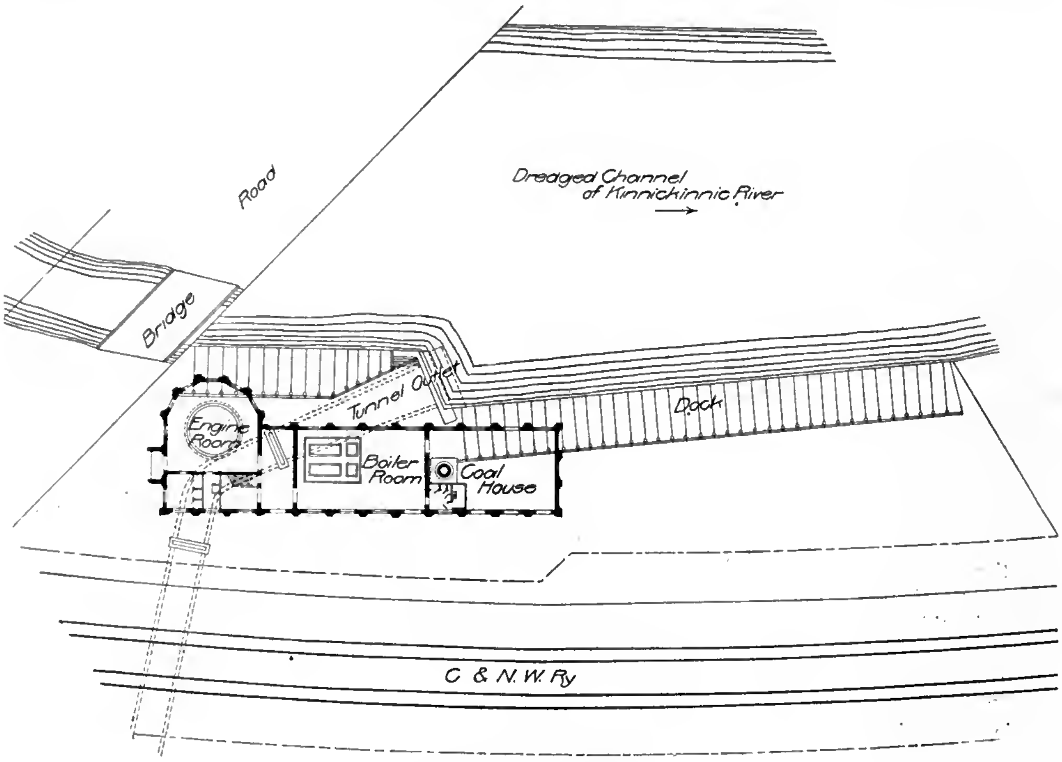
Floating debris and ice will be prevented from entering the tunnel through the intake by a heavy iron rack across the latter near the mouth of the tunnel. This rack is 37½ ft. across the face and is built in sections each 5 ft. wide and 19½ ft. high, the top of the rack extending 2 ft. above the water level. Each section consists of a ¾x6-in. plate frame having vertical 1-in. rods spaced 4 in. apart on centers between these plates. These sections slide in 8-in. I-beams placed vertically, so they can be removed and repaired readily.

The tunnel was built under city streets for almost its entire length. The invert of the tunnel is 16 ft. below Milwaukee city datum, which is approximately the average water level in Lake Michigan, at the inlet end, and 20 ft. below that level at the outlet end in the river. The excavation was all carried on in tunnel, with the exception of a short length of about 450 ft. where an old creek valley was crossed in open trench. The cover over the top of the tunnel varies from 5 to 80 ft. The tunneling was handled from six shafts, and on the whole, no difficulties were encountered while it was in progress, as the work was practically all through clay, or sandy clay, which for the most part could be shored with light timbering. Quicksand was encountered for a short stretch, however, and some trouble was occasioned in building this section of the tunnel.

The tunnel is lined with four rings of Milwaukee sewer brick laid in Milwaukee Portland cement mortar. Manholes for entering the tunnel are provided at each end of the latter. A 12-ft. cast-iron sluice gate is placed in the tunnel at the inlet end. A gate of the same size and type is also placed in the tunnel on each side of the pump at the river.

The pumping station was located at the river end of the tunnel instead of at the lake end, as is the pumping station for the Milwaukee River tunnel because a better site could be had at the river. The station is immediately along the bank of the river, between the latter and the Madison division of the Chicago & Northwestern Ry. and faces on a public highway, so the best of transportation facilities are available.

The building has a concrete substructure carrying a red brick superstructure trimmed with Bedford sandstone. The roof of the building is of 4-in. concrete slab, reinforced with expanded metal and carried by steel trusses resting on the side walls. The concrete slabs are covered



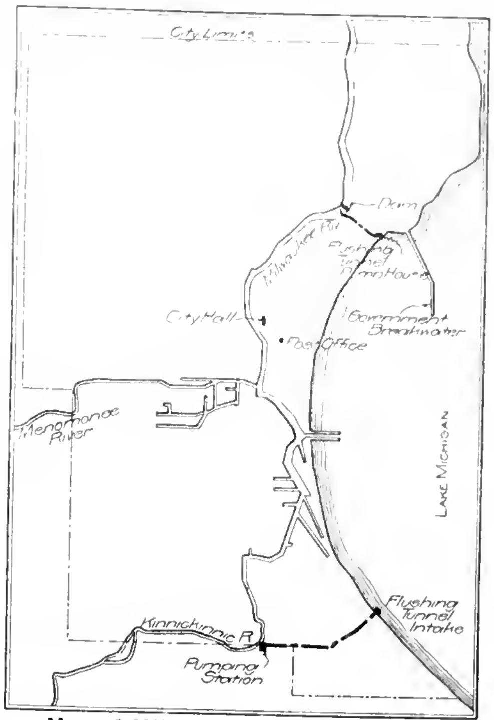
Plan of Pumping Station.

by green interlocking terra-cotta tile, which are laid in roofers' cement and have a glazed surface finish.

The general arrangement of the station and its surroundings is shown in an accompanying illustration. The station building is 34x165 ft. in plan in the clear, the front end being made wider to accommodate the engine which drives the pumps in the tunnel. The building is divided into an engine room, an engineer's office and storage room at the front, then a repair shop, boiler room and coal storage room, in order.

The screw pump and the engine which drives it are of the same type and generally the same arrangement as the pump and engine of the Milwaukee River flushing tunnel. The pump has a wheel 12.5 ft. in diameter made up with six impeller blades attached to a 12-in. shaft. This wheel revolves in a casing set in the tunnel lining. A cone, 6 ft. in diameter at the base, is placed concentric with the wheel on the side from which water approaches the latter and directs the flow on the blades. A second casing placed just beyond the wheel contains stationary deflector blades which reduce the swirling motion given to the water by the wheel.

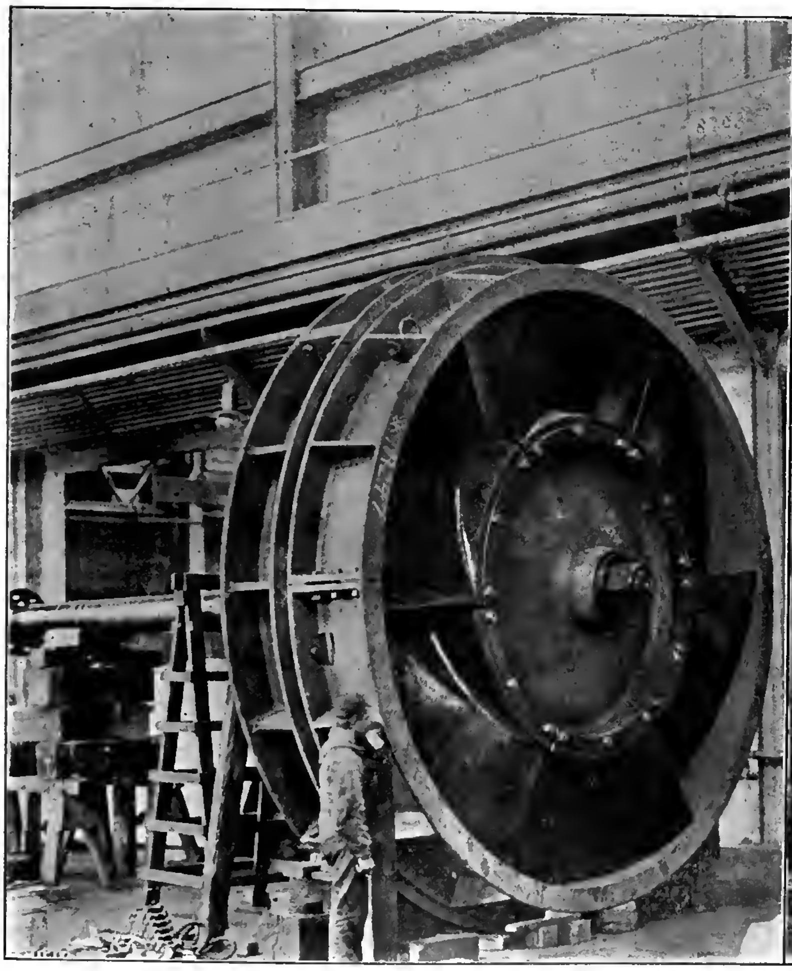
The 12-in. shaft on which the wheel is mounted is carried by an outboard bearing in the center



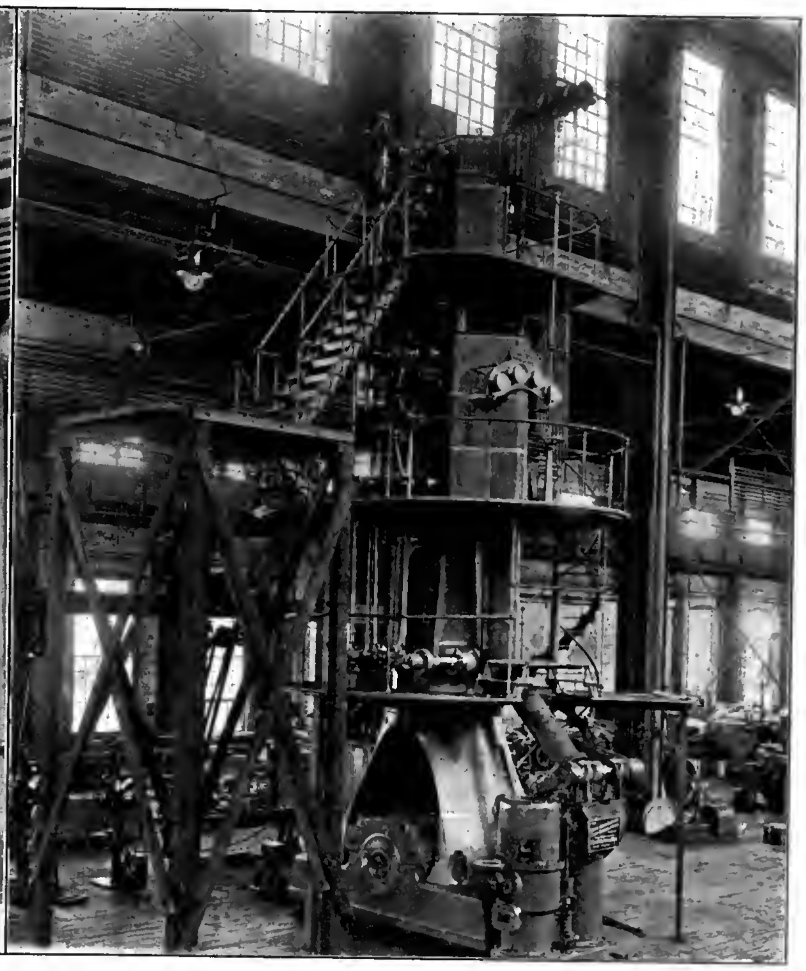
Map of Milwaukee Showing Tunnel.

the lake. These valves are all of the same general design. The two at the pumping station were built by the Coffin Valve Co., and the third by the Wm. Bayley Co. The valve disks are cast-iron. They carry on both sides at their circumference, a turned and planed brass ring, each of which seats against a brass ring carried by the valve box. A 2-in. pipe extends from the surface to a connection in the valve box so the sediment may be flushed out of the bottom of the latter. Each disk has two 3-in. steel stems, one on each side, which rise in channels in the sides of the valve chamber. These stems are each geared to a worm on a horizontal shaft on an operating stand over the chamber. This shaft is fitted with a windlass crank at each end and will be turned by hand, as experience with the original flushing tunnel has shown that the gates are rarely moved. 2.5-ft. sluice gate operated from the surface through a non-rising stem is placed on each of the large valve disks, and is used to equalize the pressure on both sides of the latter.

The station was designed and built under the direction of Mr. Chas. J. Poetsch, M. Am. Soc. C. E., city engineer of Milwaukee. Mr. B. W. Perrigo, assistant city engineer, was immediately in charge of the design and construction. The pump and engine in the station were built



Wheel of 12.5-Ft. Screw Pump.



Pump Engine Set Up in Shop.

of the second casing, where it is supported by the reflector blades. The pull on the shaft is taken up by a thrust bearing of the marine type, which is placed inside the engine pit. The shaft is 32 ft. long and extends through a stuffing box in the side of the engine pit and is direct-connected to the crank disk of the engine.

The engine is of the vertical tandem-compound condensing type with a Corliss valve gear, and is practically a marine engine without the reversing gear. It has sufficient capacity when supplied with steam at 140 lb. pressure, and running at 55 r.p.m., to drive the pump so the latter will raise 30,000 cu. ft. of water per minute against a head of 3½ ft. The pump for the jet condenser, which is supplied with water from the tunnel, and all other auxiliaries are driven by rocker arms attached to the cross-head of the engine.

Steam is supplied by two 72-in. by 18-ft. return tubular boilers equipped with Hawley down-draft furnaces and Foster superheaters. The furnaces are connected to a Custodis radial brick stack, 135 ft. high. The superheaters supply steam to the engine at a temperature of 100° Fahr. above that of saturated steam.

A 25-kw. direct-current generator direct-connected to a De Laval steam turbine furnishes power for lighting.

The large sluice gate valves on each side of the pump permit the latter to be shut off from the river and from the tunnel. The valve at the lake also permits the tunnel to be shut off from by the Allis-Chalmers Co., of Milwaukee, the Edward P. Allis Co., one of the constituent companies of the Allis-Chalmers Co., having built the pump and engine for the pumping station of the Milwaukee River flushing tunnel.

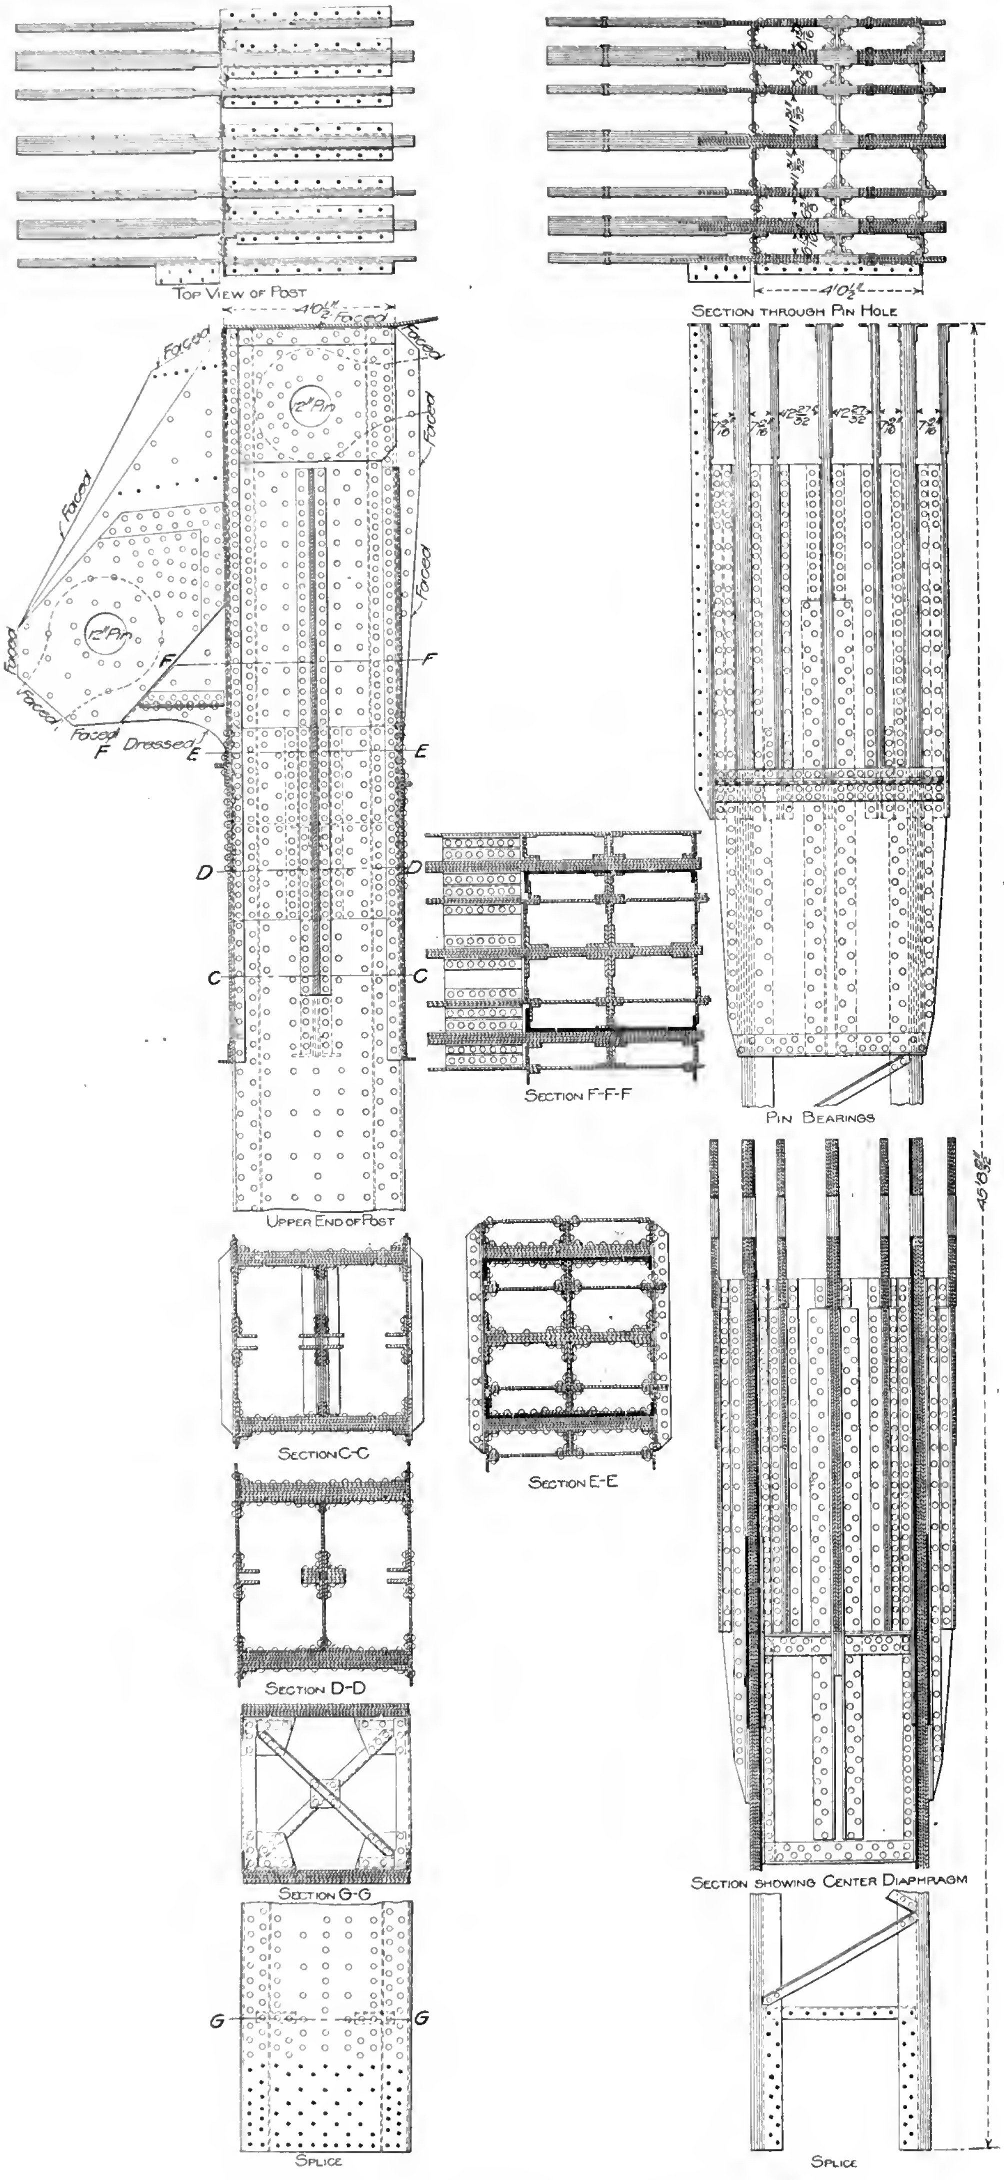
Fire-Killed Timber is being used more extensively each year in the West for railroad ties, and where tried in the same track with ties cut green, has been found to be as good as the latter. Despite the fact that dead timber is often regarded as unsound there are many tracts of it, killed by fire 15 or 20 years ago, that are still sound. The strength is not impaired, and the durability is often increased. The Forest Service is selling such timber on its reserve.

Widening Blackfriars Bridge, London.

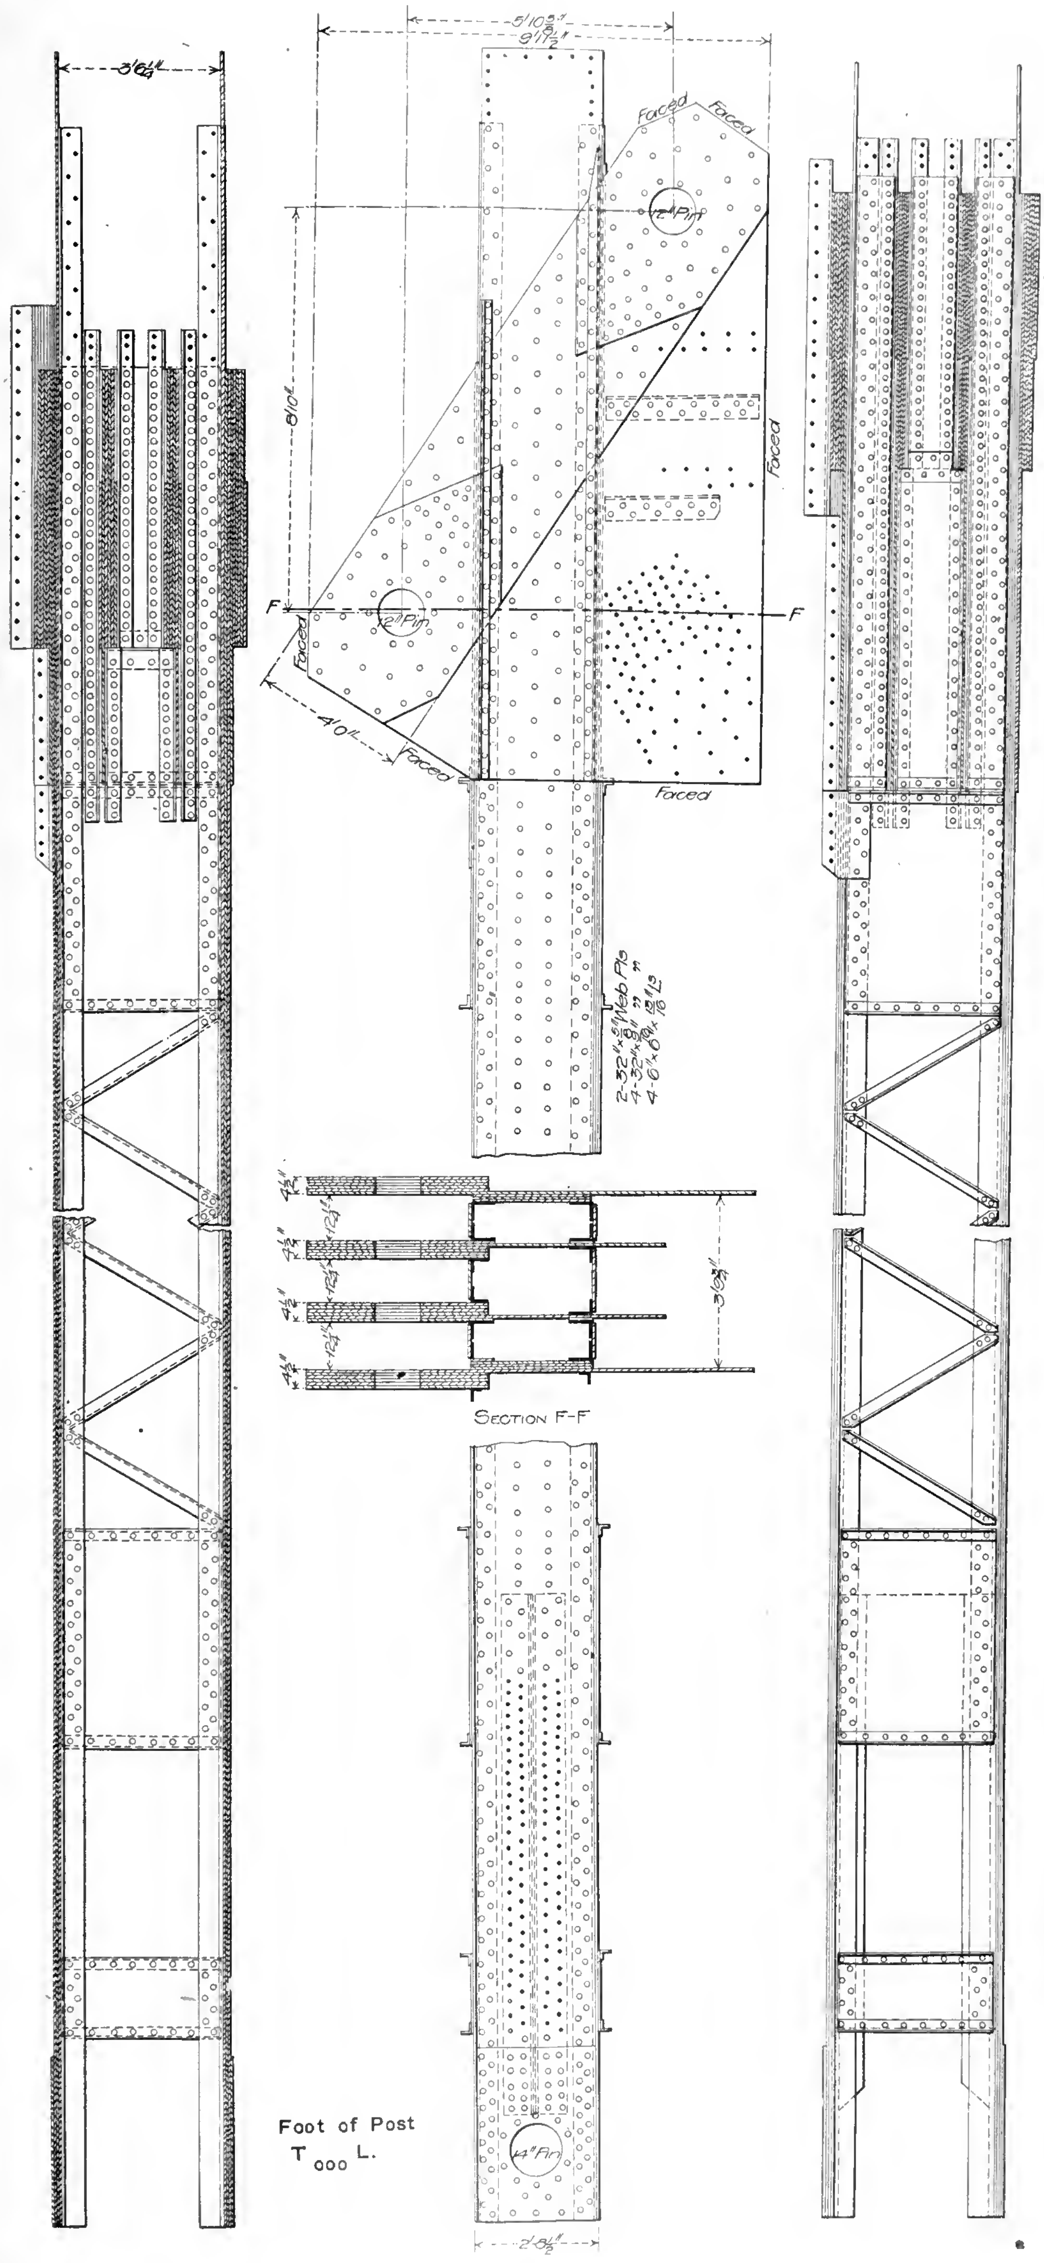
Improvements estimated to cost about $1,000,000 are now in progress on the Blackfriars Bridge across the Thames, at London, and include the extension of the upstream ends of the piers and abutments to receive three new lines of steel arch ribs 10 ft. apart increasing the width of the superstructure to 105 ft., which will make it the widest bridge across the Thames. Pile platforms at a level of about 5 ft. above high water have been built to enclose the upstream ends of the piers and to support during construction the steel caissons and cofferdams in which the extensions of the substructure will be built by the pneumatic process. On these platforms the permanent steel caissons are riveted up complete to a total height of about 13 ft., after which each of them is suspended from four overhead hydraulic jacks seated at the ends of two pairs of steel girders supported on timber trestles. Brackets bolted to the caissons are pin-connected to the lower ends of suspension links, each of which is formed of alternate single and double flat steel bars 10 ft. long, pin-connected together for convenience in the insertion of additional lengths as the caisson descends. The upper length passes through the hollow plunger of the hydraulic jack and engages a pin bearing on the saddle of the jack. The slotted pin holes in the links are 12 in. apart to correspond with the stroke of the jack. As the caisson descends, the successive courses of the steel cofferdam above it are built on, the shoe concreted, the caisson lowered to rest on the bottom of the river and the overhead girders and jacks removed. Air pressure will then be admitted and the caisson excavated to the required depth of about 27 ft. below low water, where it will be concreted and grouted and will be subjected to a test load before the superstructure is built on it.

Wooden cofferdams puddled with clay will be built to enclose the adjacent ends of the new caissons and of the old piers, enabling the end walls of the caissons and the adjacent masonry in the old piers to be removed and allowing the new masonry to be bonded with the old and additionally secured by a pair of steel trusses built into the masonry and serving to carry the skew-backs for the new arch ribs. Riveting and other work will be done by pneumatic tools operated by air from electrically driven compressors and all hoisting engines will also be driven by electricity. The parliamentary plans were prepared by the late Sir Benjamin Baker and the work is in charge of Mr. Basil Mott and Mr. E. M. Wood. Sir Wm. Arrol & Co. are the general contractors and, according to "Engineering," the work is to be completed in three years with a penalty of $100 a day for all time in excess and an equal bonus to be given for time saved.

Technical Clubs among the employes of large engineering offices are among the most useful means of keeping men interested in their work and acquainted with the problems that arise in other departments than their own. They are generally encouraged by the officers of such companies on account of this good influence. The last to be organized is the Engineers' and Constructors' Club, which has been formed among the staff of Dodge & Day. Its object is to discuss subjects relating to engineering and construction, and to give all members the benefit of the experience gained by each in his particular line of work. During recent meetings papers have been presented and discussed on civil engineering preliminaries for an interurban trolley, electric welding, gas producers and internal combustion engines, and concrete piling, the discussions showing much interest in the subjects.



Upper Part of Vertical Post, UP_1 L, Quebec Bridge.



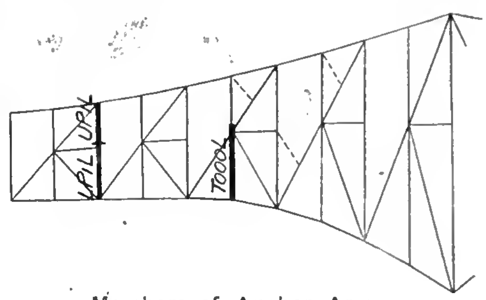
Foot of Post T 000 L.

The Quebec Bridge Superstructure Details; Part V.

Vertical Post P_1.—The dimensions and stresses of the vertical posts change rapidly toward the ends of the anchor arms. They are typical in post P_1, about 114 ft. long over all, which has a cross-section of 370 in. to provide for a uniform maximum stress of 5,365,000 lb. throughout. It is nearly 4 ft. sq. and has a rectangular cross-section made of two built channels 4 ft. deep. Each channel is made with five plates riveted together to make a solid web 3 3/16 in. thick and two 8x6x13/16-in. flange angles turned inward with their flanges latticed except at the ends of the posts with 3x3-in. diagonal angles.

The upper part of the post is 45 ft. 8 in. long over all and weighs about 120,000 lb. It differs from the upper part of post P4, in that it only has one pin for the top chord bars, all of which from both panels interlock on the same center line. The outside webs and three additional interior webs, making seven in all, are provided for the bearings of the top chord pins and are extended on one side to afford a connection for the diagonal eye bars which also have a 12-in. pin taking bearing in all seven webs. The webs are connected by a center transverse diaphragm and by two side diaphragms in the planes of the flange angles of the post.

The regular 4-ft. web plates are cut short and are extended to the upper ends of the post by



Members of Anchor Arm.

special wide plates about 12 ft. long which are shop riveted to the continuous flange angles. The plates are reinforced to give pin bearings from 1¼ in. to 2⅞ in. long, and like the webs in the other similar members of the bridge they were assembled and shop riveted separately to form independent ribs with I-shaped cross-sections which were then shop riveted between the transverse plates of diaphragms and the pin holes were bored and counterbored to templates. A horizontal cover plate is bolted across the top of the post to exclude snow and rain.

The lower part of post P_1 is 68 ft. 7½ in. long over all, and weighs about 150,000 lb. The cross-section is the same as that of the upper part and its bottom chord and diagonal connections closely resemble those described in a previous article for foot of post P4, but have much smaller dimensions. The main ribs and intermediate ribs are reinforced to total thicknesses of 5½ in., giving a combined length of bearing of 22 in. for the diagonal eye-bar pin. The holes for the chord pin bearing in the same webs are bored at a point where they are less heavily reinforced and have thicknesses of only 2⅞ in. and 3¼ in.

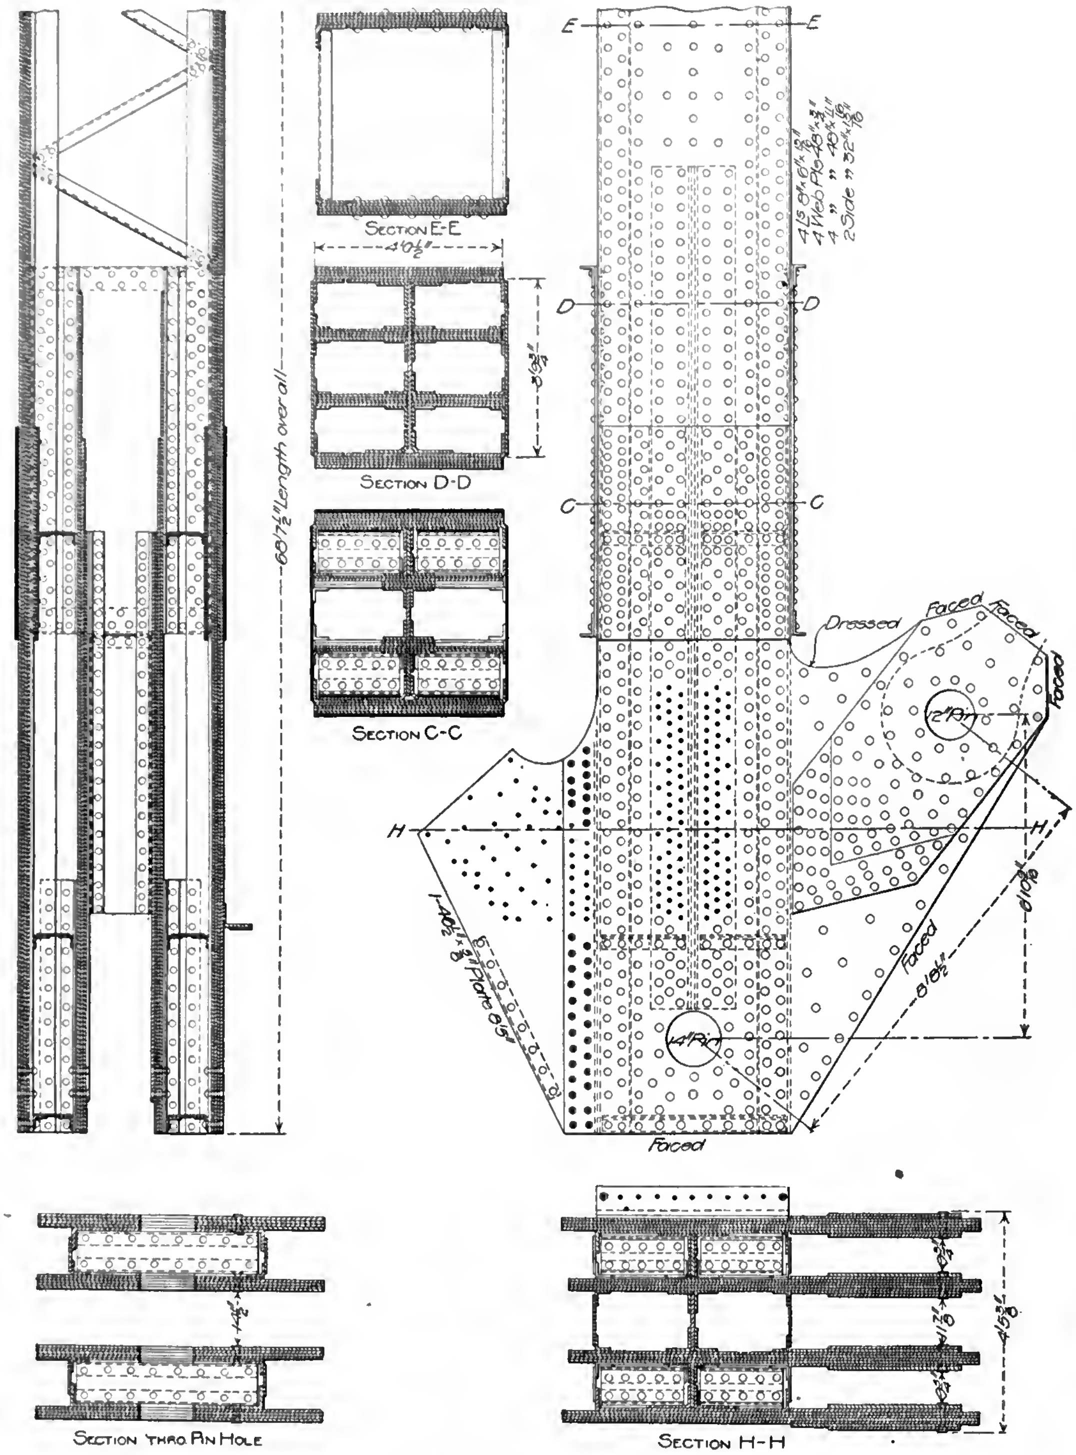
The center transverse diaphragm clears the upper flange of the lower chord and beyond it the two pairs of outside webs project in the spaces between the lower chord webs and are themselves stiffened by I-shaped diaphragms to make double jaws interlocking with the lower chord. The wide outer web plates are spliced to the regular 4-ft. web plates of the post channels with inside and outside shop-riveted cover plates, and the upper ends of the two inner web plates is coincident with the center of the splice and is stiffened

by two horizontal transverse diaphragms. The center vertical transverse diaphragm is shop riveted between the post webs and extends about 8 ft. above the center of the web splices and nearly 13 ft. below it to he end of the post, but is slotted for a depth of 4½ ft. at the bottom to clear the center rib of the bottom chord.

The sub-verticals at intermediate panel points of the truss are compression members made in two or more sections each with riveted splices and pin connections to the top and bottom chords. A fair example is the post marked T000 between vertical posts 2 and 3 at about the middle part of the anchor arm. This member has a total stress of 58,000 lb. in the upper part and 1,307,000 lb. in the lower part, which is 72 ft. long over all, weighs 92,000 lb.; the upper and lower parts are each shipped separate and complete from the shop and field riveted at the splice just above the intersecting diagonal.

Like the main vertical posts this member has a rectangular cross-section made with two built channels having their flanges turned inward and latticed. Each channel has a total thickness of 1⅞ in. and is made with three 32-in. web plates riveted together, and two 6x6x13/16-in. flange angles. At the lower ends there are two 31x½-in. flange plates nearly 5 ft. long, which produce a

Foot of Post, Quebec Bridge.



Foot of Vertical Post, L P₁ L, Quebec Bridge.

closed rectangular cross-section and have a center transverse I-shaped diaphragm to make a rigid connection between the two webs and stiffen them to receive the floor beam connection on the inner face of the post which is made with 110 ⅞-in. field-driven rivets. The webs project beyond this diaphragm to form jaws engaging the lower chord pin betwen the center and outside webs of the chord.

Just below its upper end this part of the post intersects the main diagonal member of the panel which consists of sixteen eye-bars made in two lengths and connected at this point. The large number of heavy pieces meeting here would require a long pin and develop difficult packing besides throwing the bars somewhat out of alignment if all were assembled on the same pin. To avoid this two pins are provided through opposite ends of a series of four oblique plates forming short links riveted to the post at the point of intersection so as to provide for the pins in opposite ends outside of the post flanges.

These links are riveted to the post webs and to two intermediate diaphragms, thus forming four longitudinal webs similar to those already described for the upper ends of the main vertical post. On one side of the post the two outer web plates are extended below the connections for the upper eye-bar pins to form jaws for the sub-diagonal strut connected at this point with 198 ⅞-in. field-driven rivets. The eye-bar connections are reinforced to have thickness of 4½ in. thus giving a total length of bearing of 14 in. for the 12-in. pins. At the upper end there are somewhat thinner pin plates, reducing the total length of bearing there to 12¼ in. On the side adjacent to the sub-diagonal the ribs are also stiffened by two horizontal transverse diaphragms about 2 ft. apart at the point where one end of a light horizontal strut is riveted between the outside ribs.

(To be continued.)

An Australian Irrigation Project.

The barren jack dam is the leading feature of a great irrigation undertaking for which plans have been prepared by Mr. L. A. B. Wade, principal engineer for rivers, water supply and drainage of New South Wales. It is to be constructed across the Murrumbidgee River, at a place where the catchment area is about 5,000 sq. miles. The dam will be 232 ft. high from foundation to coping, the latter 12 ft. above the maximum water level, and 910 ft. long, being curved upstream with a radius of 940½ ft. The cross section, according to "Engineering," is that suggested by Major Tulloch. The width of the base at the deepest place is 160 ft. The lower faces on both sides rise vertically for 20 ft. and the thickness of the dam then decreases rapidly to 145 ft. Then the upstream face has a batter of 1 in 20 and the downstream face 1 horizontal to 1½ vertical up to a point 60 ft. below the coping. Above this level the upstream face is vertical and the downstream face is curved, the width at the coping being 18 ft. The reservoir impounded by this dam will hold 33,380,000,000 cu. ft. The dam is to act merely as a regulating structure, and the impounded water will be let out through outlets in the body of the dam into the river-bed, down which it will flow for about 220 miles to a large weir so located that the water impounded by it can be discharged by gravity to the 6,500,000 acres to be irrigated. The water will be distributed over the land by a very extensive system of canals and ditches controlled by head gates.

Sewage-Disposal by Biological Processes.

Presented to the Engineering Conference of the Institution of Civil Engineers by John Duncan Watson.

An absolutely essential feature of a good scheme of sewage-purification should be an efficient method of eliminating solids without nuisance. At Birmingham this is done by mechanical precipitation and septic treatment. The elimination and removal of grit, etc. (50 per cent. water), costs 5*d*. per cubic yard. The elimination and removal of sludge (90 per cent. water) costs one-third of a penny per cubic yard. (Both figures are exclusive of the capital cost of tanks, etc.)

No matter by what method the tank-liquor is prepared for oxidation and nitrification on a biological filter, it is desirable that it should be rendered as free from suspended matter as possible. It is possible to reduce the suspended solids in septic liquor from 29.1 to 6.1 parts per 100,000 for the sum of 2*s*. per million gallons treated.

The tank capable of effecting the above result had the Dortmund tank for its prototype, but it is essentially different, both as regards principle of construction and form.

The Birmingham tank is pyramidal in shape, with vertical walls rising to the surface in the form of a square. The sewage is made to enter the tank by a submerged pipe, the downward velocity being 1 to 2 ft. per second. As it emerges from the mouth of the pipe, it spreads out laterally and ascends to the square portion of the tank at a gradually decreasing velocity, the average velocity throughout being 7 ft. per hour. As this velocity approximates to the falling velocity of the particles in suspension, the tendency is for the latter to separate out and collect in that region of the tank between the mouth of the inflow pipe and the apex or bottom of the pyramid. The sludge-pipe terminates in a sump at the bottom, and whenever the pipe is opened by operating the sluice-valve, the sewage affluent ceases to ascend, or it may even become a downward flow precipitating the suspended matter towards the mouth of the sludge-pipe. The sludge or irreducible residuum of the septic process in this tank amounts to 1.027 tons of dry solid matter per million (imperial) gallons treated, and may be removed and buried for 8*d*. per million gallons, a figure that includes sludge main and labor, but excludes rent of land. The cost of an installation of the tanks of a sufficient capacity to effect the necessary reduction of suspended matter amounts to £520 per acre of bed supplied.

A biological filter should be constructed, whenever possible, on the percolation principle; it should rest on a concrete floor laid with an inclination towards an effluent-channel. Before the surface hardens it is advisable to lay thereon an aerating tile or false floor capable of sustaining the medium. The chief purpose of the aerating tile is to allow the free exit from the bed of all matter in suspension, whether due to disintegration or imperfect washing of medium, and to admit of the natural evacuations of the bed itself, such as colloidal matter, hydrated oxide of iron, sand, living and dead bodies of organisms, etc.; but the aerating floor also—as its name implies—provides for a free passage of air from end to end of the bed.

A percolation bed should be a permanent structure that requires no renewal, and little or no displacement of medium for cleansing purposes, and this can be obtained only by the employment of good rock or other equally durable material. The qualities next in desirability are roughness of surface, and pieces that approximate to cubes, so to prevent the particles from uniting too closely. Observe those conditions, and almost any medium will answer the purpose of providing a habitat for the bacteria. The accompanying table shows that no merit attaches to medium substance *per se*, and the beds which I am now constructing contain various kinds of stone (including gravel) and hard slag from different places, mixed together indiscriminately.

It must be admitted that the smaller the medium the more perfect the effluent depth for depth, but there are other and more important considerations than to obtain a perfect effluent. A perfect effluent is not an ideal one; the ideal is to obtain by natural means an effluent which will not putrefy, and which will continue to improve when it is discharged into a stream: this, when a strong sewage has to be purified, can be done for little more than half the cost by adopting large instead of small medium. Compare bay 7 with bay 6 of bed No. 5 on the table accompanying this note, and it will be seen that bay 7 (small) was at work for only one-half of its time, whereas bay 6 was at work 94 per cent. of the full time. The cost of purifying one million (imperial) gallons was £3 7*s*. 3*d*. against £1 12*s*. 8*d*. in favor of bay No. 6.

No doubt the purification obtained was greater in the case of bay No. 7, but what of that when both effluents were non-putrescent?

It cannot be too often reiterated that what may be a suitable medium for one sewage may be quite unsuitable for another. The character of the effluent desired, the depth of the percolation bed, the quantity of sewage to be dealt witl the periods of rest necessary, and the faciliti for removing suspended solids, all have a di and reciprocal bearing on the selection of most suitable size for media.

One of the most important questions t sider is the best way to distribute sewa the surface of a bed, and it will pro admitted that the ideal to be aimed imitation of rainfall. The fixed spray

up the liquid other method distribute an this respect tributor, w or travel

the other hand, it is much cheaper, e.g., spray jets cost (initial outlay) £500 per acre against anything between £1,000 and £4,000 required to install moving distributors, and reference to column 4 will show how much time may be wasted owing to the repairs required by a mechanical apparatus. Now if it could be shown that the moving distributors were instrumental in producing better results, I should be the last to disparage the use of the traveling distributor on large works; but it cannot. Compare the results from bed D, which is served by a Candy distributor, with fixed spray jets on bed No. 6. In both cases the medium is nearly similar in size, the only difference being that bed D is 7 ft. deep, and bed No. 6, 6 ft. deep. The results show a purification of 83.6 in the case of bed D, against 80.4 in the case of bed No. 6, both non-putrescent effluents.

For a considerable time I have been suspicious of crystalline effluents, fearing that they would some day result in serious chokage in the bed itself. I have, therefore, encouraged effluents that contained as much or more suspended matter than was present in the sewage when applied to the surface, and as this represented from 7 to 8 parts per 100,000 of dry solid matter, it became necessary to arrest the solids before discharging them into the river. This was done by the Birmingham separator, constructed as already described. The cost is *1s. 4½d.* per million (imperial) gallons treated; pumping silt and digging it into land, costs *6d.* per million gallons more.

The accompanying table contains facts culled from weekly reports prepared for my own information and guidance; in it and others of like nature ample justification will be found for inculcating caution in estimating the amount of strong sewage which an acre-bed 6 ft. in depth is capable of purifying. On an installation of 20 acres of such beds at Birmingham, not more than 15,000,000 (imperial) gallons of dry-weather flow can be efficiently purified; with an occasional augmentation of a like quantity for a very short period. Again, the table shows that the adoption of fine medium, although capable of producing a slightly better effluent than large medium, is too costly to become popular; and lastly, the fixed spray jet for large works has not, so far, been seriously rivalled by the traveling distributor either for circular or rectangular beds.

A LARGE GAS ENGINE rated at 1,650 h.-p. at 107 r. p. m. when using furnace gas of 80 B. t. u. has recently been completed by the Wm. Tod Co., for the Ohio works of the Carnegie Steel Co. The unit consists of a pair of two-cylinder tandem four-cycle engines connected by an operating platform at the level of the axes of the cylinders. The latter are 30 in. in diameter and have a stroke of 42 in. They are held together by tie rods and are so mounted that they are remarkably free to expand and contract. The valve gear is driven by eccentrics, one for the inlet and exhaust valves of each end of each cylinder. Mushroom inlet valves are used, mounted on top of the cylinders, and the exhaust valves are at the bottom and readily accessible from the space below the operating platform. The main valve is opened by a rolling lever and seated by a spring. The mixing and governor valves are in the upper part of the valve bonnet and the former may be controlled individually or together by hand. A fly-ball governor is provided for each pair of tandem cylinders and the two governors are connected for ordinary operation although they may be disconnected if either half of the engine is to be used independently. Make and break ignition with 90-volt direct current is employed. The engine weighs 900,000 lb., and occupies a space of 27 x 60 ft.

The Municipal Ownership Investigation for the National Civic Federation.

The Commission on Public Ownership and Operation of the National Civic Federation has completed its work, and abstracts of its special reports are now being given out from time to time. Labor conditions and the character of the gas, water and electric service rendered by public and private plants are covered by the official reviews that have been made public up to the present. The Commission appointed a committee of investigation of 21 members, which engaged in turn a staff of engineers, accountants and statisticians to examine thoroughly every undertaking in this country and Great Britain which was visited by the committee. These experts were so chosen that, in each examination made, both sides of the municipal ownership question were represented. Thus, one engineer, accountant or statistician approached the subject under consideration favorably disposed toward municipalization, while his colleague began his task holding views in opposition to that principle.

Labor Conditions.—The labor conditions under private and public ownership are discussed by Prof. John R. Commons, of the University of Wisconsin, and Mr. J. W. Sullivan, editor of the "Clothing Trades Bulletin." Starting with the same information gathered by the experts as a basis for argument, the former reaches the conclusion that corruption under municipal control is no greater than under private ownership, while the latter makes caustic reference to political rottenness which he declares to be evident in Syracuse, Allegheny and Wheeling.

According to Prof. Commons, the investigations have shown that "the strongest safeguard for a manager against the pressure of outside recommendations is the recognition of organized labor within his department. Wherever we have found a class of employees organized and dealt with as such through their representatives we have found those positions exempt from politics. This follows from the nature of labor organization, which cannot survive if individuals are given preference on political, religious, personal or any other grounds than the character of the work they do. Even in the politically honeycombed municipal undertaking at Allegheny, the union of electrical workers stopped the practice of paying assessments by its members for political campaigns. The success of the civil system of Chicago is owing more than anything else to the fact that organized labor has one of the three members on each examining board. The manager of the Manchester tramways ascribes his freedom from interference by individual councillors to his recognition of the union that holds 90 per cent. of his motormen and conductors."

The minimum payment for common labor by the private companies in the United States, except in Atlanta, is lower than that of the cities investigated, and the hours of labor are longer. The laborers employed by the municipalities are in all cases citizens, but most private companies employ foreigners when colored labor is unavailable.

Mr. Sullivan sums up his observations with the conclusion that in all but the most poorly paid forms of labor, and for tramway employees, municipalization has not raised the wages or improved working conditions of the employees above conditions in the private undertakings. With respect to "common, unorganized labor," however, the investigators found a difference somewhat favorable to British municipal employees. The report cites two causes for this condition; first, that the municipal laborer is a picked man, and second, that this class of labor is capable of exerting on city councils a combined pressure which obtains for them better terms than the employing councillors accord to the men they hire in their private capacity for similar work. "No street car undertaking in Great Britain has ever been a 'private' enterprise in the sense in which the word is applied in this country," says Mr. Sullivan. "The twenty-one years' term of the franchise, the veto of company petitions by village authorities, the enormous cost of Parliamentary powers and local assents, and various other restrictions non-existent in the United States, shackle and impoverish British tramway company management and consequently forbid an intelligent investigator to employ British example to illustrate possibilities in America through change from private to municipal ownership. British tramways have always been semi-municipal. As by the terms of their franchises all English tramway undertakings may be taken over by the municipalities, directors manage their properties with that end in view. Compared with the remarkable changes for the better in wages and hours in the American street car industry under companies, the best of the British municipal labor improvements seem hardly more than trivial."

American Water and Lighting Plants.—The reports of the investigating staff for water and lighting plants have been reviewed by Vice-Pres. Walton Clark, of the United Gas Improvement Co.; Pres. Charles L. Edgar, of the Edison Electric & Illuminating Co., of Boston; Pres. Frank Parsons, of the National Public Ownership League, and Supt. Edward W. Bemis, of the Cleveland water-works. The experts examined the public gas works at Wheeling, W. Va., Richmond, Va., Holyoke and Westfield, Mass.; the private gas plants at Atlanta, Ga., Norfolk, Va., Philadelphia, Pa., and Fitchburg and Beverly, Mass.; the municipal water works at Cleveland, Ohio, Chicago, Ill., and Syracuse, N. Y.; the private water-works at New Haven, Conn., and Indianapolis, Ind.; the public electric light and power plants at Chicago, Ill., Allegheny, Pa., South Norwalk, Conn., Detroit, Mich., and Danvers, Holyoke, Westfield, Marblehead, Peabody, Taunton, Chicopee and North Attleboro, Mass.; and the private lighting plants at Northampton, Fitchburg, Salem, Beverly, Gardner, Abington and Attleboro, Mass.

The Wheeling gas plant is severely criticized by Messrs. Clark and Edgar, while the plants at Norfolk and Atlanta are considered satisfactory. They say: "If we consider together the price the Wheeling consumer pays for gas and the character of the service rendered, we may not doubt that he gets less of net result per dollar expended than does the gas consumer in Atlanta or Norfolk. Low and varying pressure, uncertain candle power, influenced at times by a dash of natural gas (at Wheeling), will bring troubles to studying children that, while not factors in financial calculations, has a proper place in this inquiry. Wheeling's gas plant is not an important factor in the well-being of Wheeling's citizens. What with fast meters, charges for service and meter setting, absence of any gratuitous work, the admixture of 15-cent, 8-candle power natural gas, insufficient and irregular pressure, and general inefficiency in the complaint department, Wheeling gas is a dear commodity at any price. Our experts found nothing to praise in Wheeling's service and little to criticise in the service of the companies at Norfolk and Atlanta."

Mr. Bemis, on the contrary, holds up the Wheeling plant as an example of what may be accomplished by a municipality, even under unfavorable political conditions. Despite its admitted defects, he says, the Wheeling experiment has been a financial success, and has been "the pioneer throughout the United States in low charges." He does not agree with Mr. Edgar and Mr. Clark as to the value of the free instal-

lation by the private companies at Atlanta and Norfolk, saying on this point: "The gas sold in Wheeling during the sixteen months ending with May 1, 1905, was 162,515,200 feet. The difference between the price charged at Wheeling, 75 cents, and at Norfolk and Atlanta, $1.00. or 25 cents multiplied by these sales, would be $40,628.80. In other words, the saving to the consumer in the price of gas in less than one year will cover all the difference between the free services and the meter setting from the curb to the house in Atlanta and Norfolk, and the cost of the same at Wheeling."

There is the same difference of opinion concerning the Philadelphia gas works. Messrs. Edgar and Clark quote Dr. L. S. Rowe as authority for the statement that the quality of the gas supplied has been improved by the company now operating the service, and that through the rental paid, the city has received for eight years an average profit of $491,674 annually, while for the last few years under city operation there was a loss of $245,398 per year. The private company, however, charges no more than did the city, but supplies better gas. "The Commission's records," say Messrs. Edgar and Clark, "indicate a high degree of efficiency in the company operation of the Philadelphia gas works, and kindly and liberal treatment of employees. On these latter points Dr. Rowe speaks as follows: 'As has been shown (under municipal management), there were abuses in almost every branch of the operation. The purchase of coal and the residual product were each under the control of favored individuals; the wages account was padded with incompetents, the friends of men prominent in city politics. It is unquestioned that there were leaks in the management of the gas works at other points than the distributing system; it is true that the labor account was debauched, and it is certain that in the purchase and sales departments there were influences at work which worked harm to the city's interests. But the loss through such sources was inconsiderable when compared with those inflicted by councils by the senseless blocking of the way to improvement in cutting off the appropriations for modernizing the plant. During the entire period of municipal operation the officers in charge were engaged in a losing fight to preserve the works from ruin. There never was a time during the entire period of responsible control when it could truly be said that the works were in an efficient condition.'"

Prof. Parsons claims that the experience at Philadelphia is of no value in settling the problem of municipal ownership. "It does not appear," he says, "that Philadelphia ever had real public ownership of the gas works. She had government ownership of gas works. But government ownership is not public ownership unless the people own the government. Philadelphia had the paper title to the gas works, but the people did not own or control them because they did not own the city government. The councils were full of the agents and allies of the private street railway, telephone, gas and electric light interests and they purposely mismanaged the gas works, allowed them to be filled with supernumeraries and let them get out of repair by refusing year after year to appropriate, even out of the receipts of the plant itself, the money necessary to keep it in order, so that they might have an apparently good excuse for executing a lease of the works to themselves. Philadelphia did not have real public ownership of gas, but one of the worst forms of private ownership—ownership by political grafters, in the pay of corporations, but masquerading as public servants."

With regard to water-works. Messrs. Edgar and Clark summarize the reports of the experts regarding the quality of the supplies in the cities previously mentioned as follows: "This phase of the question may be summarized with the statement that while the natural conditions in the different cities call for different methods of treatment, it is evident that the two companies examined were more solicitous regarding the purity of the water supply, and adopted more thorough means for insuring the same than did the three municipalities who ran their own water department. The conclusion drawn as a result of our investigation into the quality of the water is that the water supplied by the two companies is good, sanitary water; that its quality is much better than the water supplied in Chicago, somewhat better than the water supplied in Cleveland and quite as good as the water supplied at Syracuse. The latter place is blest with water from a source which, down to the date of this report, has remained pure without any special expense or effort on the part of the water department. It seems that the citizen obtains the cheapest water in Cleveland, while New Haven is the second cheapest. At Indianapolis the poor man gets water fairly cheap, but the cost increases rapidly as the class of dwelling improves. At both Chicago and Syracuse the poor man pays a high price for water.

Mr. Bemis, on the other hand, quotes the following typhoid fever death rates as proving municipalities are furnishing good water, as the lowest rates are in cities with public plants:

	New Haven.	Indianapolis.	Chicago.	Syracuse.	Cleveland.
1905	42.8	30.2	16.5	7.1	14.9
1906	52.0	34.2	18.1	9.2	20.2
Aver.	47.4	32.2	17.3	13.2	17.6

In reviewing the charges for water, he states that the rates are more favorable to the consumer with municipal plants, and particularly commends the low meter rates at Cleveland. He also declares that in spite of great reductions of rates in Syracuse on going from private to municipal ownership, and the phenomenally low charges for all residence consumers under the present meter system in Cleveland and the moderate charges also in Chicago, the financial results of municipal ownership, from the standpoint of the community and the taxpayer, are far better in the three municipal plants than in the case of the two private companies studied.

The municipal electric plants are criticized in various adverse ways by Messrs. Clark and Edgar. They state that the municipal lighting department of Chicago is run at an annual loss of $11.07 per lamp, although the city claims it makes a profit; that the character of the South Norwalk plant is such that the current costs 20 per cent. too much; that the Detroit plant is old and incapable of expansion, and the Allegheny plant is poorly designed, inefficient and expensive to operate. Mr. Bemis, on the other hand, states that the South Norwalk plant is one of the most successful in the world, and the Chicago plant is furnishing light at a lower cost than a private company would charge for similar service. Detroit, he considers the most successful plant after South Norwalk. Allegheny, he claims, has saved enough to pay for her plant out of the difference between her operating expenses and the $96 a year Pittsburg paid for similar arc lights prior to 1906.

Municipal Ownership in Great Britain.—The investigations made by the experts sent to study municipal ownership in Great Britain have been reviewed by Mr. Milo R. Maltbie, a member of the Public Utilities Commission, of New York City, and by Messrs. Clark and Edgar. Mr. Maltbie declares that, of the plants examined, those operated by municipalities gave in almost every instance a superior service at a lower cost than the private works. He does not consider actual ownership and operation to be necessary for the success of the municipal ownership idea; the power of a city to operate a public service undertaking has been as effective as actual operation in some cases. The same expert reports are held by Messrs. Clark and Edgar to prove that municipal ownership is productive of many and serious ills with little or no compensating good. They see various present difficulties which can only be met by electing municipal officers who will protect the people against injustice.

The gas plants examined by the Investigating Committee of the Commission were those conducted by the municipalities of Birmingham, Glasgow, Manchester and Leicester, and by private companies at Sheffield, the Newcastle and Gateshead Company, and the South Metropolitan Company of London. On the important subject of maintenance of plants, etc., Mr. Maltbie says that during last year every municipality set aside out of earnings a larger total to maintain or extend the plant or wipe out indebtedness than did any private company. As to the price of gas to the consumer, Mr. Maltbie points out that the private company at Sheffield is able to buy good gas and coke-making coal at a lower price than any other company or municipality and finds a market for its coke at its very door in which it receives more per ton than any other undertaking save one: and that it sold its by-products for more than the cost of its coal, oil and other supplies, making profit thereon of 2.13d. per thousand cubic feet of gas sold. No other undertaking was so fortunate, and a comparison as regards prices and costs between Sheffield and any other plant not so well situated would be misleading and unfair.

Mr. Edgar and Mr. Clark open their comments on the British gas situation by pointing out that the private companies supply gas at lower prices than do the municipalities. Thus, the relatively small cities of Newcastle and Sheffield get cheaper gas from private companies than do the larger cities of Manchester, Birmingham or Glasgow. The difference in cost per ton of coal does not explain this difference in the selling price of gas, according to the reviewers, who find that the greater efficiency in management and in energy in selling the by-products has much to do with the lower prices. The service given the consumer by the private companies is declared to be superior to that given by the cities, although it is pointed out that the investigation of the candle power of the light supplied was incomplete in the municipal plants because of the declination of the authorities to permit the experts to make full examination.

"The whole question of the quality of the product of the municipalities is in doubt," say the reviewers. "The members of the Commission and the experts who are familiar with gas and photometry see no escape from the conclusion that the above facts show that the service of the municipalities is not what it is claimed, that the municipalities are unwilling to have the actual quality of their service determined by independent and competent authorities, and that the gas supplied by private companies is much superior in candle power to that supplied by municipalities.

"In the year covered by this investigation, if, in the city of Birmingham, the Newcastle price of gas had prevailed, the consumers would have been £262,600 better off: if the Sheffield price had prevailed, the Birmingham gas consumers would have saved £350,000. The amount paid by the Birmingham gas undertaking into the common good was £69,813. So it seems that this city is playing a losing game with its municipal plant; it is mulcting its gas consumers from £250,000 to £350,000 a year in order that it may help out the municipal treasury with a paltry £70,000.

"In the case of Manchester, if the Newcastle price had prevailed, the gas consumers would

have saved £47,500; at Sheffield's price they would have saved £111,300. The amount contributed to the city treasury by the gas business was £60,000.

"In the case of Leicester, at Newcastle's price, the consumers would have saved £65,200, while if Sheffield's price had obtained they would have saved £90,500. The amount contributed by the gas business to the common good was £43,400."

A Problem in Underpinning.

The Mount Royal pumping station in Baltimore is one of the handsomest water-works stations in the country. It was designed for three 17,500,000-gal. Worthington horizontal triple-expansion engines and four batteries of two 200-h.-p. water-tube boilers, and has been a source of much pride to the city. It was recently asserted that the walls at a corner of the engine-room were insecure and underpinning operations have been commenced to strengthen their foundations. In an article in this journal on March 24, 1900, the following statement was made concerning the foundations: "After the site had been selected, test pits were driven at a number of points within the proposed limits of the station and bed-rock was found uniformly at a depth of 30 to 35 ft. To carry the walls, circular concrete piers from 4½ to 12 ft. in diameter were built up at intervals from the rock to about the height of the basement floor, and the spaces between the piers spanned with masonry arches springing from the piers as abutments. . . . As a large storm sewer runs through the site directly underneath the buildings, considerable trouble and ingenuity were required to locate the foundations so as not to strike this sewer, and at the same time properly distribute the weight of the superstructure and permit of the desired architectural effect."

The wall of the engine-room cracked somewhat in one corner and this was asserted to be due to failure to carry all the piers to bed-rock. The architect of the building, Mr. Henry Brauns, stated that the cracks need cause no apprehension, but the mayor determined to underpin the walls. Since the work was begun, Mr. Brauns made a strong protest against its character in a letter to the mayor, and submitted with it a report on the methods, written by Mr. Richard C. Sandlass, chief engineer and general manager of the Chesapeake Iron Works of Baltimore. This report discusses underpinning work from a point of view rarely mentioned in print, as will be seen from the following extracts from it. It was based on measurements made at a time when two of the needles, Marked 4 and 5 in the accompanying diagrams, were not in position, but openings cut in the wall showed their location.

The needle marked 1, consisting of three 18-in. 55-lb. I-beams 29 ft. long between centers of bearings has to support, Mr. Sandlass says, a concentrated load of 179,610 lb. arising out of one-half of the weight on pier 41 and one-half of the weight on pier 42, as shown in the diagrams. This load causes a stress of 56,400 lb. per square inch of section in these beams, and is very close to their ultimate strength. This is aggravated by the fact that the beams incline about 1 in. in 1 ft.

Needle 2, consisting of two 20-in. 65-lb. I-beams 22 ft. long between centers of bearings has to support two concentrated loads, one arising out of the reaction of needle 1, which is 108,386 lb., the other from one-half load on pier 41, which is 89,805 lb. This load produces a stress of 33,090 lb. per square inch of section in these beams, which is about the elastic limit of the material.

Needle 3, consisting of two 18-in. 55-lb. beams 13 ft. long between centers of bearings, receives a concentrated load arising out of one quarter of the weight on pier 23, equal to 56,400 lb., which causes a tensile stress of 7,895 lb. per square inch of section in both of the beams.

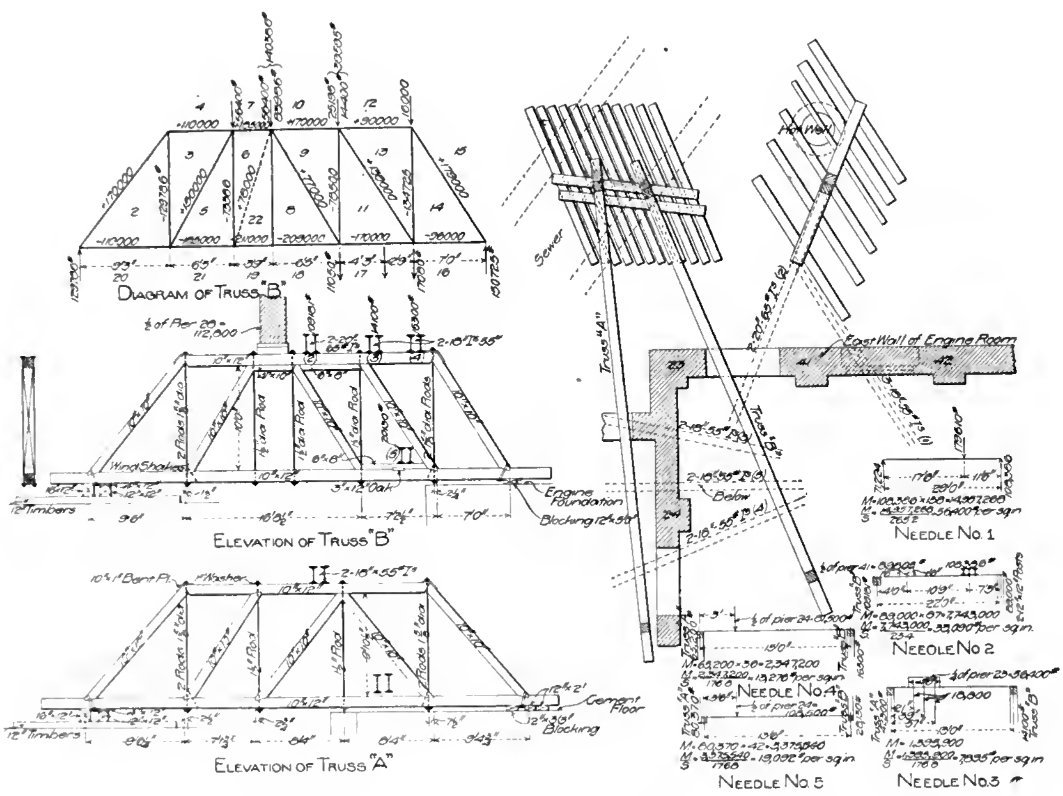
Needle 4, which was not in position at the time of the examination, consisting of two 18-in. 55-lb. I-beams 15 ft. long between centers of bearings receives a load of one-half of the weight on pier 24, equal to 81,500 lb., which causes a tensile stress of 13,276 lb. per square inch of section.

Needle 5, which was not in position at the time of the examination, receives a load of 10,500 lb., arising out of one-half of the load on pier 24, and two 18-in. 55-lb. beams would be sufficient in this case, as there is a stress of 19,092 lb. per square inch of section arising from this load.

Truss B receives a total load of 280,511 lb. distributed over four panel points in the top chord and two panel points in bottom chord, arising out of the reactions of needles 2, 3, 4 and 5 and from one-half of load on pier 23. The end asmuch as member 14-13 consisting of two rods 1⅝-in. in diameter not upset, each having a net area of 1½ sq. in., receive a total stress of 44,908 lb. per square inch. The net area of 1½ sq. in. of rod is assumed at the root of the thread.

Member 9-11 consisting of one rod 1½-in. in diameter, having a net area of 1.35 sq. in., receives a total tensile strain of 78,500 lb. This, however, divided by the net area gives a stress per sq. in. of 57,810 in. The reaction of 109,181 lb. of needle 2 causes a compression in the top chord, crosswise, of 873 lb. per square inch and is mostly on one edge of the top chord only, inasmuch as this needle has a slight incline. The ultimate resistance to compression crosswise of Georgia yellow pine is about 1,260 lb. per square inch, which would leave but little margin for safety.

The timber foundation under the east end of trusses B and A consists of one 12 x 16-in. timber, one 12 x 12-in. and one 4 x 12-in. laid flat,



Underpinning Employed at Mount Royal Pumping Station.

post 14-15, of 10 x 10-in. Georgia yellow pine, 14 ft. 6 in. long between chords, with an area of 100 sq. in., receives a compressive strain of 179,000 lb., which is equal to 1,790 lb. per square inch. The ultimate strength of a post this length, about 5,757 lb. per square inch, divided by 1,790 lb., gives a safety factor of 3.2.

Bottom chord number 8-18, consisting of 10 x 12-in. Georgia yellow pine, having a net area of 102 sq. in., receives a tensile strain of 209,000 lb., or 2,049 lb. per square inch. Bottom chord 11-77, being 10 x 12-in. Georgian yellow pine, having a net area of 105 sq. in., receives a tensile strain of 170,000 lb., and a moment of 563,640 in.-lb., arising out of the reaction of needle 5. This causes a tensile stress of 4,210 lb. per square inch. This gives a safety factor of three, assuming the ultimate resistance of the timber to tension as 12,600 lb. per square inch. While all these stresses in wood members of the truss referred to are in excess of those usually assumed in good engineering practice, Mr. Sandlass states, especially in view of the fact that the timber used is not of the very best, the wooden portion of the truss will probably carry the loads that come on it now with a small margin.

The unit stresses in the steel rods of the trusses, however, are considered by him to be so excessive as to endanger the construction, in-

and distributes the reaction of both trusses over twelve timbers 6 x 8-in., 8 x 8-in., 8 x 12-in. about 16 ft. long aggregating about 205 sq. ft. The total reaction of truss A being about 87,000 lb. and truss A 130,000 lb. makes a total of 217,000 lb. and this divided by the area of the timber gives a total load of 1,058 lb. per square foot on the ground. While this is not considered by Mr. Sandlass to be excessive on firm or even bad ground, he does not regard this foundation as absolutely safe because it is immediately above a large sewer.

The foregoing calculations are based on loads figured from the architect's drawings, but Mr. Sandlass reduced all crane, roof and floor loads by half in order to eliminate live loads in the calculations. This, while not exactly conservative, would with proper safeguards be permissible in this case, he believes. All wall loads assumed in the calculations do not include the weight of the wall from the engine room floor to the concrete foundations, except in the case of needle 5. If the full wall loads are ultimately carried by the trusses the strain in the different members will be proportionately increased. Truss B is not considered by Mr. Sandlass as a perfect system inasmuch as it should have another brace 6-22, indicated in the diagram by a dotted line, in order to develop the full capacity of the truss.

Power Plant of the West Street Building, New York City.

The West St. Building is a 23-story, steel-cage structure recently completed on West St., on the Hudson River front, in New York City. It is intended solely for office purposes, to which all floors above the basement are devoted. It occupies an irregular plot about 120 x 160 ft. in extreme dimensions, with the West St. front parallel to and about 300 ft. distant from the Hudson River bulkhead line. Interesting structural features of the building and of the substructure, necessitated by the proximity to the water front, were described in an article in The Engineering Record for Dec. 29, 1906.

It is a large building, rising to a total height of about 300 ft. above the sidewalk level, and having about 1,200 sq. ft. on each of its 23 floors, or a total of nearly 275,000 sq. ft. of floor space in the entire building, exclusive of the basement. The upper office floors can be arranged for subdivision into a maximum of 20 offices, if required, there being about 300 office groups in the entire building as it is now sub-divided, an average of about 12 suites to every floor. Accordingly an extensive mechanical plant was necessitated for the operation of the building, which includes not only the elevator and heating service, but also electric current for both lighting and power purposes. Besides this the usual auxiliary services have been provided for, including a vacuum outfit for office cleaning purposes.

Owing to the sub-structure conditions encountered in the construction of the building, very limited basement space could be provided, the difficulties in excavation rendering a minimum of sub-surface space advisable. Accordingly there is only a single basement with its floor level 11½ ft. below the main floor of the building, with the exception of a section in the southerly central portion where the floor was depressed some 7 ft. further, to provide ample head-room for the boiler equipment. The greater part of the basement is below ground-water level, so that the cellar floor and all the walls were carefully waterproofed to prevent leakage. Provisions have, however, been made to provide for the removal of any leakage that might possibly occur, consisting of a series of sub-floor drains which discharge through a 6-in. vertical cast-iron pipe into a deep central sump pit which has been provided for the natural drainage within the basement due to the leakage from piping systems and other causes. This pipe connection will normally be closed, but in case of unexpected leakage through the foundations at any place, it may be connected to a pump and water thus pumped from beneath the foundation and floors to keep the basement dry. This was installed as an emergency provision, however, and it is not expected that it will be needed under ordinary conditions.

About two-thirds of the basement is devoted to the mechanical equipment, that under the front portion and under the West St. sidewalk being used as store rooms for the offices and salesrooms on the main floor front. The space is divided into a 40x60-ft. boiler room in the south central portion of the basement, with a coal bunker under the Albany St. sidewalk; at the rear of this, a 30x85-ft. engine and dynamo room; a 15x50-ft. space in the center for the elevator mechanism and operating valves, and the large irregularly-shaped space in the northeasterly corner, 80 x 90 ft. in extent, in which are located the elevator pumps and tanks, the miscellaneous pumping equipment and other auxiliary apparatus. The head-room in the basement is very limited, averaging but 9½ ft. in the greater part, except in the boiler room which is depressed 7 ft. lower, giving 16½ ft. clear head-room to accommodate the overhead flue and piping connections. All inside drainage in the basement is accordingly directed to the boiler room in which there is at one corner a sump pit containing a 3x4-ft. cylindrical steel tank from which drainage can be removed by the sump pump. The interior of the pump and machinery sections is attractively finished, the ceilings and walls being plastered with an asbestos finish and the floors laid with tile. Very little daylight lighting is available, however, except at the outer edges of the basement where lighting is had through sidewalk lights.

For the generation of steam, four 250-h.-p. Keeler water-tube boilers have been installed. They are set in two batteries of two each between building columns in the boiler room, giving a total boiler capacity of 1,000 h.-p., while there is also space available for the addition of two more units of equal size. A 7-ft. space was left at the rear of the settings for the breeching and blow-off connections, while at the front there is a 12-ft. firing floor, in which an industrial track of 24-in. gauge is laid for the handling of coal and ashes. The former is, as above noted, stored in the bunker space underneath the Albany St. sidewalk, which is 10 ft. in width and extends from the boiler room to the West St. front. The floor of the bunker is depressed to the level of the boiler room floor alongside of that room, but to the west of the latter it was, for foundation construction reasons, raised to the level of the basement. The bunker is filled by dumping through sidewalk coal holes on the Albany St. side, and has a total capacity of over 200 tons. The narrow-gauge track extends into and through the lower portion of the bunker on which the charging cars are filled by shoveling, while in the raised portion at the front, there is a short section of the narrow-gauge track on which runs a 500-lb. dumping car into which coal may be shoveled and wheeled to the front for dumping into the charging cars on the lower track. There are two steel charging cars of one-half ton capacity, and a branch of the narrow gauge track permits them to be run around to the ash lift at the rear of the bunker for handling ashes in cans up to the sidewalk for removal. The products of combustion are removed from the furnaces through a 4½x5½-ft. breeching on the ceiling at the rear of the settings, which connects in the pump room with an elliptical steel stack rising above the roof line, to a level about 350 ft. above the grates.

The boilers are of the horizontal inclined tube type built by E. Keeler Co., Williamsport, Pa. They each have 124 4-in. tubes 18 ft. in length, which are arranged in 14 rows, each 9 tubes high. The steam drums are 48 in. in diameter by 20½ ft. long, to which the forged steel tube headers are directly attached, the total heating surface presented by each unit being 2,500 sq. ft. The boiler units are hung in steel frames, enclosed in substantial brick settings with brickwork arched over the steam drums, and are fitted with Ajax shaking grates of 52 sq. ft. grate area for hand firing. Owing to the arrangement of settings necessitated by lack of space horizontal baffles were required between tubes instead of the usual vertical arrangement. The boilers deliver steam at 150 lb. pressure and recent calorimeter tests at the plant indicate less than 0.99 per cent. of moisture. Each boiler has a 2½-in. blow-off connection from the rear tube header to a 3-in. blow-off line at the rear of the boilers which discharges into a blow-off tank, with cooling coil at the rear of the boiler room. This tank, being below the sewer level, is emptied by a duplex steam pump of 40 gal. capacity, which is under the control of a float mechanism adjusted to maintain the tank always partly filled. The boilers are fed by both injectors and pumps, each boiler having an independent injector, which draws from the city water connection and may be used for feeding or boiler testing, as desired. There are three pumps used for boiler feeding, each of which is a brass-fitted, outside-packed Platt Iron Works duplex pump of the double plunger type, having a capacity of 40,000 lb. of water per hour at 50 strokes per minute. Two of them, having 6x4x6-in. cylinders, are located at the rear of the boilers and connected to return condensation from the heating system, while the third, an 8x5x10-in. pump, is on the side of the settings and draws from city water connections or from the feed water heater, all delivering through a 3-in. feed line to the boiler fronts. The principal source of feed will be condensation returned from the heating system which is delivered to a 3x6-ft. condensation surge tank at the rear of the boilers and pumped thence by the condensation pumps under control of a pump governor through the feed main to the boilers. The feed heater is an exhaust muffler and separator tank, which is connected in the exhaust steam main and serves both as an oil separator and feed water heater. It is located in the pump room near the corner of the boiler room, and is 5 ft. in diameter by 9½ ft. long, being connected directly into the exhaust steam main with by-pass.

The high pressure steam piping departs from usual practice in that the mains are not in duplicate, the system consisting of a 12-in. header in the engine room adjacent to the boiler room wall, which has 7-in. supply connections from each of the boiler units and 5-in. delivery connections to the generator engines, a 3-in. live steam make-up connection to the heating system and an 8-in. delivery line to the steam pumping units in the pump room. All of the high-pressure piping is of extra heavy wrought-iron pipe with long-radius bends, the boiler branches having gate valves at the header and stop and check valves at the boiler nozzles. All of the high-pressure piping is run on the ceiling and is covered with 2-in. of magnesia covering, canvas jacketed, while the low-pressure piping from the engines and steam pump exhaust connections is carried in trenches to the muffler tank. The trenches extend to all engine cylinders and to all of the pumps, and are for the greater part 18 in. in depth, ranging from 20 to 36 in. in width. The low-pressure system consists of two divisions, one of which is a 12-in. line to the engine room and the other a 12-in. line to the pump room, the two joining into a 16-in. connection to the muffler tank, in the boiler room. The engine room division has 8-in. valve connections to each of the generating units and a 6-in. branch extending into the boiler room to receive the exhaust of the condensation sump and boiler feed pumps. The pump room exhaust main has 3 and 6-in. branches to a number of small auxiliary pumps and a 10-in. extension which serves the large and small elevator pumping units and the jack pump. From the muffler tank outlet, a 16-in. low-pressure riser is carried up to the roof of the building to connect with the overhead distributing mains of the heating system and thence through a back-pressure valve to the roof exhaust head. Condensation is dripped from all of the high-pressure piping by the Holly gravity return system, while for the low-pressure piping connections, there are two drip systems, one for the clean drip and the other for the oily drip; the former consists of all bleeder and drip connections from low-pressure piping, engine exhaust valves and other points where clean condensation water will be obtained, while the unclean drip system consists of the cylinder cock connections, the oil drip chambers, and the like. The clean drips are returned to the feed water heater and the condensation surge tank in the boiler room to be delivered to the boilers, while the unclean drips are discharged into the boiler room sump for delivery to the sewer.

With the original considerations of design, the electrical generating plant was laid out for a total capacity of 800 kw. to provide for a very heavy lighting load occasioned by some special illumination which was planned for a large tower on the roof of the building. Subsequently the tower feature and its illumination were temporarily abandoned and a total generating capacity of but 550 kw. provided, although space has been arranged for an additional 200-kw. unit to be installed at any later period desired. The present capacity is divided into two 200 and one 150-kw. units, so that with the addition of the possible future 200 kw. unit, the total generating capacity would be increased to 750 kw. The generating units consist of Western Electric slow-speed, engine-type generators which are direct connected to Fitchburg four-valve compound engines, which operate non-condensing. The engines are of the heavy-duty, side-crank type with Tangye frames and have the usual Fitchburg valve gear with double eccentrics for independent operation of admission and exhaust valves and giving results approaching very closely to that of the Corliss valve gear. The governors are of the centrifugal shaft type providing for a long range of cut-off and regulate within 1½ per cent. The two larger units have 16 and 24x26-in. cylinders and when operating at 150 r.p.m. and 125-lb. steam pressure have a capacity of 320 h.-p. The small unit has 14 and 22x20-in. cylinders and operates at 200 r.p.m., at which it has a rating of 225 h.-p.

A feature of the engine installation is the use of particularly massive engine foundations with sand cushions to prevent possible communication of vibration from the generating units to the building. All three of the engines are carried on a single large block of monolithic concrete, 3¾ ft. in maximum depth, which, it is calculated, will absorb initially the motion of the reciprocating parts of the engine. Between the concrete block and the underlying earth and also the adjacent building column footings, a continuous sand cushion is provided, which effectually maintains the position of the block yet insulates it mechanically from any part of the building. The sand cushion is made 6 in. in thickness in all horizontal planes and 3 in. in thickness between the edges of the block and the adjoining building foundations. The block is continuous longitudinally under the engine cylinders, being cut into at the fly-wheel ends only, in order to straddle building columns which are encountered. The engine equipment was installed complete by E. H. Ludeman & Co., New York.

The generators are multipolar direct-current generators wound for 125 volts, and arranged to operate on the two-wire systems for which the building is wired. They are compound wound, the over-compounding amounting to 5 per cent., with a variable shunt so as to allow maintaining the voltage constant automatically from no load to full load. They are so rated as to permit of operation at 33⅓ per cent. overload for two hr. duration without excessive heating. The generator and electrical distribution circuits are controlled on a 9-panel marble switchboard at the northerly end of the engine room, which consists of four generator panels, one totalizing panel and three lighting and one power panels. The panels have the usual equipment of instruments and switches, the total panel having wattmeters for both power and lighting services, a tie switch and ground detector equipment. There are 20 circuits controlling the lighting of the building and 15 circuits controlling the power circuits to the various motors, every motor in the building service being operated on an independent circuit for direct control from the switchboard. The generators and switchboards were built and installed by the Western Electric Co., New York, general contractors for the electrical installation.

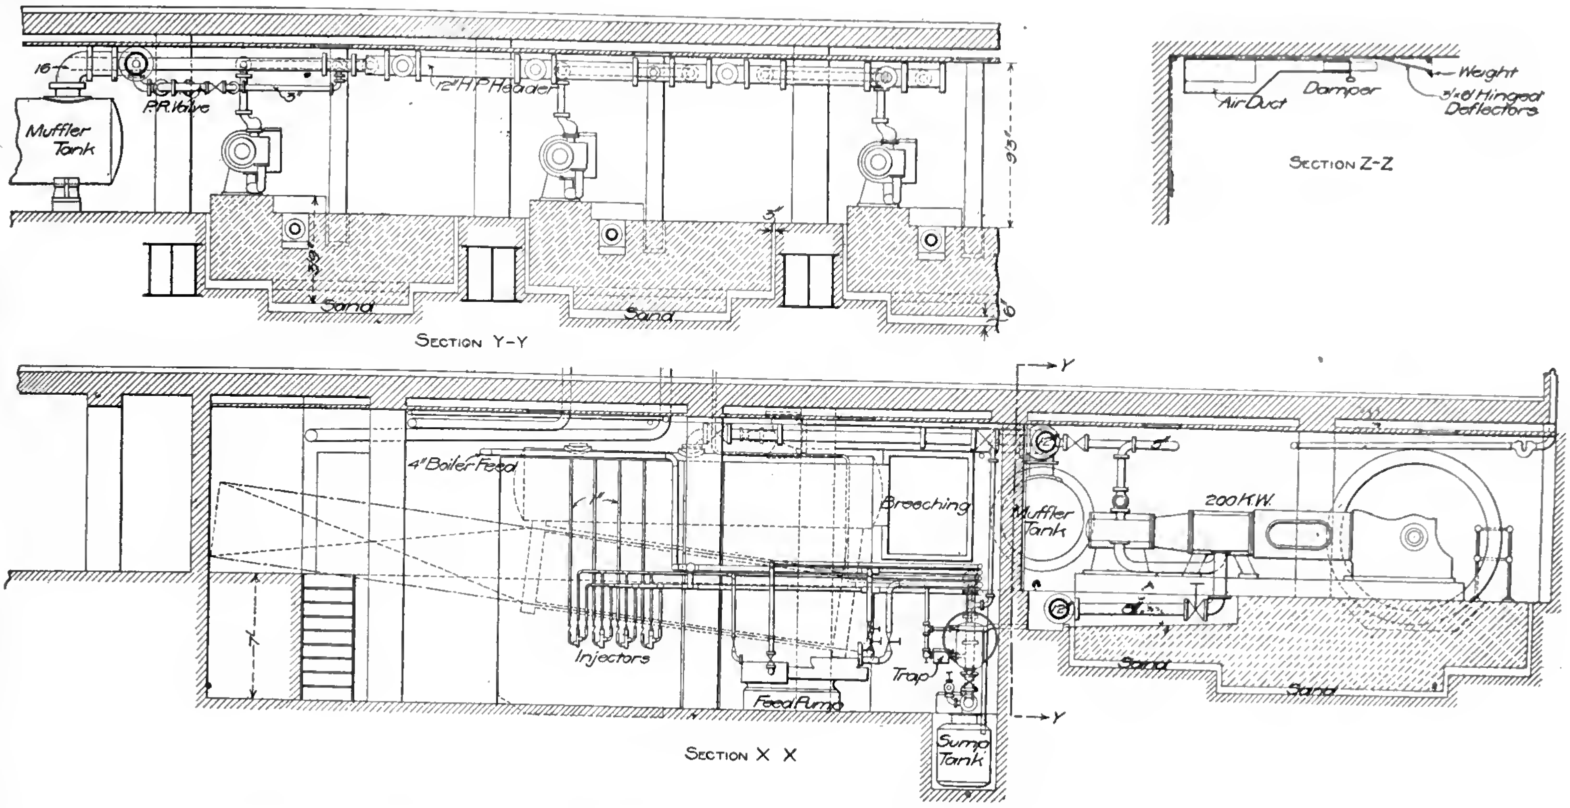
The heating system of the building involves direct radiation throughout, operated with low pressure exhaust steam from the power plant, there being no mechanical ventilation provided for, except in the heated machinery sections of the basement. The radiation is proportioned in the usual manner to maintain the temperature of the interior to 70° Fahr. in all conditions of weather, the radiators being located under window-sills for direct counteraction of the glass exposure. Owing to the large amount of exterior exposure of the building and the open unsheltered position of the building itself, a large amount of radiation was necessary. Over 52,260 sq. ft. of radiation are installed on the main and upper floors of the building, which is an average of 2,270 sq. ft. on each of the 23 floors. Cast-iron Peerless radiators have been installed throughout, which are of the 4-column type, 23 in. high, on the main floor; in all corridors and elevator halls of the 2-column type, 39 in. high, while in all of the offices from the second to the twenty-third floors inclusive, they are of the 2-column type, 26 in. high, for location under window sills. A feature of the distribution of radiation is the location of individual radiator units under each of the outside windows, no matter how the office spaces are at present sub-divided; with this method the radiation is evenly and thoroughly distributed throughout all parts of the building and thus no future re-arrangements of office partitions will necessitate the changing or addition of radiators in any part of the building, as is usually the case in office building alterations.

The radiation is supplied with steam on the one-pipe system with the Paul system of air-piping for positive circulation. The heating supply mains embrace an overhead distribution system to which down-feed risers are connected, the latter being connected at their lower ends in the basement to return gathering mains which deliver the condensation to the surge tank in the boiler room for return to the boilers. The heating supply system originates in the 16-in. exhaust steam riser which leads from the muffler tank in the pump room up to the roof of the building through the elevator shaft, and ends in a back-pressure valve and exhaust head at the roof line. At the 21st story level, a 16-in. branch connection is made from this riser to a series of distribution mains under the floor, which connect with and deliver steam to each of the entire group of 32 down-feed risers. This distribution system consists of a 12-in. line extending longitudinally through the building in either direction from the 16-in. connection, and supplying branches along the outer walls which taper in size as connections to the risers are taken off. These risers drop down from the supply connections as 3½ and 4-in. lines, tapering as connections are made to radiators, at the fifteenth floor to 3 and 3½ in., at the eleventh floor to 2½ and 3 in., and at the fourth to sixth floors down to 2-in. lines, which are carried through at that size to the basement return gathering mains. Twenty-two of the risers are carried above the twenty-first floor for the supply of radiation in certain portions of the twenty-second and twenty-third floors as 2-in. lines. Owing to the height of the building the expansion of these risers introduced a troublesome factor. It is provided for by the anchorage of all of the risers to the building construction at six points, namely, the fourth, seventh, tenth, fourteenth, seventeenth and twentieth floors, between which points slip expansion joints are inserted; the latter occur at five points, namely, above the fifth, eighth, twelfth, fifteenth and eighteenth floors, and consist of Crane iron-body expansion joints with brass sleeves.

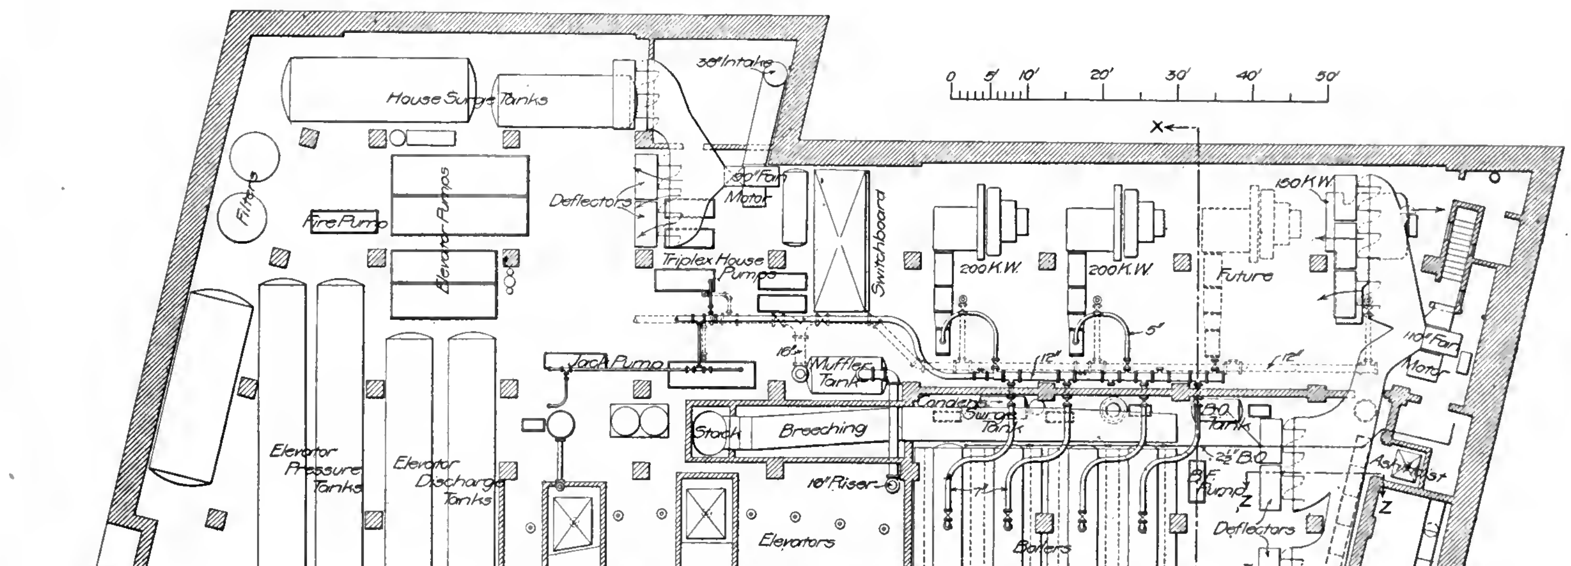
The riser lines are, of course, all dripped directly into the condensation gathering mains in the basement with which the risers connect at the base. The return gathering system consists of a series of 3-in. lines which connect with the various branches from the risers and pitch sharply toward the condensation surge tank for proper drainage. Owing to the extreme distance of supply from the muffler tank in the basement to the lower floor radiators, by way of the twenty-first story distributing main, a dry equalizer system has been installed in the basement connecting the muffler tank and the lower end of practically all of the riser lines. This system consists of a 6-in. main extending from the muffler tank and parallel to the return gathering mains, which has 2-in. connections into the majority of the risers at points above the first floor level. These connections are so made as not to drain condensation from the risers, but to supply only such a limited amount of steam to them as may be necessary to equalize their lower ends against drop in pressure which might occur in case of heavy consumption of the low pressure steam.

Ventilation is, as above stated, provided only in the heated machinery sections of the basement, where it is desired to moderate the temperature for comfort of the workmen. Communication of heat to the main floor is prevented by an asbestos ceiling finish in all machinery sections of the basement consisting of 1½ in. of asbestos plaster on wire lath, over a 1½-in. air space. The basement ventilation is accomplished by separate ventilating equipments installed for both the boiler and engine rooms, and the pump room, which are arranged to deliver untempered fresh air in either case. They are installed of sufficient capacity to change the air in the rooms served approximately twenty-five to thirty times per hour. The blowers are conveniently located, as shown in the basement plan, near outer walls, for in-take connections, that for the pump and machinery room under the lighting and ventilation court at the rear of the building, to which a 38-in. intake duct is carried up from the fan intake. The engine and boiler room system is conveniently located adjoining a stairway entrance from the Albany St. sidewalk into the engine room, so that the fan has a short direct connection from its intake to the open stair-well. The fans are 90 and 110-in. steel plate centrifugal fans of the full-housed peripheral-discharge type, built by the American Blower Co., and are driven by Western Electric motors of 12 and 25 h.-p. respectively, which operate on the power and lighting circuits of the building. The systems are each fitted with a novel arrangement of deflectors for directing the blast from the outlet registers in any direction desired for the comfort of the workmen. These consist of both horizontal and vertical vanes, the vertical vanes being butterfly dampers located directly in the duct outlet openings and may thus serve as dampers for adjusting the volume of flow, or to control the direction of the flow, in a horizontal plane; the horizontal deflectors are 36-in by 6-ft. galvanized iron sheets mounted on steel frames which are hinged to the ceiling in front of the register outlets and arranged for adjustment of position by cords passing over pulleys to the outer edge and controlled from the adjoining side-wall. The latter permit the blast to be diffused generally into the room or directed toward the floor close to the register outlets, while the butterfly dampers allow the air to be blown forward directly into the room, spread to the sides or partially closed off.

The elevator equipment of this building consists of nine passenger elevators and two sidewalk lifts, which are all of the plunger type installed by the Standard Plunger Elevator Co., New York. Five of the passenger elevators have travels from the first to the twentieth floors, a rise of 245 ft., two from the first to the twenty-



Sections through Boiler and Engine Rooms, West St. Building.



Plan of the Mechanical Plant of the West St. Building, New York City.

third stories, a rise of 285 ft., one from the basement to the twentieth story, a rise of 256 ft., and the other from the basement to the twenty-third story, a rise of 296 ft. These are all operated by a 6⅞-in. plungers, working in 10-in. cylinders and with a hydraulic operating pressure of 180 lbs. per square inch, have a maximum capacity of 2,500 lb. each, or 1,500 lb. each at the maximum speed of travel of 600 ft. per min. A sidewalk lift on the West St. side of the building and the passenger elevator rising from the basement to the twenty-third story are fitted for operation with extra pressure for lifting safes and extra heavy weights; when operated by the jack pump for this purpose, they have a maximum lifting capacity of 8,000 lb. at a speed of travel of 50 ft. per minute. The other sidewalk elevator is an ash lift which rises from the boiler room floor to the Albany St. sidewalk for the purpose of communication with the boiler room and the removal of ashes.

The elevator plant is operated by a novel equipment of compound and triple expansion duplex pumps which provide in an interesting manner for emergency operation and reserve. There are two pumps, the larger unit a triple-expansion pumping engine with 15 and 24 and 36 steam cylinders, and a 14½-in. water cylinder, all with 24-in. stroke, while the other unit is a compound pump, having 16 and 26 in. steam cylinders, and 14½-in. water cylinder with 24-in. stroke. The pumps, although of duplex construction, are built with separable valve gear in both the compound

and triple expansion units, and have independent steam and water connections throughout, so that in case it is desired to operate at reduced capacity, either unit may be sub-divided into one-half of its total capacity and either side operated while the other is shut down. It is estimated that this arrangement has saved the installation of an extra pump, as there are thus provided four independent units, although under normal operating conditions they will be operated as two. For regular service the large triple expansion unit will be used, although while either side of this unit is under repairs, the other side and the smaller unit may be utilized as necessary. The pumping plant as thus installed is figured to be capable of operating the passenger elevators and sidewalk lifts when running on a schedule of a round trip every two minutes, for the passenger elevators, allowing five of them to go up at the same time, and a round trip of the sidewalk elevators every three minutes. The elevator tank equipment consists of two pressure tanks and two tanks for discharge, all of which are cylindrical steel tanks horiontally arranged in the front portion of the pump room, the two pressure tanks having each a capacity of 12,000 gal. and the discharge tanks a capacity of 10,000 gal. Air pressure for maintaining the necessary air space in the pressure tanks is furnished by two Westinghouse locomotive-type steam air pumps. The Jack pump is a 9x4½x10-in. duplex pressure pump which has independent piping connections to the sidewalk lift and the passenger elevator rising from the basement to the twenty-third floor. The entire pumping equipment was supplied by the Platt Iron Works Co.

For cleaning and renovating purposes a vacuum sweeping system was installed as a permanent part of mechanical equipment, embracing steam ejectors and dust separators in the basement with suction lines extending to all upper floors, the equipment having been installed by the American Air Cleaning Co., New York. This apparatus is located in the central portion of the pump room, and from the separators, a 3-in. vacuum line extends to either side of the building to connect with the two 3-in. vacuum risers in the corridors. These risers are conveniently placed for reaching any of the offices and at each floor there is a 1¼-in. branch connection ending in a 1-in. air cock attachment for the sweeper hose.

The architect of the building was Mr. Cass Gilbert, New York City, and it was built by the John Pierce Co., general contractors. The power plant, heating and ventilating and entire mechanical equipment was designed by Mr. Burt S. Harrison, consulting engineer, New York.

A DRY-DOCK, 1,050 ft. long and 114 ft. wide at the coping will be built at San Francisco by the San Francisco Dry Dock Co., from the plans of Mr. Howard C. Holmes.

Notes on Water Purification at St. Louis.

Abstract of a paper read before the American Water Works Association by Mr. W. F. Monfort, Chemist of the St. Louis Water Department.

The necessity of coagulation in purification of turbid waters of high color, such as occurs in many of our Western rivers, is generally recognized. It has been thought that the interest in the matter of coagulation and sedimentation as an essential part of any method of purifying such waters, whether in connection with, or apart from filtration by slow-sand or mechanical filters, will justify the presentation before this association of a brief statement of chemical and bacterial results for the past year at one of the larger plants, treating daily an average of 70,000,000 gal. of a water whose average turbidity is above 1,200, whose color is above 40, and of an alkalinity equivalent to 135 parts per million of calcium carbonate, using lime and iron sulphate as coagulants, without the use of filters.

The low-service pumping station and coagulating plant of the St. Louis water works system are located in the extreme northern part of the city at a point on the Mississippi River, about five miles below the mouth of Missouri. From this intake tower in the stream some 1,500 ft. from shore, the supply flows through a tunnel to a well or uptake shaft beneath the coagulant house, where it receives its charge of iron sulphate, thence through the inshore tunnel to the wet well. At this point it is freed from ice, when necessary, by bucket conveyors. From the wet well, the water with its charge of iron sulphate is lifted by the low-service pumps to the distributing well, where the charge of milk of lime from the coagulant house is delivered by centrifugal pumps. It then flows by gravity to a series of six uncovered sedimentation basins, 670 x 400 x 14 ft. (average depth), having a working capacity of about 24,000,000 gal. The weirs between the successive basins are 610 ft. long. A conduit runs on either side of the system of basins, allowing filling and drawing from any basin at will; in practice the end basins alone are used for filling. From the drawing conduit, the treated and settled water passes by a conduit 7 miles long to the most southerly high-service pumping station at Bissell's Point, where there are four smaller storage basins, and the clear well. From the latter as also from a basin connected with the conduit at an intermediate point three miles above, the high-service pumps deliver the water to storage reservoirs and to the mains.

The raw water partakes very largely of the character of the Missouri River water, being ordinarily so much higher in turbidity than the Mississippi above the confluence of the rivers that the line of demarcation between the two waters is plainly noticeable. As showing the variable character of the water, Diagrams Nos. 1, 2 and 3 are introduced, giving in graphic form the maxima and average for each month of the past year of a few prominent characteristics.

Fluctuations in turbidity of 2,000 or more parts per million occur in April, June, July, September and January; the difference between maxima and minima is less than 1,000 in May, November, December and March. The maximum turbidities for June and July were 3,600, for September and January 2,400, with a minimum of 120 for February. The year's average was 1,248 parts per million.

Fluctuations in suspended solids as determined by weighing are even greater than those of turbidity, being above 3,000 for June, July and January, about 2,000 for February and March and less than 1,000 for four months, May, October, November and December. The maximum of the year falls in June 5,300 parts per million or almost 31 grains per gallon, while for January it was 3,678 or 21 grains per gallon. The year's minimum was 122 parts per million or 7 grains per gallon. The monthly average follows generally the curves of maxima and minima. The year's average was 1,205 parts per million or about 70 grains per gallon.

The wide variation in the character of the suspended matter is shown in Diagram No. 2. From a minimum fineness of 0.555 in September to a maximum of 2.415 in January, with the year's average at 0.953, slightly less than the standard fineness. The peaks of June (1.6) and January (2.4) mark flood stage, with consequently coarser material transported.

The minimum alkalinity of the year, 63 parts per million, occurs in January flood water, when the variation was more than 100 parts per million. Otherwise the monthly variations lie within smaller limits of 10 to 80 parts per million. The average for the other months runs from 107 to 167 parts per million. The color range is from 25 to 71 with a yearly average of 43.

Diagram No. 4 shows two typical cases of fluctuation in character of the river water, the curves of this diagram having been plotted from the data in Table 2. From January 17 to 24 the river rose 11.5 ft., with a corresponding rise in turbidity from 400 to 2,500 parts per million, and a decline in alkalinity from 137 to a minimum on the 23rd of 63 parts per million. The dissolved solids declined from 255 to 138, color fluctuated irregularly, but remained high throughout. This is typical of a seasonable flood. It was on January 19 that the coefficient of fineness reached 2.4.

TABLE 2. TYPICAL FLUCTUATIONS IN CHARACTER OF RIVER WATER.

1907.	Gauge.	Turbidity.	Color.	Alkalinity.	Dissolved Solids.
Jan. 17	85.8	400	45	137	255
18	88.4	600	60	120	220
19	90.3	1000	60	107	192
20	94.0	1500	60	104	...
21	96.7	1800	65	80	138
22	97.1	2400	55	65	141
23	97.3	2400	55	63	142
24	96.9	2100	45	68	155
May 27	86.2	750	50	127	219
28	86.9	600	35	130	238
29	87.0	1500	50	130	221

The other case occurred in May, 1907, and is typical of the Missouri habit of cutting a new channel suddenly. Accompanying a rise of 0.1 ft. comes an increase of turbidity from 600 to 1,500 parts per million, while the dissolved solids, alkalinity and color waver slightly but independently of the turbidity. Cases less marked than this latter one have been of constant occurrence througout the year, wherein the shifting of the channel of the Missouri and of the Mississippi just below their confluence, has caused similar wide and sudden fluctuations.

It has been stated already that in the St. Louis plant the removal of suspended matter is accomplished without appeal to filters. On passing to the first or filling basin in the series of six previously mentioned, the coagulated

water from the distributing wells carries its natural sediment and added coagulum. Sedimentation is so rapid that before the first basin is traversed the water is very largely clarified. The turbidity is reduced to about 15 parts per million on leaving the first basin; most of the suspended matter is fairly coarse at the first weir, and drops out in passing the succeeding basins, so that at the third weir the turbidity approximates 12, at the fifth 10 or less. It will be understood that the suspended matter in the earlier basins is too coarse for accurate determination by optical methods. Direct weighing of the suspended matter show results which are tabulated with other data in Table 3.

The figures given are monthly averages for March, 1907. The daily data for the same period vary but slightly from the averages. In the accompanying diagram, No. 5, these data have been reduced to a percentage basis, save the color, which is platted in parts per million.

Accompanying a reduction of suspended matter to less than 2 per cent., the bacterial reduction through the basins goes with almost even progress. When it is remembered that a portion of the suspended matter carried over the weirs is adventitious, produced by the softening reaction, and not bacteria laden, as is the original river sediment, it will not be surprising that the sudden decline in the solids has accomplished the removal of so large a percentage of bacteria. Most of the original sediment and the coagulum fall out in the first half of the first basin, leaving the deposit heaviest about the filling gates.

Basin No. 1 was put into commission January 8 and the March data plotted show results in the third month of use. It must be stated, however, that the sewer of the filling basin is opened daily without interrupting its use, to allow the lighter accumulated flock and sediment to flow out.

The March averages plotted in Diagram No. 5 are representative of the best working of the system and of the best results attained. During the period January 8 to March 30 the average removals were almost as satisfactory, as shown in Table 4.

TABLE 4. AVERAGE BACTERIAL REMOVAL—PER CENT.

	Basin 1.	3.	5.	Tap.
Jan., 1907	93.7	96.	97.4	98.87
Feb.	95.9	98.4	99.0	98.8
Mar.	96.1	99.1	99.8	99.88

As typical of results through the year a period in March, showing the character and extent of the changes in the raw water effected by the treatment, was selected for presentation here. The results obtained during this period are given in Tables 5 and 6, and are shown graphically in Diagrams Nos. 6, 7 and 8.

Consideration of the Diagram No. 8, makes it evident that there is no necessity for carrying caustic alkalinity through the basins to secure satisfactory bacterial removals. Not only was the tap water free from caustic during the period under consideration (March 4-11), but no caustic appeared in any samples on passing weirs 1, 3 and 5, save on the 9th and 11th of March. This conclusion finds further support by consideration of daily data for the entire month, as well as the longer period, January to March. It appears, further, that removal of colon bacillus is likewise not dependent upon the presence of free lime through the basins, since tests for coli were negative throughout the week represented by Diagram No. 8, and also throughout the month.

The averages given for this period differ but slightly from the averages for the year, save in the extent of the removal of the magnesium, and in the actual number of bacteria per cubic centimeter, which are unusually low.

The raw and treated water at Bissells' Point (the Southerly high-service station) for the year averaged as follows:

	River.	Treated Water.
Suspended solids	1,188	3.8
Color	43	10.7
Alkalinity	135	49.
Calcium	42.3	22.8
Magnesium	13.1	4.5

being a reduction of the calcium to 54 per cent. and of magnesium to 57 per cent. of the original content of the raw water. In the river water there is approximately 0.05 parts per million dissolved iron; in the treated water 0.02 parts per million dissolved iron, while the total iron content of the water from the clear well varies from 0.1 to 0.25 parts per million. Most of this is in the form of ferric hydroxide adherent to or absorbed by fine suspended siliceous matter and is in large part carried down with it in the after reactions, which are still incomplete in the clear well.

The color reduction has not been pushed below an average of ten because the popular appreciation of colorless water has not yet developed beyond this point in the scale.

With reference to the matter of cost, it may be said that on an average 2.13 grains of iron and 7.39 grains of lime have been used and the following is the detailed cost per million gallons of water treated:

Iron, $1.442; lime, $2.454; making a total chemical cost of $3.896; labor, $0.579; power, $0.064; improvements, $0.021; repair, $0.063; producing a total cost of treatment $4.623 per million gallons treated. The waste of water due to the daily flushing out of loose sediment from this filling basin, together with that used in flushing out the accumulated deposit when the basins are cleaned is approximately 2 per cent. of the amount pumped.

Some members of the association may be interested in a method for continuous slacking of lime for water treatment which has been introduced at St. Louis during the past year as a result of an investigation carried on by the writer—based upon the heat of hydration of lime, and the increase in efficiency of the milk of lime produced by hot slaking.

Prior to this year the method of slaking used at St. Louis since the installation of the plant was as follows: Cooling water from an auxiliary condenser was heated to 120° Fahr. by live steam, and the water thus used for slaking, giving a maximum temperature in the tanks of about 180°. During part of the past year a higher initial temperature (approximately 160° Fahr.) was maintained for the hot-water supply, and a temperature of 200° or more in the slaking tanks, since it appeared that using the same lime in like slaking tanks with only the difference in the initial temperature of the water, the efficiency of the effluent from a tank in which a temperature of 200° Fahr., or more, prevailed was 15 per cent. greater than when a temperature of 165 to 170° Fahr. prevailed. In other words, a serious loss in efficiency was caused by the low temperature of the water used. The accompanying Table 7 shows results of several series of comparative experiments, the same lot of lime being used throughout the experiments of each series.

TABLE 7. RESULTS OF COMPARATIVE EXPERIMENTS TO DETERMINE EFFECT OF WARM SLAKING WATER.

Series.	Tank.	Initial Temperature of Water. Deg. Fahr.	Maximum Temperature of Suspension. Deg. Fahr.	Efficiency. Per cent.
A	1	110	156	70.3
	1	120	171.3	78.13
	4	122	156	72.85
	3	172	202	83.65
B	4	127	165	66.04
	3	165	200	81.25
C	4	117	153.5	79.35
	3	172	208	94.6

For several months a device has been in use which heats the hydrant water supplied for slaking by utilizing the heat developed in the slaking process.

The effluent milk of lime from the slaking tank flows through a circular steel tank. A coil of 2-in. copper pipe is submerged in this latter tank, the contents of which are agitated by paddles on a vertical shaft. The hydrant water passes through this coil to a head tank, its temperature being raised during the passage from 60 to 70° Fahr. above the initial temperature of the cold water. From the head tank the hot water flows through adjustable orifices to the slaking tanks, where a temperature of 200° Fahr., or more, has been maintained by the heat of hydration. In a long series of observations these are representative temperatures:

Cold Water.	Head Tank.	Lime Tank. No. 1	Lime Tank. No. 2.	Heater Tank.
51	118	204	200	134
51	118	206	203	136
51	114	206	204	135

The apparatus has been successfully operated since February, and in a slightly modified form is incorporated in the plans of the new coagulating plant for which bids have been recently received. The suspension used is adapted to the individual tanks. Two of the slaking tanks now in use have short pipes carrying the effluent to the heater tank. These have their water supply adjusted so that the milk of lime has one pound of lime in 3½ lb. of water. In two others having longer effluent pipes of 6 and 8 ft., respectively, a suspension of 1 to 3¾ is maintained. Inasmuch as it is necessary to cool the milk of lime before it passes the centrifugal pumps, the amount of water needed for this purpose is actually reduced, making the process economical from every point of view. The estimated saving over heating the water by live steam is nearly $3,000 per year.

The residue left in the slaking tanks after sixteen hours continuous operation is reduced to less than 1 per cent., where formerly 3 per cent. was a minimum. There is thus a further economy of time and labor in its removal.

THE NATAL GOVERNMENT RAILWAYS in 1906 operated 880 miles of line, the earnings from which amounted to $10,443 per mile, and the return after paying for operation and maintenance, $3,412.80 per mile. The gross earnings per train mile were $1.905. The new lines constructed during the year brought the total mileage of the system to 1,024 miles, most of which is of the standard gauge of the colony, 3½ ft., the remaining mileage being 2 ft. gauge. Most of the rail is 61-lb., though 313 miles are laid with 78-lb. rail.

Reinforced Concrete Abutments on the Atlanta, Birmingham & Atlantic R. R.

The bridges of the Atlanta, Birmingham & Atlantic R. R., which has now over 300 miles of line under construction, are of two general types; semi-circular concrete arches up to 30 ft. in diameter, and for larger openings steel bridges on plain concrete piers and reinforced-concrete abutments. The resident engineer on each ten miles of line determines the waterway required for each bridge, either by making a survey of the run-off area and calculating the required waterway by Talbot's formula, or by measuring at the site the stream section below the high-water line.

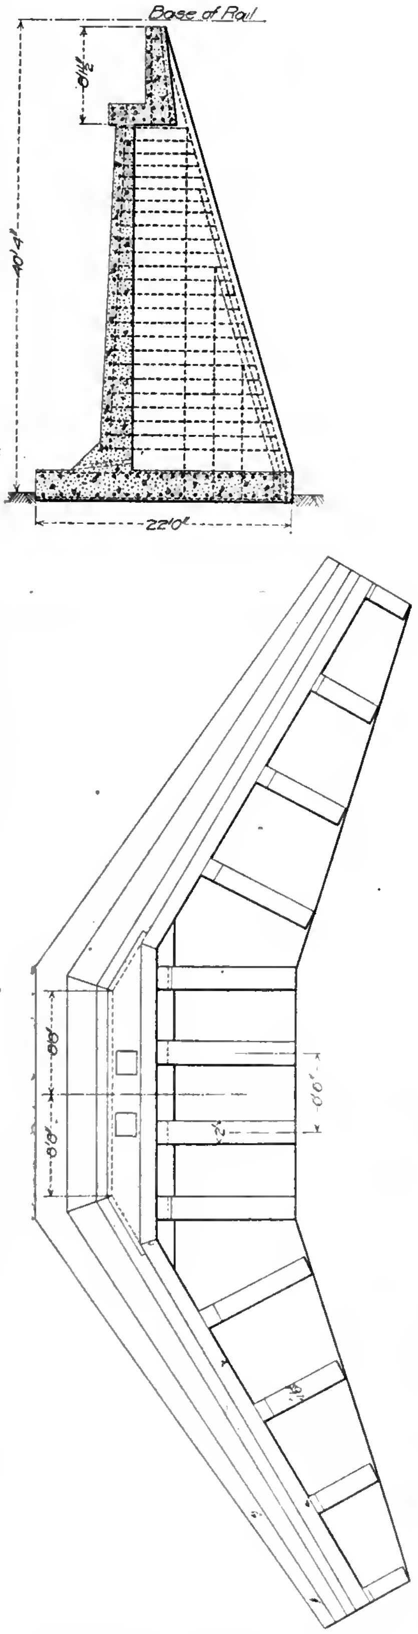
All bridges on the line are founded either on rock or piles. The footings are started 1 ft. below the pile tops and are carried up to 4 in. above the top before any reinforcing bars are used, thus forming a 16-in. cap of plain concrete, in which the piles are imbedded 1 ft.

The abutments are provided with counterforts as shown in the accompanying illustration of a plan and cross-section of a typical structure. According to Mr. S. L. Morrow, office engineer of the road, from whose paper published by the Engineering Association of the South, these notes have been taken, the ratio of base to height, in abutments of this character, must be 0.5 to 0.55 in order to make the resultant of the external forces intersect the middle third of the base. In calculating the pressure due to the backing, the engineers of the Atlanta, Birmingham & Atlantic use Rankine's formula: $P = \frac{1}{6} wh^2$ where P = the total pressure on the back of the wall applied at the lower 1-3 point, w = the weight of the backing, and h = the height of the wall.

Th reinforcement in the counterforts is, according to Mr. Morrow, of great importance, since the bars in the back take practically all the bending moment. The bending moment is calculated at the base and at points one-third and two-thirds down from the top. Assuming that the horizontal pressure is one-third the vertical for any fraction of h down from the top, the resultant will be $w\ h^2$; where w is the weight of the earth, the bending moment will be $p\ h \div 3$, or $w\ h^3 \div 18$. Assuming w to equal 100 lb. per cubic foot of earth, the moment is $5.5\ h^3$.

Considering the buttress, together with the front wall, as a T beam, and using as its effective depth the distance from the center of the rear bars to the inner face of the front wall, and supposing the buttresses to be spaced 10 ft. apart, the bending moment for a depth of 14 ft., down from the top will be $M = 5\frac{1}{2} \times 14^3 \times 10 = 190920$ lb. Supposing the effective depth of the beam at 14 ft. down to be 4 ft., then 2.3 sq. in. of reinforcement will be required, using a unit stress of 16,000 lb. for the steel. In addition to the above, the horizontal components of the live load and the dead load, due to the reaction of the bridge on the abutment, must be added to the bending moment. The live load is assumed at 1,000 lb. per square foot, and the re-150,920 ft. lb. Supposing the effective depth of the cific case. The above calculations are repeated for the other depths below the surface and the sectional area of steel for each point obtained. The bars should be placed well in the rear of the counterfort and the bottom ends of them hooked over the horizontal bars near the bottom of the footing course. The steel is calculated to carry the entire overturning moment because the concrete is placed in the forms in horizontal courses, and may have planes of cleavage at the points where one day's work joins another. Main counterforts are placed under each bridge bearing or point of concentrated loading. The parapet walls and face walls are treated as slabs supported by the counterforts.

The bridge seat proper receives no direct load, since the main buttresses are designed to carry the entire weight of the bridge, but it carries a portion of the overturning moment from the parapet wall and this is taken care of by lateral reinforcement. The bridge seats are heavy enough to transfer the load to the buttresses if the girders should become displaced through accident.



Reinforced Concrete Abutment.

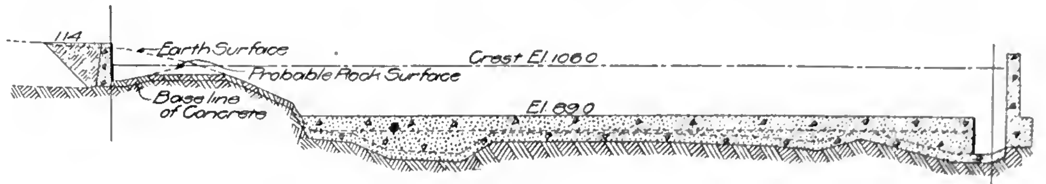
The footing course is considered as a beam supported by the counterforts. The pressure is greatest near the toe and gradually decreases until it becomes a minus quantity at the back of the abutment. The footing course near the front of the abutment is therefore heavily reinforced, and the reinforcement is decreased as the back of the footing course is approached. The sketch given herewith shows the dimensions and proportions of one of the typical abutments.

Hydraulic Development at West Buxton, Me.

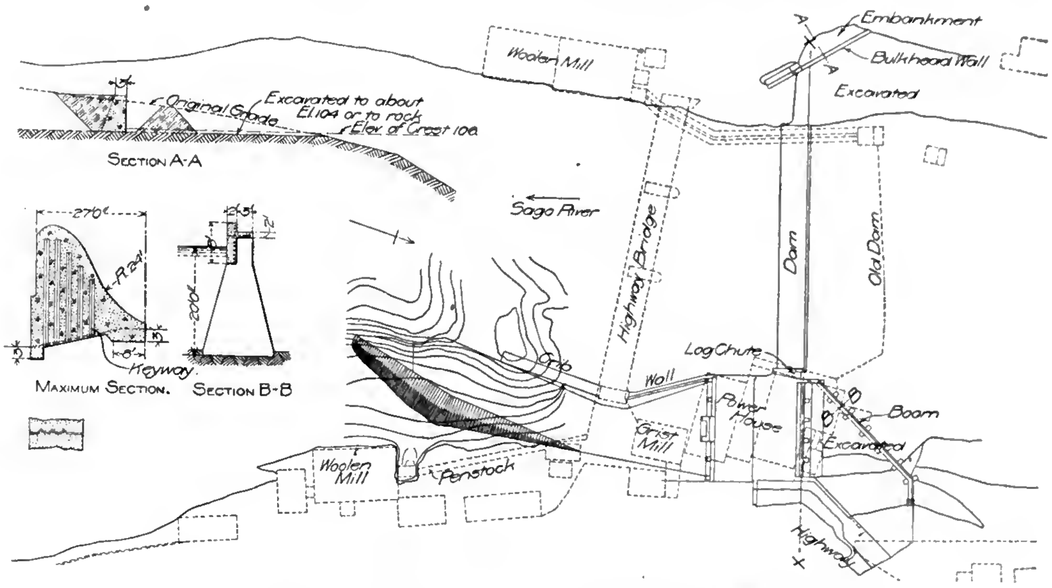
There is now being installed at West Buxton, about 20 miles west of Portland, Me., a 3,000-kw. plant for the transmission of a 3-phase, 60-cycle, 30,000 volt current to the Electric Lighting Co., at Portland. It will be operated by hydraulic power developed in the Saco River and involves the construction of a dam about 300 ft. long, 33 ft. in extreme height and 28 ft. in width at the base, a 100 x 100-ft. power house, a 40 x 100-ft. dynamo house, with four 750-kw. units, turbines and other machinery required, a 150-ft. boom, a log-chute, and a 50 x 300-ft. tail race.

At the site the river has a width of 350 ft. an average depth of 3 ft., and a velocity of about 6 ft. per sec. at ordinary stages of the water. A 4-span highway bridge formerly crossed the river about 100 ft. below the present dam and slightly oblique to it, a crib dam crossed the river about 50 ft. above it and connected at the east end with an old grist mill and other buildings which occupied the site of the power house.

The dam is approximately perpendicular to the shore line and has a standard cross section with curved crest and ogee face downstream, a vertical face upstream, and a depressed footing or cut-off wall at both the up and downstream longitudinal edges of the foundation. The west end of the dam makes an oblique angle with a concrete abutting wall which it intersects and with which it is integral, the footings of this wall are carried down to rock and it has a maximum height of 10 ft. with a top width of 3 ft. It extends about 100 ft. upstream from the dam to intersections with the maximum flow lines of the impounded water and is carried up to a height of 8 ft. above the crest of the dam, thus concentrating all flow over the crest of the dam and protecting the bank on the downstream side. The wall was built in an open cut with 1:1 slopes and was back filled on the shore side, the river side being left unfilled and excavated near the dam to a depth of 3 ft. below the crest. At the opposite end of the dam a sluice 11 ft. wide and 2 ft. deep below the crest is built to afford



Section X-X. Longitudinal Profile of Dam.



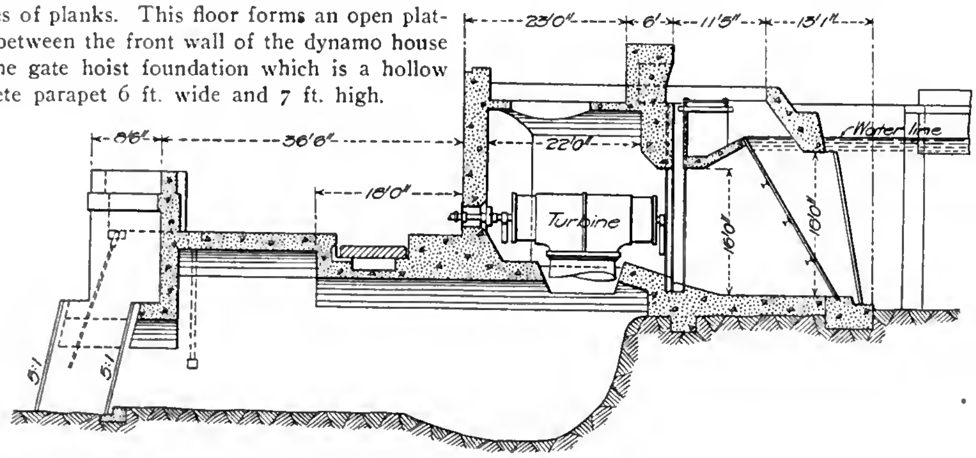
Location of Dam and Power House, with Sections.

General View of Dam and Power House.

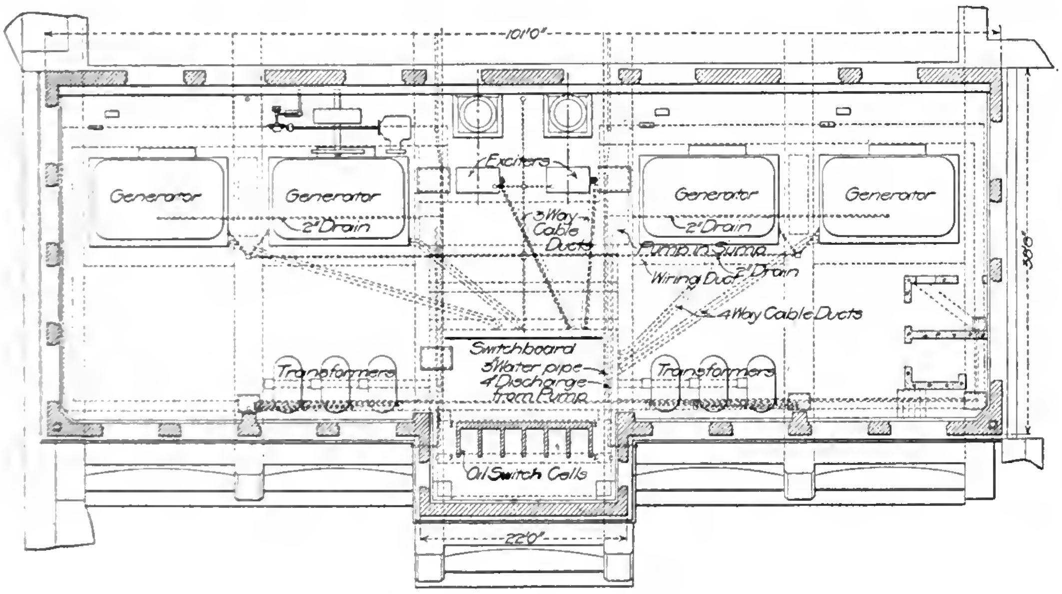
a runway chute for logs and slopes rapidly downward to a point about 10 ft. beyond the lower face of the dam where it is below water level. The sluice is integral on the river side with the dam and on the shore side with the outer wall of the power house foundations. Normally, the sluice is opened and the water discharged through it somewhat reduces the depth on the crest of the dam, but provision is made for closing it if necessary by stop planks fitting recesses in the side walls near the upper end.

The power house foundations are of concrete up to a level 75 ft. above the dynamo floor, above which the structure is entirely of brick and steel except on the side towards the turbine chambers, which are separated from the dynamo room by a concrete wall extending 8 ft. above the crest. The floor of the dynamo room is 13 ft. below the crest of the dam and in order to provide for a possible flood such as was caused by an ice gorge eight years ago, the windows and doors are 7½ ft. above the floor and the walls are made reasonably tight up to that height. Water is admitted to the turbine chambers through five rectangular 16 x 16-ft. openings between the four longitudinal interior foundation walls which are extended about 23 ft. beyond the intake gate to form piers with slightly inclined cut waters and a concrete foundation on the solid rock 22 ft. below the crest of the dam. The piers support on their upstream faces a continuous reinforced concrete girder with an irregular cross section about 8 ft. deep and 7 ft. wide, having its lower surface 2 ft. below the crest of the dam to form a sort of boom to intercept any floating material and also a support for needles for closing any penstock above the gates, as well as making foundations for a future house over gates, hoists and screens. A depressed walk 2½ ft. wide and 3 ft. above the crest of the dam provides a platform from which it is easy to push the débris along the face of the boom and from which needles may be placed. About 7 ft. in the clear downstream from this girder there is a second thin horizontal girder supported on the piers and extending across the full width of the power house. It has a horizontal and inclined surface forming the bottom and one side of a trough opening into the log chute. The downstream side of the trough is vertical and is formed by horizontal planks separating it from the gates. The upstream edge of the trough is at the level of the dam crest and forms a support for the inclined rack bars 23 ft. 3 in. long and 2 in. apart on centers. The feet of these bars take bearings on a concrete footing and they are intermediately supported by three lines of equidistant horizontal I-beams. A timber platform is carried by transverse I-beams 4 ft. above the top of the trough and permits an attendant easily to float the ice which may accumulate against the masonry or rack over the edge of the trough and thence push it or allow the current in the trough to carry it down to the log sluice.

The floor of the turbine room is made with massive concrete arches without reinforcement which are 2.5 ft. thick at the crown and are carried by the 3-ft. longitudinal interior walls in the plane of the outside piers above mentioned. The tops of these walls are pitched both ways from the centers to the springing line so as to give radial surfaces for the skewback bearings. The footings of these walls are carried down 39 ft. below the crest of the dam or 1 ft. below the level of the main excavation. The roof over the turbine room is similar in construction to its floor, but the arches are only 1 ft. thick at the crown and are pierceced over the centers of the turbines with large circular holes closed with doors made with two crossed courses of planks. This floor forms an open platform between the front wall of the dynamo house and the gate hoist foundation which is a hollow concrete parapet 6 ft. wide and 7 ft. high.



Section through Forebay and Tailrace.



Plan of Power House.

The entire area of the dynamo room is commanded by a traveling crane of 34½ ft. span, and 15-tons capacity, with its rails 5 ft. clear of the lower ends of the 20-in. roof beams 7 ft. 8 in. apart on centers which are pitched about 1 in 36 and carry a continuous 4-in. slab of concrete, reinforced by No. 10 expanded metal with 3-in. meshes and covered with tar and gravel.

The intakes are closed by vertical wooden gates made with 4-in. horizontal planks with pairs of 8 x 10-in. vertical lifting beams bolted, keyed and X-braced to them and provided with cast-iron racks engaging pinions operated by hand from the deck above. Many logs are run down the river and are diverted from the power house by the main boom which extends from the log sluice to the river bank at a point about 110 ft. upstream, thus making an angle of about 45 deg. with the face of the power house and facilitating the movement of logs and other drifting material to the sluice. It is a horizontal concrete girder with a T-shaped cross section 8 ft. deep and 5 ft. wide with vertical and horizontal webs respectively 2 ft. and 1 ft. in thickness. The vertical web is reinforced by 19 rods with areas of 1 sq. in. spaced 5 in. apart lapped 2 ft. at joints and located 2 in. from the downstream face of the beam. The horizontal web is reinforced by six bars each with an area of .62 sq. in. spaced 6 in. apart, lapped 13 in. at joints and located 2 in. above its lower surface and forms a walk. The booms are supported on concrete piers, 4 ft. thick, with both sides battered 4:1 and nearly 23 ft. apart on centers. The girder is made continuous with three-panel lengths and butt joints for expansion on the center line of the center pier, the river abutment, and the last pier at the shore side.

The existing dam over 100 years old was made with cribs filled with stone and although in excellent preservation was so leaky that all the silt and sediment had washed through it from the pond above. It was made tight with sand bags put in place by divers and the crest was raised 5 ft. with flash boards supported on triangular wooden frames, the west end being torn out to take the flow. A low earth dam or dyke sheeted on the lower side, was built nearly across the river below the site of the new dam and the river diverted to a channel near the west bank by a cofferdam 200 ft. long on the east side of the channel parallel to the shore line and connecting the old dam and the dike below. It was made with timber cribs, 15 ft. high, 12 ft. long and 16 ft. wide floated to place, filled with sand and sheeted with 3-in. tongue and groove vertical planks. The area between the dams was drained and kept dry with a single pulsometer and a 6-in. steam pump. The surface of the granite rock was found smooth and regular, but on account of the deep seams it contained was excavated with steam drills and dynamite to a depth of 4 to 8 ft. for the footings of the new dam.

A concrete platform 33 ft. above the river bottom was built on falsework trestle bents at the level of the highway on the east bank of the river. Stone from the excavation was broken in a Gates crusher and stored in a 1,000-yd. pile on the opposite side of the road from the plaftorm, where sand and gravel were also delivered by wagons. Cement was stored in adjacent buildings and all of the material was delivered by wheel-barrows to the center of the platform where they were measured and chuted through trap doors to two Smith mixers under the platform which delivered the concrete to 1-yd. bottom dump steel buckets on flat cars on a 2-ft. track on a service platform about 400 ft. long and 16 ft. above the bottom of the river. The concrete was delivered to six guyed derricks with 5-ton, 60-ft. booms which commanded the entire length of the dam and handled the forms and all ma-

terials. They were operated by Lidgerwood double drum engines and handled a maximum of about 200 yd. of concrete daily.

The concreting was carried on without interruption during the coldest weather and when the temperature was as low as minus 47°. The only precautions taken were to mix the concrete with hot water and to soak the broken stone in a hot water tank large enough for two 1-yd. skips and heated by exhaust steam from the steam engine and live steam from the hoisting engine boilers. Although the sand was used cold, the concrete was so hot when first mixed that sometimes the men could scarcely walk in it with rubber boots. It was covered at night with tarpaulins and in the morning was found still moist and unfrozen.

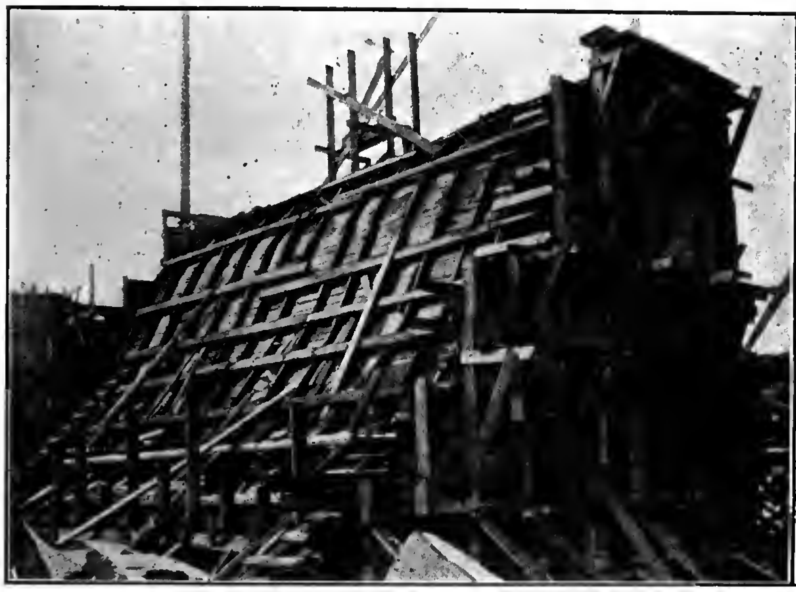
The dam was made in alternate sections 40 ft. long, bonded together with four vertical triangular 12x12-in. keys 18 in. apart in the clear. They terminated 2 ft. below the upper surface of the dam.

Derrick stones up to 1 yd. in volume were bedded in the concrete and formed about 30 per cent. of its mass. Care was taken in filling the molds to complete a horizontal course over the whole surface each day, a requirement which necessitated the men sometimes working from 12 to 14 hr.; corresponding heights of from 3 to 8 ft. a day were secured according to whether the work was at the base or the top of the dam. Successive courses were bonded together by large stones imbedded in the surface so as to project half-way above the top of the lower course and tooth with the upper course. The forms were built of 2-in. square edged dressed pine planks and were not interchangeable, being knocked down as each one was stripped and rebuilt for the next.

The contract was awarded Aug. 20, 1906, and work at the site was commenced Sept. 1, and has been carried on continuously ever since and the concrete work is now completed with the exception of two 40-ft. sections of the dam at the waste channel. Conditions have been favorable and low water has prevailed except during the spring freshet, when the discharge amounted to about 12,000 cu. ft. per second. The principal quantities include 150,000 ft. board measure of lumber in the forms, 25,000 cu. yd. of excavation, and 11,000 yd. of concrete made with Atlas and Vulcanite Portland cement. About 400 men were employed on the work during the fall, until it was seen that it would be impossible to complete the dam before the ice went out in the spring, and at Christmas the force was reduced to 200 men and maintained at that figure during the winter. J. G. White & Co. are the contractors, Mr. A. S. Crane, chief hydraulic engineer, and Mr. C. H. Nichols, superintendent of construction.

The Loring N. Farnum Co. are subcontractors for the dam and power house.

The turbines are supplied by the S. Morgan Smith Co.; the electrical apparatus by the General Elec. Co., and the water wheel governors by the Lombard-Replogle Co.



Mould for One Section of Dam.

Offsets and Recesses for Bonding Sections.

Power Plant of a Paper Mill.

What electricity will do in improving conditions in paper production is well shown in the new works of the Willamette Pulp & Paper Co., at Oregon City. The company's first mill was built at a 25-ft. fall in the Willamette River. The location was not particularly good for manufacturing and since the development of electric power transmission and shop operation it has become possible to build the new mill 1,000 ft. from the falls and drive it by motors receiving current from a turbine-driven unit at the old mill. In this way it has become possible to develop 750 h.-p. additional at the falls and to use it at the most advantageous site. The turbine is rated at 1,000 h.-p. and was built by the Platt Iron Works; it is direct-connected to a 600-kw., 3-phase, 600-volt General Electric generator, and power is transmitted directly at the generator voltage. The machinery in the mill is driven mainly on the group system by induction motors. A 200-h.-p. motor drives a 12 x 13-in. chipper, a chip separator, a saw-dust conveyor and a chip elevator. A 200-h.-p. motor drives three pumps and four beaters; owing to the large starting effort required for the beaters, a friction clutch is inserted in the line shaft so that the motor can come up to speed without load and then take the load gradually by means of the clutch. A 100-h.-p. motor drives two chest agitators and three pumps, and another motor of equal rating runs the Jordan engine. A 50-h.-p. motor drives four wet machines and three Decker machines. Motor operation is not used with the 152-in. paper machine, since the drying cylinders require a large amount of steam for warming purposes and a 650-h.-p. non-condensing engine furnishes the most economical operation, as the exhaust can be used for warming.

A HORIZONTAL EXPANSION JOINT has been provided between the top of the Wachusett dam and the granolithic surfacing above it, which averages $5\frac{1}{2}$ in. in thickness. This was done by covering the top of the dam with powdered mica, which prevented the adhesion of the two surfaces. The granolithic pavement is in squares about 9 ft. 9 in. on a side, with ½-in. joints filled with asphaltum.

Report of the British Joint Committee on Reinforced Concrete.

In October, 1905, the Royal Institute of British Architects invited a number of leading organizations and government departments interested in reinforced concrete to appoint representatives on a joint committee to draw up rules for the guidance of architects for the use of reinforced concrete. Up to that time, there had been no authoritative rules prepared in the country, owing to the practical prohibition of reinforced concrete for complete buildings by the ordinary building regulations. Only railway and dock companies and other bodies exempt from these restrictions had been able to avail themselves of this method of construction. The committee was made up of the following members: Royal Institute of British Architects, Sir Henry Tanner, chairman, Messrs. T. Walmisley, William Dunn, Max Clarke and H. D. Searles-Wood; District Surveyors' Association, Messrs. Thomas H. Watson and E. D. Drury; Institute of Builders, Messrs. B. I. Greenwood and Frank May; Municipal and County Engineers' Association, Messrs. A. E. Collins and J. W. Cockrill; War Office, Col. C. B. Mayne, vice-chairman, and Major E. M. Paul; Admiralty, Mr. C. H. Colson; special members, Prof. W. C. Unwin, vice-chairman, Mr. Charles F. Marsh and Col. F. Winn. The aim of this committee was to produce a good working guide, laying down the necessary conditions and stating safe rules for a proper disposition of the parts of a reinforced concrete structure. Previously every specialist in the country made his own rules and the margin of safety was occasionally cut too fine. In preparing its rules, the committee endeavored to avoid giving any preference to patented systems and materials, and confined itself to stating principles for all kinds of structures reinforced with ordinary bars. The report reads as follows:

1. Reinforced concrete is used so much in building and engineering construction that a general agreement on the essential requirements of good work is desirable. The proposals which follow are intended to embody these essentials, and to apply generally to all systems of reinforcement.

Good workmanship and materials are essential in reinforced concrete. With these and good design structures of this kind appear to be trustworthy. It is essential that the workmen employed should be skilled in this class of construction. Very careful superintendence is required during the execution of the work in regard to—

(a) The quality, testing and mixing of the materials.

(*b*) The sizes and positions of the reinforcements.

(*c*) The construction and removal of centering.

(*d*) The laying of the material in place and the thorough punning of the concrete to ensure solidity and freedom from voids.

If the metal skeleton be properly coated with cement, and the concrete be solid and free from voids, there is no reason to fear decay of the reinforcement in concrete of stone, gravel, cinder, coke-breeze, etc., made with clean, fresh water.

2. The By-Laws regulating building in this country require external walls to be in brick, or stone, or concrete of certain specified thicknesses. In some places it is in the power of the local authorities to permit a reduced thickness of concrete when it is strengthened by metal; in other districts no such power has been retained. We are of opinion that all By-Laws should be so altered as to expressly include reinforced concrete amongst the recognized forms of construction.

A section should be added to the By-Laws declaring that when it is desired to erect buildings in reinforced concrete complete drawings showing all details of construction and the sizes and positions of reinforcing bars, a specification of the materials to be used and proportions of the concrete, and the necesary calculations of strength based on the rules contained in this report, signed by the person or persons responsible for the design and execution of the work, shall be lodged with the local authority.

3. (*a*) Floors, walls and other constructions in steel and concrete formed of incombustible matetials prevent the spread of fire in varying degrees according to the composition of the concrete, the thickness of the parts, and the amount of cover given to the metal.

(*b*) Experiment and actual experience of fires show that concrete in which limestone is used for the aggregate is disintegrated, crumbles and loses coherence when subjected to very fierce fires, and that concretes of gravel or sandstones also suffer, but in a rather less degree. The smaller the aggregate the less the injury. The metal reinforcement in such cases generally retains the mass in position, but the strength of the part is so much diminished that it must be renewed. Concrete in which coke-breeze, cinders or slag forms the aggregate is only superficially injured, does not lose its strength, and in general may be repaired. Concrete of broken brick suffers more than cinder concrete and less than gravel or stone concrete.

(*c*) The material to be used in any given case should be governed by the amount of fire resistance required as well as by the cheapness of, or the facility of procuring, the aggregate.

(*d*) Rigidly attached web members, loose stirrups, bent-up rods, or similar means of connecting the metal in the lower or tension sides of beams or floor slabs (which sides suffer most injury in case of fire) with the upper or compression sides of beams or slabs not usually injured are very desirable.

(*e*) For main beams a covering of 1½ to 2 in. of concrete over the metal reinforcement appears from experience in actual fires to afford ample protection to the structural parts. In floor slabs the cover required may be reduced to 1 in. All angles should be rounded or splayed to prevent spalling off under heat.

(*f*) More perfect protection to the structure is required under very high temperature, and in the most severe conditions it is desirable to cover the concrete structure with fire-resisting plastering which may be easily renewed. Columns may be covered with coke-breeze concrete, terra-cotta, or other fire-resisting facing.

Materials.—4. Only Portland cement complying with the requirements of the specification adopted by the British Engineering Standards Committee should be employed; in general the slow-setting quality should be used. Every lot of cement delivered should be tested, and in addition the tests for soundness and time of setting, which can be made without expensive apparatus, should be applied frequently during construction. The cement should be delivered on the works in bags or barrels bearing the maker's name and the weight of the cement contained.

5. The sand should be composed of hard grains of various sizes up to particles which will pass a quarter-inch square mesh, but of which at least 75 per cent. should pass ⅛-in. square mesh. Fine sand alone is not so suitable, but the finer the sand the greater is the quantity of cement required for equal strength of mortar. It should be clean and free from ligneous, organic or earthy matter. The value of a sand cannot always be judged from its appearance, and tests of the mortar prepared with the cement and the sand proposed should always be made. Washing sand does not always improve it, as the finer particles which may be of value to the compactness and solidity of the mortar are carried away in the process.

6. The aggregate, consisting of gravel, hard stone, or other suitable material, should be clean and angular, varied in size as much as possible between the limits of size allowed for the work. In all cases material which passes a sieve of a ¼-in. square mesh should be reckoned as sand. the maximum allowable size is usually ¾ in. The maximum limit must always be such that the aggregate can pass between the reinforcing bars and between these and the centering. The sand should be separated from the gravel or broken stone by screening before the materials are measured.

7. In all cases the proportions of the cement, sand and aggregate should be separately specified in volumes.

As the strength and durability of reinforced concrete structures depend mostly on the concrete being properly proportioned, it is desirable that in all important cases tests should be made as described herein with the actual materials that will be used in the work before the detailed designs for the work are prepared.

In no case should less dry cement be added to the sand when dry than will suffice to fill its interstices, but subject to that the proportions of the sand and cement should be settled with reference to the strength required, and the volume of mortar produced by the admixture of sand and cement in the proportions arranged should be ascertained.

The interstices in the aggregate should be measured and at least sufficient mortar allowed to each volume of aggregate to fill the interstices and leave at least 10 per cent. surplus.

For ordinary work a proportion of one part cement to two parts sand will be found to give a strong, practically watertight mortar, but where special watertightness or strength is required the proportion of cement must be increased.

The amount of cement added to the aggregate should be determined on the work by weight. The weight of a cubic foot of cement for the purpose of proportioning the amount of cement to be added may be taken at 90 lbs.

8. The metal used should be steel having the following qualities:—

(*a*) An ultimate strength of not less than 60,000 lb. per square inch.

(*b*) An elastic limit of not less than 50 per cent., or more than 60 per cent. of the ultimate.

(*c*) An elongation of not less than 22 per cent. in the lengths stated below.

(*d*) It must stand bending cold 180° to a diameter of the thickness of pieces tested without fracture on outside of bent portion.

In the case of round bars the elongation should not be less than 22 per cent., measured on a gauge-length of eight diameters. In the case of bars over one inch in diameter the elongation may be measured on a gauge-length of four diameters, and should then be not less than 27 per cent. For other sectional material the tensile and elongation tests should be those prescribed in the British Standard Specification for Structural Steel.

Before use in the work the metal must be clean and free from scale or loose rust. It should not be oiled or painted, but a wash of thick Portland cement grout is desirable.

Welding should in general be forbidden; if it is found necessary, it should be at points where the metal is least stressed, and it should never be allowed without the special sanction of the architect or engineer responsible for the design.

The reinforcement ought to be placed and kept exactly in the positions marked on the drawings, and, apart from any consideration of fire resistance, ought not to be nearer the surface of the concrete at any point than 1 in. in beams and ½ in. in floor slabs or other thin structures.

9. In all cases the concrete should be mixed in small batches and in accurate proportions, and should be laid as rapidly as possible.

When the materials are mixed by hand they are to be turned over and thoroughly mixed on a clean platform until the color of the cement is uniformly distributed over the aggregate.

Whenever practicable the concrete should be mixed by machinery.

10. The thickness of loose concrete that is to be punned should not exceed 3 in. before punning, especially in the vicinity of the reinforcing metal. Special care is to be taken to ensure perfect contact between the concrete and the reinforcement, and the punning to be continued till the concrete is thoroughly consolidated. Each section of concreting should be as far as possible completed in one operation; when this is impracticable, and work has to be recommenced on a recently laid surface, it is necessary to wet the surface; and where it has hardened it must be hacked off, swept clean, and covered with cement grout. Work should not be carried on when the temperature is below 34° Fahr. The concrete when laid should be protected from the action of frost, and shielded against too rapid drying from exposure to the sun's rays or winds, and kept well wetted. All shaking and jarring must be avoided. The efficiency of the structure depends chiefly on the care with which the laying is done.

The amount of water to be added depends on the temperature at the time of mixing, the materials, and the state of these, and other factors, and no recommendation has therefore been made. Sea-water should not be used.

11. The centering must be of such dimensions, and so constructed, as to remain rigid and unyielding during the laying and punning of the concrete. It must be so arranged as to permit of easing and removal without jarring the concrete. Provision should be made wherever practicable for splaying or rounding the angles of the concrete. Timber when used for centering may be advantageously limewashed before the concrete is deposited.

12. The time during which the centres should remain up depends on various circumstances, such as the dimensions or thickness of the parts of the work, the amount of water used in mixing, the state of the weather during laying and setting, etc., and must be left to the judgment of the person responsible for the work. The casing for columns, for the sides of beams, and for the soffits of floor slabs not more than 4 ft. span must not be removed under eight days; soffits of beams and of floors of greater span should remain up for at least fourteen days, and for large span arches for at least twenty-eight days. The centering of floors in buildings which are not loaded for some time after the removal of

same may be removed in a short time; the centering for structures which are to be used as soon as completed must remain in place much longer. If frost occurs during setting, the time should be increased by the duration of the frost.

13. Before the detailed designs for an important work are prepared, and during the execution of such a work, test pieces of concrete should be made from the cement, sand and aggregate to be used in the work, mixed in the proportions specified. These pieces should be either cubes of not less than 4 in. each way, or cylinders not less than 4 in. diameter, and of a length not less than the diameter. They should be prepared in moulds, and punned as described for the work. Not less than four cubes or cylinders should be used for each test, which should be made twenty-eight days after moulding. The pieces should be tested by compression, the load being slowly and uniformly applied. The average of the results should be taken as the strength of the concrete for the purposes of calculation, and in the case of concrete made in proportions of 1 cement, 2 sand, 4 hard stone, the strength should not be less than 2,400 lb. per square inch.

Loading tests on the structure itself should not be made until at least two months have elapsed since the laying of the concrete. The test load should not exceed one and a half times the accidental load. Consideration must also be given to the action of the adjoining parts of the structure in cases of partial loading. In no case should any test load be allowed which would cause the stress in any part of the reinforcement to exceed two-thirds of that at which the steel reaches its elastic limit.

Methods of Calculation.—1. In designing any structure there must be taken into account:—

(*a*) The weight of the structure.

(*b*) Any other permanent load, such as flooring, plaster, etc.

(*c*) The accidental load. By "accidental" load is meant the imposed load additional to the weight of the structure for which the structure is calculated.

(*d*) In some cases also an allowance for vibration and shock.

Of all probable distributions of the load, that is to be assumed in calculation which will cause the greatest straining action.

The weight of the concrete and steel structure may be taken at 150 lb. per cubic foot.

In structures subjected to very varying loads and more or less vibration and shock, as, for instance, the floors of public halls, factories, or workshops, the allowance for shock may be taken equal to half the accidental load.. In structures subjected to considerable vibration and shock, such as floors carrying machinery, the roofs of vaults under passage ways and courtyards, the allowance for shock may be taken equal to the accidental load.

In the case of columns or piers in buildings, which support three or more floors, the load at different levels may be estimated in this way. For the part of the roof or top floor supported, the full accidental load assumed for the floor and roof is to be taken. For the next floor below the top floor 10 per cent. less than the accidental load assumed for that floor. For the next floor 20 per cent. less, and so on to the floor at which the reduction amounts to 50 per cent. of the assumed load on the floor. For all lower floors the accidental load on the columns may be taken at 50 per cent. of the loads assumed in calculating those floors.

2. Spans may be taken as follows: For beams the distance from centre to centre of bearings. For slabs supported at the ends, the clear span + the thickness of slab. For slabs continuous over more than one span the distance from centre to centre of beams.

3. In the most ordinary case of a uniformly distributed load of w lbs. per inch run of span the bending moments will be as follows:

(*a*) Beam or slab simply supported at the ends. Greatest bending moment at centre of span of l inches is equal to $w\ l^2/8$ inch-lbs.

(*b*) Beam continuous over several spans, or encastré or fixed in direction at each end. The greatest bending moments are at the ends of the span, and the beam should be reinforced at its upper side near the ends. If continuity can be perfectly relied on, the bending moment at the centre of the span is $w\ l^2/24$, and that over the supports — $w\ l^2/12$. If the continuity is in any way imperfect, the bending moment at the centre will in general be greater, and that at the supports less, but the case is a very indefinite one. It appears desirable that generally in building construction the centre bending moment should not be taken less than $w\ l^2/12$. The bending moment at the ends depends greatly on the fixedness of the ends in level and direction. When continuity and fixing of the ends, whether perfect or imperfect, is allowed for in determining the bending moment near the middle of the span, the beam or slab must be designed and reinforced to resist the corresponding bending moments at the ends. When the load is not uniformly distributed the bending moments must be calculated on the ordinary statical principles.

4 The internal stresses are determined, as in the case of a homogeneous beam, on these approximate assumptions:

(*a*) The coefficient of elasticity in compression of stone or gravel concrete, not weaker than 1:2:4, is treated as constant and taken at one-fifteenth of the coefficient of elasticity of steel: Coefficient for concrete = E_c = 2,000,000 lb. per square inch; coefficient for steel = E_s = 30,000,000 lb.; $E_s \div E_c = 15$. It follows that at any given distance from the neutral axis, the stress per square inch on steel will be fifteen times as great as on concrete.

(*b*) The resistance of concrete to tension is neglected, and the steel reinforcement is assumed to carry all the tension.

(*c*) The stress on the steel reinforcement is taken as uniform on a cross-section, and that on the concrete as uniformly varying.

5. If the concrete is of such a quality that its crushing strength is 2,400 to 3,000 lb. per square inch after twenty-eight days, and the steel has a tenacity of not less than 60,000 lb. per square inch, the following stresses may be allowed:

Concrete, in compression in beams subjected to bending, 600 lb. per square inch; concrete in columns under simple compression, 500 lb. per square inch; concrete in shear in beams, 60 lb. per square inch; adhesion of concrete to metal, 100 lb. per square inch; steel in tension, 15,000 to 17,000 lb. per square inch.

It is desirable that the reinforcing rods should be so designed that the adhesion is sufficient to resist the shear between the metal and concrete. Precautions should in every case be taken by splitting or bending the rod ends, or otherwise to provide additional security against the sliding of the rods in the concrete.

When the proportions of the concrete differ from those stated above the stress in compression allowed in beams may be taken at one-fourth, and that in columns at one-fifth of the crushing stress of cubes of the concrete of sufficient size at twenty-eight days after gauging. If stronger steel is used than that stated above, the allowable tensile stress may be taken at one-half the stress at the yield point of the steel.

Let b be the width and d the effective depth of the beam in inches.

$A = bd$ the area of cross-section.

$m = E_s/E_c$ the ratio of the coefficients of elasticity of steel and concrete.

M = bending moment at the section considered, in inch-pound units.

t = tensile stress in metal in pounds per square inch.

c = compressive stress in concrete per square inch.

z = distance of resultant thrust in concrete from compressed edge of beam in inches.

kd = distance of neutral axis from compressed edge in inches.

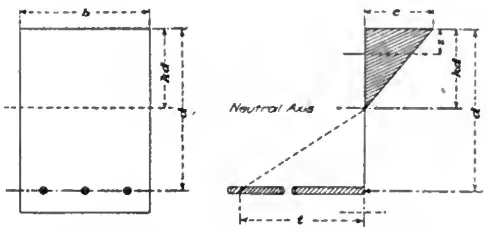
$A_c = kbd$ = area of concrete in compression in square inches.

A_t = area of metal in tension in square inches.

$p = A_t/bd$ the ratio of section of metal to section of concrete.

l = span in inches.

w = load per inch run of span.



(*a*) *Beams of Rectangular Section with Single Reinforcement.*—In a homogeneous beam the stresses are proportional to the distances from the neutral axis. In a discrete beam, such as a beam of concrete and steel, on account of the greater rigidity of steel, at a given distance from the neutral axis the stress in the steel will be m times as great as in concrete. Hence—

$$\frac{mc}{t} = \frac{kd}{d\,(1 - k)} = \frac{k}{1 - k}$$

But equating the total tension and compression

$$\tfrac{1}{2}\,cbkd = pbdt$$
$$ck = 2pt.$$

Replacing c in terms of t

$$k^2 \div m\,(1 - k) = 2p$$
$$k = \sqrt{(p^2m^2 + 2pm)} - pm.$$

Thus for $m = 15$

p = 0.007, 0.010, 0.015, 0.020.

k = 0.365, 0.417, 0.483, 0.530.

That is, the neutral axis is lower as the amount of reinforcement is greater, and passes the half depth for 2 per cent. of reinforcement.

The distance of the resultant thrust from the compressed edge is $z = \tfrac{1}{3}kd$.

Equating the moments of resistance to the bending moment,

$$M = A_t t\,(d - \tfrac{1}{3}kd) = \tfrac{1}{2}A_c c\,(d - \tfrac{1}{3}kd)$$

$$t = \frac{M}{A_t d\,(1 - \tfrac{1}{3}k)} = \frac{M}{pbd^2\,(1 - \tfrac{1}{3}k)}$$

$$c = \frac{2M}{A_c d\,(1 - \tfrac{1}{3}k)} = \frac{2M}{kbd^2\,(1 - \tfrac{1}{3}k)}$$

The shearing stresses and tensions near the ends of the beam are usually resisted by stirrups or inclined steel bars, and it is always desirable to bend upwards near the supports one or more of the reinforcing bars when the reduced bending moments at the ends permit of so doing. Stirrups or rigidly attached web members or inclined bars should be provided in all cases where the average shearing stress on a vertical section of the beam exceeds 60 lb. per square inch of the section. A theoretical determination of the section required for these would be very difficult. If the simple case is taken of a uniformly loaded beam, supported at the ends with horizontal steel tension bars not bent up at the ends, the adhesion between concrete and steel which is required may be found thus: The difference of tension in 1-ft. length of bars at the end of the span will be the tangential force between steel and concrete in

that distance. The bending moment at the end is 0, and at 1 ft. from the end $6w\ (l - 12)$ inch-pounds, where w is the load per inch run. Hence the increment of tension between the end and 1 ft. from the end is

$$6w\ (l - 12) \div d\ (1 - \tfrac{1}{3}\ k) \text{ lb.}$$

If Ψ is the total perimeter of the reinforcing bars, the adhesion stress is $w\ (l - 12) \div 2\ \Psi\ d\ (1 - \tfrac{1}{3}\ k)$ lb. per square inch.

(b) *Beams of T Section with Single Reinforcement.*—In designing T beams where the upper flange forms a floor the thickness d_1 of this wall first be ascertained by considering the part between two ribs as a slab, having its own reinforcing bars transverse to the rib. The whole of this cannot in general be considered to form part of the upper flanges of the T beams. The width b_1 of the upper flange may be assumed to be not greater than one-third the span of the beams, or than three-fourths of the distance from centre to centre of the reinforced ribs. There is no satisfactory theoretical determination of the precise amount of the floor slab acting with the web. The depth d should then be determined with reference to the stiffness required in the floor. In general d is from one-twelfth to one-eighteenth of the span.

Two cases arise according as the thickness of flange is greater or less than kd, the distance from the neutral axis to the compressed edge. In the former case (d_1 greater than kd) the rules under (a) apply if b_1 is substituted for b, and $A = b_1d_1 + b\ (d - d_1)$ for bd. The equations then become

$$mc \div t = k \div (1 - k)$$

$$k = \sqrt{\left(\frac{2pAm}{b_1d} + \frac{p^2A^2m^2}{b_1^2d^2}\right)} - \frac{pAm}{b_1d}$$

$$= \sqrt{\left(\frac{2A_tm}{b_1d} + \frac{A_t^2m^2}{b_1^2d^2}\right)} - \frac{A_tm}{b_1d}$$

$$z = \tfrac{1}{3}kd$$

$$t = \frac{M}{A_td(1 - \tfrac{1}{3}k)} = \frac{M}{pAd(1 - \tfrac{1}{3}k)}$$

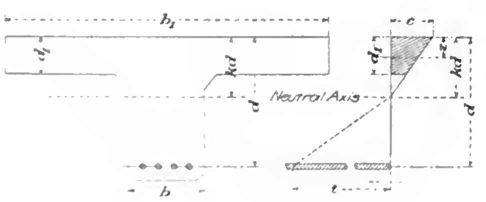
$$c = \frac{2M}{A_cd(1 - \tfrac{1}{3}k)} = \frac{2M}{kb_1d(1 - \tfrac{1}{3}k)}$$

where $pA = A_t$ the section of reinforcement. The increment of tension in 1 ft. length at the end of the beam and the adhesion stress is the same as in (a).

When d_1 is less than kd the small compression in the web between d_1 and kd may be neglected.

Let, as before, the whole area of section $= A = b_1d_1 + b(d - d_1)$, and pA be the area of reinforcement.

$$mc \div t = k \div (1 - k).$$



The mean compressive stress on the flange is

$$\tfrac{1}{2}\left\{c + c\frac{kd - d_1}{kd}\right\} = \frac{c}{2}\ \frac{2kd - d_1}{kd}.$$

Equating the total tension and compression,

$$A_tt = pAt = \tfrac{1}{2}b_1d_1c\ (2kd - d_1) \div kd$$

$$kd = \frac{b_1d_1^2 + 2pAmd}{2b_1d_1 + 2pAm} = \frac{b_1d_1^2 + 2A_tmd}{2b_1d_1 + 2A_tm}.$$

$$\text{But } z = \frac{d_1}{3}\ \frac{3kd - 2d_1}{2kd - d_1}$$

Equating the moments

$$M = A_tt(d - z) = pAt\ (d - z) = \tfrac{1}{2}b_1d_1c\ (2kd - d_1)\ (d - z) \div kd$$

$$t = M \div pA(d - z)$$

$$c = 2Mkd \div b_1d_1\ (2kd - d_1)\ (d - z).$$

It may be useful also to point out that the area of reinforcement for a given value of c/t is

$$A = pA = \frac{c}{t}\ \frac{b_1d_1\ (2kd - d_1)}{2kd}.$$

(c) *Slabs Supported on More Than Two Sides.*—It does not appear that there is either a satisfactory theory or trustworthy experiments from which the strength of rectangular slabs supported or fixed on all four edges can be determined.

(a) *Short Columns Axially Loaded.*—The reinforcement of columns should in general amount to at least 0.8 per cent. of the gross cross-section. The liability to bending of the longitudinal reinforcing bars greatly weakens the column, and should be prevented by steel binding bars. Some theoretical considerations would indicate that cross-binding is required at points not further apart than twenty-four times the least lateral dimension of the reinforcing rods. But further experiment shows that still closer cross-binding, or, better, spiral binding, greatly increases the strength of the column.

(M. Considère recommends that the distance between the coils of the spiral should not exceed from 1/10 to 1/7 of the diameter of the spiral. In the case of piles subjected to longitudinal shock in driving there are special reasons for decreasing the distance between the cross-binding near the ends.)

If the load is strictly axial the stress is uniform on cross-sections. Let A_c be the cross-section of the column (including the reinforcement), and A the equivalent section as defined below, a the section of logitudinal reinforcing bars, P the load on the column in pounds. Let c be the stress on the concrete, and t that on the steel, the ratio of the coefficients of elasticity being m.

$$c = \frac{P}{A_c + (m - 1)a} = \frac{P}{A}$$

$$t = \frac{mP}{A_c + (m - 1)a} = \frac{mP}{A}.$$

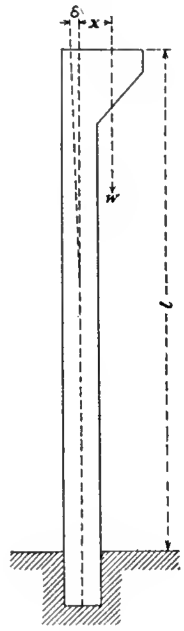
It appears that c may be taken $=$ 500 lb. per square inch, t = 7,500 lb. per square inch, and $E_s/E_c = m = 15$.

When the stress on the concrete is not greater than 500 lb. per square inch, lateral bending of the column as a whole is not to be feared if the ratio of length to the least lateral dimension is not greater than 18.

(b) *Columns Eccentrically Loaded.*—If a column initially straight is loaded eccentrically, as when a beam rests on a bracket attached to the column, it may be regarded as fixed at the base and free at the loaded end. Then it must bend in the plane passing through the load, the deflection at the top being δ. Let x be the eccentricity of the load measured from the centre of the column when straight. Then the bending moment at the base of the column is $W\ (\delta + x)$. But it is known that δ will be small compared with x, provided that W is small compared with $2EI/l^2$, and this will be the case in such conditions as are likely to occur in designing concrete columns. Then the bending moment may be taken as Wx, and the stress at the base of the column, treating it as homogeneous, will be

$$f = W\left\{\frac{1}{A} \mp \frac{x}{Z}\right\}$$

very nearly, where A is the whole section of the



column and Z the modulus of the section relatively to an axis through the centre of gravity and at right angles to the plane of bending.

In dealing with reinforced columns which are not nomogenous, it is convenient to substitute for the actual section of the column what may be termed the equivalent section, or section of concrete equivalent in resistance to the actual column. If A_c is the area of section of the column (including the area of reinforcement) and a is the area of reinforcement, then the equivalent section is

$$A = A_c + (m - 1)a.$$

If h is the depth of the section in the plane of bending, the moment of inertia relatively to the neutral axis can be expressed in the form $I = nAh^2$, and the section modulus in the form $Z = 2nAh$.

It is desirable in columns that there should be no tension, and generally when the vertical load is considerable there is none. Cases in which the eccentricity is so great that there is tension must be treated by the methods applicable to beams if it is made a condition that the steel carries all the tension. In the following cases it is assumed that there is no tension.

Case I.—Column of Circular Section, Reinforcements Symmetrical and Equidistant from the Neutral Axis. Let m be the ratio E_s/E_c of the coefficients of elasticity of steel and concrete, A_c the cross section of the column in square inches, a the area of reinforcement in square inches, h the diameter of the column, h_t the distance between the reinforcing bars perpendicular to the neutral axis. Then the equivalent section is

$$A = A_c + (m - 1)a$$

and the modulus of the section is

$$Z = \tfrac{1}{8}A_ch + \tfrac{1}{2}\ (m - 1)a\ h_t^2 \div h$$

The stress at the edges of the section can then be calculated by the general equation

$$f = W\left\{\frac{1}{A} \mp \frac{x}{Z}\right\}$$

where x is the eccentricity of the load in inches and W the load in pounds. The greater value of f must not exceed the safe stress stated above.

Case II.—Rectangular Section with Reinforcement Symmetrical and Equidistant from the Neutral Axis. Using the same notation as in the

last case, h being now the depth of the section in the plane of bending, the section modulus is

$$Z = \tfrac{1}{6}Ach + \tfrac{1}{2}\ (m - 1)a\ h_t^2 \div h$$

and the stresses are given by the same equation as in the previous case.

Case III.—Column of Circular Section with Reinforcing Bars arranged in a Circle.—Using the same notation as in Case I, h_t being the diameter of the circle of reinforcing bars, the section modulus is

$$Z = \tfrac{1}{8}\ A\ h + \tfrac{1}{4}\ (m - 1)a\ h_t^2 \div h,$$

and the stresses are given by the same equation as in Case I.

(*c*) *Long Columns axially Loaded.*—For columns more than 18 diameters in length there is risk of lateral buckling of the column as a whole. The strength of such columns would be best calculated by Gordon's formula, but there are no experiments on long columns by which to test the values of the constants for a concrete or concrete and steel column. There does not seem, however, to be any probability of serious error if the total load is reduced in a proportion inferred from Gordon's formula to allow for the risk of buckling

Let, as before, A_c = the section of the column in inches; a = the reinforcement. Then $A = A_c + (m - 1)a$ is the equivalent section. Let n be the constant in the equation, $I = nAh^2$, and h the least transverse dimension of the column.

Then for a column fixed in direction at both ends, Gordon's formula is

$$W/Af = 1 \div (1 + l^2/cnh^2) = 1 \div (1 + K)$$

so that the column will carry less than a short column of the same dimensions in the ratio of $1 + K$ to 1, or, in other words, the column will be safe if calculated as a short column, not for the actual load, W, but for a load $(1 + K)W$.

The constant c has not been determined experimentally for reinforced long columns. But its probable value is $c = 4\pi^2\ E_c/f$,

where f is the ultimate crushing stress. Putting E_c = 2,000,000 and f = 2,500, then c = 32,000. Looking at the well-understood uncertainty of the rules for long columns, very exact calculation is useless.

VALUES OF $1 + K$ FOR THREE VALUES OF n.

l/h	Case I. $n = 0.098$	Case II. $n = 0.075$	Case III. $n = 0.0646$
20	1.13	1.17	1.19
25	1.20	1.26	1.30
30	1.29	1.38	1.44

The differences of $1 + K$ for considerable differences of n are not very great.

In the case of columns fixed at one end and rounded or unfixed at the other, $2K$ must be substituted for K. If the column is rounded at both ends, $4K$ must be substituted for K.

Rock Breaking on the Suez Canal.

Rock breaking on the Suez Canal has been done since 1902 with Lobnitz chiseling machines having 13-ton rams. The average height of fall of these rams is from 5 to 10 ft. On the average 132 blows are delivered per hour of effective rock breaking, but as the passage of ships through the canal requires the rock-breaking barge to be drawn aside 30 per cent. of the time, the actual work of the barge is 83 blows per hour of work paid to the crew. The average thickness of the rock bed shattered is 2 ft. 7½ in., and it requires about 5.4 blows per cubic yard to shatter the rock. There is a considerable range in the cost of the work, but it averages 1s. 4.1d. per cubic yard, exclusive of general charges. This does not include the cost of dredging the rock. Similar machines are being used on canal work in western New York.

The Rectification of an Auditorium Roof.

The pitched wooden roof of an auditorium is carried by five 80-ft. Howe trusses 7 ft. deep and 12 ft. apart on centers which also carry the light suspended ceiling. The top chords are made with 1-in. boards spiked together and the bottom chord is made with 2-in. and 4-in. planks. Pairs of vertical screw ended rods divide the trusses into eight 10-ft. panels which are X-braced with solid diagonals abutting at the ends on wooden angle blocks of the usual type. In the many years since the trusses were built they have sagged and shrunk until the deflection at the center panels was about 6 in., which, of course, threw the roof and ceiling badly out of alignment and induced stresses in the walls and framework which it was thought desirable to relieve.

The trusses were sound and otherwise in good condition and it was determined to adjust them without removing or destroying the roof or ceiling. The latter is attached to the trusses with scarcely any clearance below their bottom chords and the height was so great and the working space so small that the job presented many difficulties.

The plan finally adopted was simply to support each truss simultaneously at two intermediate panel points and from them to jack it up to the required height and adjust the vertical rods and diagonals at that elevation so as to retain permanently the camber, after the temporary supports were removed. The roof trusses are parallel with the proscenium arch and their lower chords are all in the same horizontal plane about 59 ft. above the auditorium floor. It was decided to support each truss at the third panel point from each end where a false-work tower 8 ft. square was built up to the bottom chord. These towers were 20 ft. apart on centers and 30 ft. from each end of the truss which projected beyond them like cantilevers. Each tower was made with four 4x8-in. vertical posts with butt joints with scabs spiked on both sides. Each face was divided into panels about 10 ft. high and X-braced between them with 2x6-in. boards nailed on. All of the ten towers are braced together by continuous horizontal struts and by occasional diagonal braces.

Three of the roof trusses in the rear of the auditorium are over the wide sloping floor of the upper gallery. The fourth truss is partly over this floor and partly over the main auditorium floor and the fifth truss is wholly over the orchestra circle at a clear height of nearly 60 ft. above the main floor. The two towers which support it are seated directly on the main floor and the latter is reinforced to carry them by temporary transverse beams under the cellar ceiling and supported on vertical shores and sills set in the cellar. A third similar parallel transverse beam is placed in the cellar to support the legs on one side of the towers for the second truss, which are also carried down to the main floor. The rear legs of the same towers are, however, supported on the balcony where they are carried through the floor and are seated on the tops of the girders just above the heads of the cast-iron columns. Part of the posts of the towers for the three rear trusses are seated in the same manner on the floor beams over the gallery columns and the remainder are seated on horizontal transverse sills supported at the front end by posts from these columns and at the rear end on longitudinal sills distributing their load over the upper foyer floor at the top of the gallery. In this way each of the shorter towers are terraced up over the inclined floor of the gallery and solid well-braced footings are in every case provided for them. The entire roof load is thus transferred to forty 4x8-in. posts which are well braced and are sufficient to carry several times the greatest loads that can possibly be imposed on them here.

The posts of each tower are capped by two 8x8-in. transverse timbers carrying in the center another pair of 8x8-in. longitudinal timbers on which are supported two pairs of short 8x8-in transverse sills close together. On each pair of upper sills there is seated an ordinary 3-in. cast-iron jack screw with a capacity of 5 tons. Space is left between the sills for the screw to move up and down and its head engages a bearing plate on a short cross timber set under the bottom chords of the roof truss. The jack screws are placed close together on opposite sides of the panel points and the four screws for each truss are simultaneously operated to raise the truss about 8 in., thus giving it a permanent camber of about 2 in. It is estimated that the total load on the 20 jack screws used for the five trusses is only about 20,000 lb., so that a very large margin of safety is provided to allow for irregularity in loading or settlement.

About 18,000 ft. of timber, board measure, has been used for the falsework and the difficulty of bringing it in and erecting it in the confined spaces without injuring the interior has been the principal trouble thus far encountered.

Book Notes.

The Association of American Portland Cement Manufacturers, Land Title Building, Philadelphia, has issued two bulletins containing information of general interest. The first, on concrete bridges, was written by Mr. George S. Webster, chief engineer of the Bureau of Surveys, Philadelphia, and describes certain features of the work of this class now being done under his direction. The second pamphlet contains two articles; the first, by Mr. H. L. Weber, is on concrete roadways, and the second, by Mr. Walter E. Hassam, is on cement concrete roads. Mr. Weber first laid concrete pavements in Richmond, Ind., in 1896, and sixteen such pieces of work have been done in that city up to the present time. The article explains the important points to be considered in laying these pavements and gives complete specifications for them. In the second article, the author explains the method of laying the pavement that bears his name and gives a number of suggestions of a practical nature concerning it. The bulletins can be obtained on application to the association.

The National Fire Protection Association has issued the "Proceedings" of its eleventh annual meeting, held last May, in a well-illustrated book of 415 pages. The Association has for its object the improvement of methods of fire protection, and its work is largely of an engineering and architectural nature. It is unusually interesting for two reasons; the first is that upon its recommendations are based in a large degree the rates we must pay for insurance on buildings of all sorts, and the second is that the members of the Association discuss the designs of buildings from a point of view that rarely receives the attention it should. Owing to the amount of information collected by the Association and its affiliated societies concerning the cause and progress of fires in all sorts of buildings, it is able to discuss fire resistance with the aid of information that others do not have. As a result, many of the requirements made by insurance interests seem unnecessarily severe; indeed, it is probably true that they are too burdensome on the intelligent and conscientious contractor and yet fail to hold down the scamp who intends to do crooked work if he possibly can. A perusal of this interesting volume will show, however, that the members of the Association are approaching the problems set before them in a spirit of fairness to all, and when

they make severe requirements it is because experience indicates that there is danger. The volume contains information of much value to architects of all types of buildings and to the managers of large industrial establishments who desire to know what is going on in the way of improvement to standard fire-protection apparatus. The volume is published by the secretary of the Association, whose office is at 382 Ohio St., Chicago.

Messrs. Wynkoop Kiersted, consulting engineer, and W. D. Hubbard, of the engineering staff of the Board of Water Supply of New York, have written a volume on "Water Works Management and Maintenance," which will be of value in the offices of all water works departments, public or private, particularly in the Mississippi Valley. Nearly half of the book is a discussion of ground and river supplies and the methods of developing and purifying them, a subject which has received particular attention from Mr. Kiersted for many years and in which he has had unusual success with novel methods and plants. These two chapters give in considerable detail the results of his experience with some of these plants and contain notes regarding the clarification and purification attained by simple coagulation and sedimentation which are particularly valuable. There is a chapter explaining the types and uses of pumping engines and one on impounded supplies in this part of the book; the latter chapter contains the statement that unless the benefits of stripping a reservoir site are liable to be impaired by deposits washed into the reservoir by freshets it is considered advisable to expend funds for the purpose of removing objectionable material from the bottom and sides of an impounding reservoir. Inasmuch as this subject of stripping is one of the most important in water works design at the present time, it might be well in the next edition of the book to embody the substance of the report on stripping made by Messrs. Hazen and Fuller to the Board of Water Supply of New York. The second part of the book is on the maintenance and operation of water works plants. It explains the methods of keeping records, making connections, metering, the prevention of electrolysis, the maintenance of the quality of the supply, the reduction of water waste, the management of repair work, accounting, and other subjects of a similar nature connected with the routine work of a water works office. The book closes with a section on franchises, water rates and depreciation. These are questions that arise mainly in the dealings of private water companies with municipalities, and are becoming of more and more importance on account of the trend of sentiment toward municipal ownership. The senior author has been engaged on many cases in which these subjects were discussed thoroughly and the notes on them which he gives in the book are particularly important in consequence. (New York, John Wiley & Sons, $4.00).

An excellent book on "American Electric Railway Practice" has recently been prepared by Mr. Albert B. Herrick, consulting engineer, and Mr. Edward C. Boynton, general manager of the Orange County Traction Co., for the purpose of bringing together in convenient form a considerable amount of practical information relating to the construction, operation and maintenance of electric railways. No attempt has been made to describe the older types of apparatus or abandoned methods of operation, and as a result the book is an unusually valuable source of information for anybody interested in the subject. While a considerable part of the volume relates to technical subjects, these have been discussed with the idea of showing the "state of the art" rather than the theory. Probably no railway officer will agree with everything in the book, but it contains so much information gathered from the columns of the "Street Railway Journal" and the authors' experience that it will doubtless be of help to all in suggesting improvements in management. The investor in street railway securities who wishes to know something about the details of electric traction properties will find the book particularly useful. The first two chapters are devoted to preliminary estimates and the field engineering methods of interurban railways, and it is interesting to notice that the authors have taken a number of hints from accepted steam railway methods in their discussion of parts of these topics. The location of the power house is next taken up, but no attempt is made to describe power house construction, since that subject is well covered in other books and its introduction here would lead to a great increase in the size of the volume without appreciable increase in its value to most readers. The chapter on the overhead circuit that comes next is a long one, and explains this costly part of an electric railway installation in a manner particularly interesting to steam railway engineers, who generally fail to appreciate its extreme significance. Two chapters follow on train despatching, signals, time tables and schedules, which show, that the time is approaching on many electric roads when the complicated schedules of the steam roads will have to be adopted in order to keep traffic moving in accordance with a predetermined plan. The importance of rolling stock is explained in one of the longest chapters in the book, which describes in considerable detail the construction and uses of different types of cars and trucks and gives illustrations of the electric equipment and the wiring. The remaining chapters are on shop design and the maintenance of track, overhead lines and equipment, and various details of the management of men and the collection of fares. (New York, McGraw Publishing Co., $3.00).

Letters to the Editor.

Responsibility for Building Collapses.

Sir.—The numerous collapses of all kinds of buildings that are taking place throughout the country, particularly buildings that are either being constructed or are in course of demolition, ought to result in a more careful consideration of the responsibility for such accidents. When anything of this sort happens, all those concerned stand in a circle and point to the man on the left as the guilty party. There are generally so many of these interested parties and the actual responsibility of each for any part of the work is so indefinite that nobody is punished. This is decidedly wrong, for the killing and maiming of people through careless disregard of safe rules of building is becoming altogether too frequent in our large cities. I do not wish to hold up foreign practice as a model in all respects for American cities, but it is certainly true that the rules of the Prussian government regarding buildings are so complete and so thoroughly enforced that anybody inclined to take chances which endanger life rarely does so, knowing that he will certainly be punished if he does, not with a light fine only but with imprisonment. The building police regulations fix the responsibility of the architect and the contractor and their assistants, and if anything goes wrong there is no question about who shall be punished. Consequently the men who are responsible for the safety of the work really take pains to see that it is safe, except in rare cases, when they invariably are made to suffer for their neglect. The theory is that it is wise to allow builders and contractors full scope of their skill, but their work must conform with the building regulations, and if any accident results from a failure to comply with these regulations, they must bear the penalties for their neglect. It seems to me that American cities are trying too much to pass on the details of plans of proposed structures and are not giving enough attention to defining the responsibilities of those engaged in building operations.

Very truly yours,

Observer.

The Operation of Water and Sewage Purification Plants.

Sir.—Will you allow me to suggest through your columns that a number of American cities are showing a poor appreciation of their responsibilities in health matters to their people in the way they operate the plants for sewage and water purification that have been built by them at considerable expense. Some time ago I had an opportunity of visiting a number of plants in the Central States and found that most of them were without proper supervision and a few were allowed to run without any supervision at all, except such as could be given by an ignorant laborer. I have also seen a number of water purification plants that needed careful attention, owing to the fluctuations in the character of the water or the large amount of sedment in it, run by rule of thumb in such a way that they could not be of much use.

It seems to me that the engineers who design such plants do not lay enough stress as a rule on the importance of operating the plants properly. When the authorities of a city take over a sewage disposal plant, they generally have the opinion that it is something which is important but rather offensive as a scene of daily work, so that good men will not take it up, and accordingly adopt a scale of wages for the attendants which is not enough to secure competent men. In a little while something goes wrong, the neighbors raise a cry, and the authorities are so disgusted with the result of the large initial expenditure for the works that they leave them to shift for themselves. Probably a little competent attention and cleaning up would bring the plant to rights again, but it will probably never get it unless there is a powerful State Board of Health to force the city to act or the people in the neighborhood of the works take the matter into the courts.

Most consulting engineers do not need to be told that the average city looks upon their modest charges for professional services as very high, for there is still a lurking impression that the only difference between the engineer who dwells in a large office and the engineer who looks after a steam plant in a shop is in their respective incomes. It is hard enough in most cases to collect reasonable fees for mere designs, yet public health would be much advanced if the designers of water and sewage purification plants strongly urged their clients to turn the operation of these plants, for a period of two to five years at least, over to them at a fixed annual compensation, they to furnish all attendants. Such plants require expert supervision when first started up more than at any other time, and by giving them this supervision the experts will be able to train local assistants so thoroughly that at a later date, when the operation of the plant under local conditions is fully understood, the management will be reduced to a minimum as respects cost.

Yours truly,

Sanitarian.

THE ENGINEERING RECORD

Published Weekly by the

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

114 Liberty Street, New York.

BRANCH OFFICES:

Chicago: Old Colony Building.
Philadelphia: Real Estate Trust Building.
Cleveland: Schofield Building.
San Francisco: Atlas Building.

London Office: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico..........$3.00 a year
Canada ....$4.50 a year
Foreign subscription.....................$6.00 a year
25 shillings. 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of The Engineering Record on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

Remittances.—Remittances should be made by check, New York draft, or money order, in favor of The Engineering Record.

Changes of Address.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

Back Copies.—No copies of issues prior to July, 1905, are kept on sale, except in bound volumes.

Date on Wrapper indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

Club Rate.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 16,000 copies are printed. Total circulation for 1907 to date 450,750 copies, an average of 14,540 copies per week.

TABLE OF LEADING ARTICLES.

Bridge Loops and Passenger Traffic Between Manhattan and Brooklyn.

One of the most complicated and troublesome questions to come before the Public Service Commission of New York is that of the passenger traffic between the boroughs of Manhattan and Brooklyn, and its bearing in some respects upon the increase of elevated railroad facilities in the former borough along the existing lines and the proposed loop between the Manhattan terminals of the Brooklyn and Williamsburgh bridges. The disgraceful and uncivilized daily crush at the Manhattan end of the Brooklyn bridge and the much discussed increased capacity of that terminal and of the bridge itself have already been subjects of the most vigorous and sometimes even fantastic consideration for a number of years. Several commissions and numerous self-appointed agents for the best solution of this important problem have put on record their conclusions, and the city has spent a considerable sum in testing at least one project. The last commission appointed by the Commissioner of Bridges reported at the end of 1906 a comprehensive plan, which has at least the merit of ultimate relief as complete as any that can be hoped for, and temporary relief to an extent limited only by the present train and structural capacity of the Brooklyn bridge.

It is altogether probable that whatever measures of relief may be perfected, it will scarcely be possible to install them before the demands of the situation will exceed their capacity. Nevertheless the present conditions are absolutely intolerable and in seeking for effective means for their cure it is essential that the broadest possible views of all elements of the problem shall be taken. There have been laid down with much persistence and emphasis by interested parties certain assumed general principles to control the solution of these difficult problems and to fix the conditions which may either govern them or result from them. The Public Service Commission will do well to recognize the fundamental differences which may exist between plans or propositions loudly advocated, frequently by representatives of semi-civic bodies, of one idea only, and those calculated to lead to the real relief of the public. What is imperatively demanded for the situation is an effective means for transporting people quickly and comfortably between the boroughs of Manhattan and Brooklyn so far as the East River bridges and the connecting lines are concerned and not the enforcement of some thesis strenuously enunciated in behalf of some impracticable proposition.

One of the most emphatic statements made in connection with the solution of this problem in its relation to the East River bridges is that there must be no addition whatever to the present elevated railroad facilities of the borough of Manhattan and consequently that there must be no elevated loop constructed between the Manhattan terminals of the Brooklyn and Williamsburgh bridges. It may be perfectly proper to assume the general principle that there should be no more elevated railroads constructed on Manhattan Island. The Engineering Record is inclined to take that view of the matter, and public sentiment probably strongly favors it; at the same time that is a long way from ruling out the construction of additional express tracks under proper conditions on the Second and Third Avenue elevated lines or even the construction of an elevated loop through streets well adapted to that purpose between the two bridges named. Elevated railways in the city of New York have given a measure of relief to its people impossible to have been secured in any other way, and they are there to stay. They will continue to render that service for an indefinite period in the future. It would be irrational and thoroughly absurd to take the position that while they have rendered, and will continue to render, such service they shall not be permitted so to develop their capacity as to greatly increase that service to the comfort and convenience of the community.

The Subway system of rapid transit certainly has extraordinary advantages, but it does not possess them all. An elevated loop between the Williamsburgh and Brooklyn bridges on the Manhattan side can be built much more quickly than a subway and when it is borne in mind that the Brooklyn bridge must be reconstructed with far greater capacity than at present, as soon as diversion of traffic to the Manhattan bridge will permit, it becomes highly probable that both subway and elevated loops will be required for the enormously increased traffic of the future, especially as both terminals afford ample facilities for the two classes of connections. It is petulantly idle and hypercritical to object that such loop connections give relief only to the rapid transit companies in handling their cars. That is precisely the kind of relief which they ought to have, for it constitutes one of the most important elements in efficient transportation. The masses of people whose comfort and convenience depend upon the best possible means of inter-borough rapid transit cannot be more effectively served than by such terminal and connecting facilities between the East River bridges and the adjacent transit systems, as will afford those systems the highest attainable efficiency in handling their cars. This is the very pith and essence of this great problem of rapid and comfortable transit to which the Public Service Commission must give its best thought and not be governed by the academic advocates of any one idea.

Accident Records in Equipment Maintenance.

The maintenance of engineering equipment includes some of the most interesting problems in the field of industrial technology. The reduction of repair costs to the lowest amounts consistent with safe and reliable service is always before the maintenance department as a desirable condition to meet, and the invention of labor and time-saving devices and methods always contributes towards this end if the quality of the work is not sacrificed in the meanwhile. As equipment is developed from year to year to satisfy varying specifications, it is always of importance to measure the effect of changes in design upon the total cost and facility of repairs and renewals, and in this connection the temporary or permanent failures of the machinery in service deserve careful and detailed study. Gradual deterioration of wearing parts is easily followed in most cases, for modern equipment is designed with accessibility as one of the important requirements to be met; but the study of sudden failures or accidents is much more difficult and often neglected by operating companies in comparison with the attention paid to current repairs and their contributory causes.

Serious accidents involving legal complications are generally analyzed at considerable length by executive and technical officers of industrial organizations, but even this work is apt to be carried out in a haphazard manner if the principal energies of the staff are occupied in replacing damaged equipment as quickly as possible in order to establish the normal rate of production again. Obviously, the return to normal conditions is usually the most important task after personal injuries are cared for, supposing that these appear in an accident, but it is well not to overlook the value of notes upon the conditions taken as soon as possible after the equipment goes wrong. In the operation of a modern street railway there is a wise appreciation on the part of the management of securing the fullest particulars of the smallest and most insignificant accidents as well as those of undisputed importance. Of course, the avoidance of damages through unjust claims on the part of the public is the main reason why street railway em-

ployees are, on large systems, provided with blank forms on which the minute details of each casualty are to be recorded, but apart from their legal aspect, such reports are often helpful in throwing light upon the performance of the equipment and suggestive of changes in design to avoid similar accidents in the future. In an industrial or power plant the use of blanks bearing upon probable accidents is seldom feasible to anything like the extent which obtains in street railway service, for in the latter work the range of accidents is limited to the car and its vicinity and certain general forms can be applied to practically every case. At the same time, reports on accidents to engineering equiment in general by technical employees to their executives can be made valuable analyses of weak spots in the apparatus if care is taken to make them up on the strength of full notes of the condition before, during and after the trouble occurs. Literary excellence in such reports is not the point—what is needed is a full memorandum of the conditions mentally noted, but seldom recorded in the haste of setting things to rights.

In the stress of emergencies there is often no time to make the notes of conditions, and no engineer with heavy responsibility can be expected to sit down and prepare a report on either major or minor accidents until all that is possible has been done to restore the original rate of production. Too often, however, the necessary notes are not made until some of the details at first clear have become uncertain. The value of all emergency notes lies in their accuracy in detail, however conflicting the data may appear at first. The smaller accidents are likely to be as suggestive of desirable improvements in equipment as casualties costing considerable sums to repair and offset.

The Civic Federation Investigation of Municipal Ownership.

The abstracts of reports made by members of the committee of the National Civic Federation appointed to examine public and private management of public service undertakings in this country and abroad, printed in this journal last week, must have seemed to some readers as partaking of the nature of a technical imitation of Joe Miller's joke book. An examination of the same data has led one set of critics to declare that municipal ownership is a failure and the other set to assert equally strongly that it is a complete success. It is hardly necessary to say that those who found muncipal ownership to be a success were well-known advocates of it, while the advocates of private ownership were gentlemen engaged in the management of public service corporations. Each party doubtless felt called upon to stick to the source of its bread and butter, even in cases of reasonable doubt. It seems a pity, however, that they could not agree somewhat, and thus make their statements carry some weight with the public, which must look upon the critical reports given out by the Federation's secretary as mere ex-parte statements, to be regarded merely as utterances of interested parties. The entirely divergent opinions which were stated in the abstracts printed last week show how futile it is to expect that those who are out-and-out advocates of municipal or private ownership under all conditions may ever reach conclusions at all harmonious.

The costly investigations conducted by the Federation must not be judged, however, by the statements of the partisan reviewers of the reports which were outlined last week. The main committee has been able to reach a number of highly important conclusions from the information collected by its investigators, and its report, signed by all members of the committee save Mr. Walton Clark, is of more than usual value and a contribution of particular interest at the present time. The committee which signs the report is made up of representatives of all classes of professions and trades. It represents all political parties and every shade of belief in municipal ownership or antagonism to it. Accordingly the practical unanimity with which certain important conclusions were reached in a gratifying indication that the work which has been carried on may be of some definite help in reconciling the present discordant views held on the subject. The conclusions reached are as follows: First, public utilities, whether in public or private hands, are best conducted under a system of legalized and regulated monopoly; second, public utilities in which the sanitary motive largely enters should be operated by the public; third, the success of municipal operation of public utilities depends upon the existence in the city of a high capacity for municipal government; fourth, the franchise grants to private corporations should be terminable after a fixed period, and meanwhile subject to purchase at a fair value; fifth, municipalities should have the power to enter the field of municipal ownership upon popular vote under reasonable regulation; sixth, private companies operating public utilities should be subject to public regulation and examination under a system of uniform records and accounts and of full publicity. Messrs. Chas. L. Edgar, of the Boston Edison Electric & Illuminating Co., and Mr. Walton Clark, of the United Gas Improvement Co., refused to concur in the second and fifth conclusions, and the reasoning upon which they are based.

For the successful municipal operation of a public service undertaking, the committee's investigations indicate, according to a report given out this week, that provision must be made for compliance with the following conditions: First, an executive manager with full responsibility, holding his position during good behavior, must be in charge; second, political influence and personal favoritism must be excluded from the management of the undertaking; third, the finances of the undertaking must be separate from those of the rest of the city; fourth, the necessary bond issue for revenue-producing utilities must be exempt from the debt limit law, and should be a first charge upon the property and revenues of the undertaking. These conclusions go practically to the root of the whole subject of the successful municipal ownership. At the present time there is little attraction to a man of even third and fourth rate calibre as a technical executive to enter municipal service. Except in a few cities where municipal affairs have been administered for many years on a business-like basis, the executive head of any department is likely to be chosen for political rather than business reasons. The fact that he often makes a good executive is due to the fact that, to a certain extent, political skill calls for much the same kind of ability that business success does. Wherever technical matters are involved, however, as they always are in public service departments, the politician fails to be a satisfactory executive head. Moreover there is hardly a municipal department in the country which is free from the blighting burden of financial mismanagement. It seems to be the fate of municipalities to have their financial affairs conducted in such a manner that a business man who for the first time becomes acquainted with them is horrified. The average public service department conducted by city officials, in case it is revenue-producing, has to pay all its surplus into the public treasury. This is a financial crime of the first order, since the earnings of such a department are diverted from the consumers, who may be but a small fracton of the total population, for the benefit of the whole body of taxpayers. Every competent business man who has ever investigated and reported on municipal financial methods is a strong critic of this almost universal practice, yet it seems impracticable to uproot it from its firm hold. As a result, it is not only impossible to reduce rates for the benefit of the consumers who are paying for the service, but it is even impracticable in many cases to pay out of the earnings of the department the sums necessary for repairs and extensions.

Beyond question this subiect of municipal ownership is fast becoming one of the most important in the country. It deserves particularly careful attention for two reasons, the first being that it affords a popular method of appealing to prejudice followed by political demagogues; and, second, there is a feeling among a good many students of governmental methods that the American system of control by popular vote is likely to receive its most severe test in dealing with such a subject. In Germany, where paternalism has always been a feature of government and those who are engaged in municipal service are highly respected, municipal executive offices attract a very fine class of men. There are a good many people, believers in municipal ownership as a theory, who nevertheless hold that the Anglo-Saxon temperament, modified by a mixture of characteristics from the lower classes of all Europe, is unfitted for the municipal management of undertakings so directly affecting all the people as street railways, electric lights, markets, water-works, and the like. Just how far this pessimism is warranted seems to be uncertain at the present time. There are some cities in the country, notably in Massachusetts, where the State regulation of public utilities is very strict, in which the municipal management of public lighting has been a marked success. Moreover, the State control of the extension of railways and other public services by private corporations has prevented unnecessary duplication of facilities, and has practically created for existing companies the monopoly of their business which the committee so strongly and properly considers essential for the successful administration of any public service, whether under municipal or private control. As the matter stands to-day, The Engineering Record believes that a fair statement of conditions is that in some cities it would be extremely dangerous to place all public services under municipal control, and turn over to politicians the direction of their vast body of employees. On the other hand, there are cities where such public service operations might properly be conducted by the city authorities, for the standard of municipal business methods is a high one.

The Water-Works Situation at Atlanta.

The situation of the water-works of Atlanta, Ga., during the past month has been an interesting one, particularly to those who believe that the successful administration of municipal departments depends upon divided control. Without going into the detail of all the troubles, it may be stated in brief that the water supply has at times been deficient in quantity and poor in quality. As a rule it is excellent and the trouble naturally aroused serious protest from the consumers. The affairs of the water department are under the charge of a general manager, a water board and the city council, the measure of responsibility of each being something which apparently few people know anything about. The manager of the department, Colonel Park Woodward, is one of the best known superintendents of such works in the country. The development of the plant and its effective service have been under his special care for years, and that he has served the city well is thoroughly well recognized among water-works men. Probably some members of the city government do not understand how carefully all details of water-works affairs are watched by those interested in them in other

cities. Some of these critics, among insurance interests particularly, have a very good reason for keeping closely in touch with water-works management throughout the country and have special facilities for comparing the results obtained in different cities. These people naturally rubbed their eyes when an attempt was recently made to shove on the shoulders of Colonel Woodward the responsibility for the recent troubles with the Atlanta supply. They have known considerably better, apparently, than a good many people in the city that the situation at Atlanta was such that, unless the recommendations repeatedly made by the manager of the works were carried out, the consumers would be subjected eventually to serious inconvenience. Now that the inevitable has happened, although its coming was foretold in the reports of the general manager of the works, the shuffling haste with which those responsible for the mud in what little water was supplied to Atlanta recently, endeavored to fasten the blame for the trouble on the shoulders of others was just a bit ludicrous.

As a city develops and its population increases there is an increased demand for water as well, a fact so self-evident that it is surprising it is overlooked so often by city fathers. It certainly was overlooked or neglected in Atlanta for a good many years. In 1902, Colonel Woodward sent a special report to the water board in which the necessity for various improvements, including an additional water main from the river which is the source of the supply to the reservoir, was very strongly stated. In each subsequent annual report he also called attention to the matter, and the president of the water board drew the attention of the city council during the same time to the subject and urged that money be appropriated to carry out the work. Owing to the lack of this main the city finally was supplied with very poor water, and a few months ago, practically five years after the construction of the main had been strongly urged by the manager of the water department, money for the work was finally appropriated.

The pumping capacity of the water department is short. There are two 10,000,000-gal. pumps and one 15,000,000-gal. pump available for use. During the day it is necessary to run one of the 10,000,000-gal. pumps and the 15,000,000-gal. pump. If the larger one should break down, the two smaller pumps could not give the necessary pressure for fire and domestic service. The situation was brought to the attention of the city council and some of the members of that body recognized its gravity and endeavored to secure a new pumping engine as quickly as possible. Bids for such an engine were opened early last May, when it was discovered that the son-in-law of one of the councilmen had put in a tender for a centrifugal pump driven by a steam turbine. This was a new combination and at the request of the bidder offering it, Mr. D. H. Maury, of Peoria, was retained to investigate the merits of the proposition. This engineer is known to look with favor on centrifugal pumping machinery, nevertheless he rejected the proposition on the ground that the combination was an experiment and it would be hazardous for Atlanta to make it. His report was discussed and he was again retained to investigate the matter, but further examination convinced him that the proposition was not one adapted for the situation in Atlanta. The party making the bid finally suggested that it would be desirable for a committee of the council to visit Brooklyn, where there was such a pumping unit in service, but it was found that the unit was not ready for operation and the trip was called off. Whether a new pumping engine has yet been ordered, this journal cannot state, but the long delay in placing the order is a thing that deserves considerable study by those who urge that the successful management of a water department by public officials demands divided responsibility.

A recent report by the engineering department of Atlanta on the water-works situation is pertinent. It was the duty of this committee to investigate the cause of the muddy water recently and it recommended the construction of settling basins at the river side, where the water could be partially clarified before it was pumped into the main reservoir. This recommendation was satisfactory to the authorities in charge of the water-works and the general manager was asked why it should not be adopted. He very promptly called attention to the fact that two years ago he suggested the necessity of such works. Apparently this suggestion had been entirely overlooked and, like a good many other recommendations of importance made by water-works superintendents in other cities, it was allowed to lapse into the limbo of forgotten things. It is merely one of many details which go to show that there is no inherent virtue in municipal ownership which makes it practicable for several different parties to have control of the same undertaking, and that the sooner such departments are placed in the charge of a technically competent administrator, the better will be the service the public receives. There is no reason why the water board of Atlanta should not be in complete control of the water-works under its charge, receiving enough compensation for its water to enable it to be financially independent of the city council, just as if the service were rendered by a private water company. Under such a plan the works could be conducted in a business-like manner, and there would be a better chance of improvements being made when necessary to avoid troubles like those that have recently occurred.

Notes and Comments.

THE ENORMOUS COVERED RESERVOIR which is under construction at Honor Oak, Camberwell, for the Metropolitan Water Board of London, contains a number of unusual features in the design of the walls. The reservoir will contain about 70,000,000 gal., and is divided by two intersecting interior walls into four basins, with a gatehouse for all the basins at the intersection. Here the connections are so arranged that each basin can be operated independently of the others. A part of the reservoir is an excavation, and here the walls are arched in plan, while the outside walls elsewhere are of ordinary section for retaining walls. The central walls are also arched in plan, 6 ft. thick at the center of each bay and 10 ft. at the heavy brick buttresses which separate the bays. These buttresses are likewise used along the outer walls, and are carried up to form part of the roof supports. The floor is made of inverted arches, supporting at the high points brickwork piers 14 ft. high, which carry the jack arches for the drum vaulting of the roof. The brick used in the work were made from the clay excavated from the site.

THE GAS SITUATION in Hamilton, Ohio, concerning which editorial mention was made in the issue of this journal for June 22, has undergone further change. The city council has passed an ordinance granting a franchise to the Columbia Gas & Electric Co. to furnish natural gas to the city for a term of 25 years. The company is to lease the mains of the moribund municipal plant, maintain them, and make necessary extensions, the rental being stated as $5,750 per year. Natural gas is to be supplied by Jan. 1, 1908, the price to be 30 cents per thousand, or 60 cents per thousand for manufactured gas, should the natural gas supply fail. Meanwhile the plant of the Hamilton Gas & Electric Co., which supplies all the gas now used in the town, has suffered considerable damage from a tornado, which on July 6 demolished the condensing house at its by-product coke-oven works, and put this division of the plant temporarily out of operation. The supply of gas, however, has been kept up with but a few hours' intermission, an auxiliary water gas plant being brought into service. It is expected that repairs to the coke oven plant will be completed, it is stated, within ninety days from the time of the accident, and operations will then be resumed as usual.

THE COST OF ANTHRACITE COAL is bound to rise steadily and for this reason the expense of operating boiler plants with such fuel in order to avoid the production of smoke is sure to rise with equal steadiness. This assertion has been made a number of times in this journal, and has generally aroused a protest from engineers who hold that the increased cost of hard coal is simply due to a combination of the producers. A few facts based on the experience at a colliery at Pittston, Pa., are worth considering in connection with this subject. The shaft reached a coal seam 10 to 12 ft. thick at a depth of 175 ft., and here coal could be taken out at the rate of 15 tons per miner per day. After this seam was worked out, the shaft was carried down to a second, about 6 ft. thick; then to a third, about 6 ft. thick, and finally to a fourth, only 3 ft. 10 in. thick and 270 ft. below the surface, where one miner can produce but 5 tons per day. Under the present conditions it is necessary to employ three times as many miners to get out the same amount of coal as originally, and also a much larger number of timber men, drivers, runners and masons. It has been necessary to more than double the ventilating equipment and to increase many times the force of men employed in keeping the ventilating system in working condition. The amount of water to be removed has increased from 300 to 3,500 gal. per minute. The wages of the miners have been raised and they are now paid for both coal and rock removed, while formerly they were paid solely for the coal. This list of increased expenses could be made much longer, but enough has been stated to indicate why it is true that the working of the anthracite fields is more expensive now than formerly.

A RIVER POLLUTION DECISION was recently made by the Massachusetts Supreme Judicial Court in Parker v. American Woolen Co., 81 N. E. Rep., 468, which merits attention. The court decides that there is no question about the right of each riparian owner to use the stream in a reasonable manner, according to the usages and wants of the community, which will not interfere with a similar use by the riparian owners above and below him. Many of the uses which properly may be made of the water of a natural stream by an upper riparian owner will have some tendency to defile the water, and it is inevitable for controversy to arise concerning what is permissible contamination. The court rules that no riparian owner has the right to use the waters of a natural stream for such purposes or in such a way as will materially injure it for the use of a lower riparian owner, or to add to it substances which will make it unfit for use. Owing to the self-purification which takes place in streams the law will not prevent the discharge of every small amount of polluting substance into the water, although this may be prevented by statute. The court also makes the important ruling that the plaintiff is entitled to an injunction restraining the pollution of the stream, even though this pollution does not now interfere with any use he is making of its waters. The court accordingly ordered a decree to be entered enjoining the defendant "from emptying or discharging or permitting to be emptied or discharged into the brook upon its premises above the plaintiff's premises any acids, soaps, compounds of soaps, or of iron, chemicals, scouring, dye stuffs, sewage or any objectionable substances whatever, in quantities that noticeably or appreciably affect the purity of the waters when they reach the plaintiff's premises, or render them materially less fit for drinking, domestic or other uses at that point than they are when they enter the de-

THE WEST NEEBISH CHANNEL OF THE ST. MARY'S RIVER.—I.

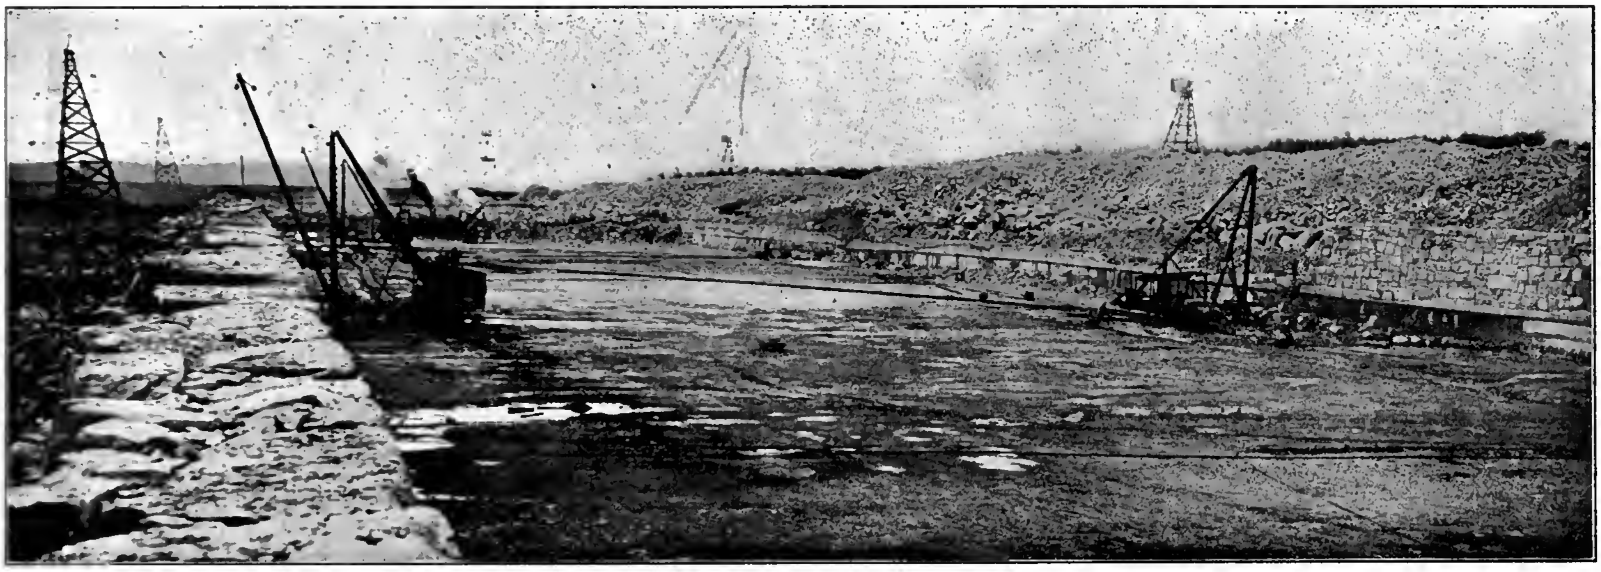
The improvement of the West Neebish channel of the St. Mary's River, which connects Lake Superior and Lake Huron, was undertaken several years ago by the United States Government and has approached a stage of completion indicating that under normal conditions this extensive work will be finished before navigation closes this fall, or at the latest by the opening of navigation next spring. One of the most serious handicaps to the great volume of traffic passing through this river between Lake Superior and the other Great Lakes will then be relieved. Originally, up-bound vessels plying the St. Mary's River were obliged, after leaving the head of Mud Lake, which is some twenty miles in a direct line from Lake Superior, to pass to the east of Neebish Island and thence follow a long circuitous route around Sugar Island through Lake George and Little Lake George to reach the locks at the Sault Ste. Marie Rapids in the River. The channel along the east side of Neebish Island was improved several years ago to provide a minimum depth of 21 ft. at the mean stage of water in the river. About the same time a channel with a minimum depth of 21 ft. was excavated between the upper end of Neebish Island and the lower end of Sugar Island; this channel was continued on up the river to deep water in Hay Lake, about 10 miles below the locks at Sault Ste. Marie. The new channel thus formed, generally called the Middle Neebish, greatly shortened the sailing distance between Neebish Island and the locks and is used by traffic practically to the exclusion of the old channel, the great fleet of large ore and grain-carrying vessels which pass through the river being included in this traffic.

At the same time the hazards presented to traffic by the Middle Neebish Channel became a serious menace to that traffic long before the latter reached its present tonnage, which during the average open navigation season of 143 days is greater than that of any other inland waterway in the world, having reached a total of over 51,500,000 tons in 1906. Several sharp turns in the Middle Neebish channel, the greater part of which is artificial, are the most dangerous features offered to the safe passage of vessels through it. In the first place the approach to them from one direction cannot be seen from the approach from the opposite direction, owing to the height of the wooded intervening land. On the other hand, the five to six-mile current in the river at this point requires the down-bound vessels to maintain a speed of eight to twelve miles an hour in order to obtain steerageway. Since the larger loaded ore and grain vessels, many of which are over 550 ft. in length and draw in the neighborhood of 19 ft. of water, form the principal portion of the down-bound traffic, it is evident that they cannot be controlled readily at the turns in the channel. Furthermore, the upbound traffic consists mostly of the same large vessels, which generally return to Lake Superior loaded with coal.

The menace offered by these turns and the conditions surrounding them has thus greatly hindered traffic at all times, and has resuled in numerous serious collisions. The extreme care that is observed in navigating this channel, frequently necessitating a vessel to lie at the mouth of the St. Mary's River during the night in order to make the channel by daylight, has, however, reduced the number of accidents to a minimum. To avoid these delays, the schedules of vessels are arranged, when possible, so the channel will be reached during the duy. A large number of vessels, nevertheless, make a night passage through the St. Mary's River, rather than wait for daylight.

The West Neebish Channel is being excavated to relieve the present situation. It will provide a shorter and straighter course than the Middle Neebish Channel, with fewer turns, all of which can be navigated safely, and will have a minimum depth of 22 ft. below extreme low water. It connects the lower end of Hay Lake with the upper end of Mud Lake, passing between the west side of Neebish Island and the mainland, and has a total length of approximately 13.5 miles. The upper and lower reaches of this channel extending, respectively from Hay Lake to the West Neebish Rapids of the St. Mary's River and from those rapids to Mud Lake were excavated in sand, clay and mud and are finished. The remaining section of the channel, extending through the rapids, with a total length of about 2.5 miles, forms the most difficult part of the whole project, as it has to be excavated almost entirely in solid rock. This section is now rapidly approaching completion, however, the expectation being that, with reasonable success, it will be done before December 1st. After the opening of the new channel on the west side of Neebish Island, the Middle Neebish Channel will be deepened to the same depth of 22 ft. at extreme low water. Downbound traffic will be diverted through the West Neebish Channel after the improvements are finished and upbound traffic will continue to use the Middle Neebish Channel, making a double sailing course in the most difficult part of St. Mary's River, and a practically double course from Lake Superior to Lake Huron.

The new channel has a minimum width of 300 ft., and a clear swept depth of 22 ft. at the lowest stage of the water in the river. The upper reach, extending from Hay Lake to the rock section through the rapids, has a total length of approximately six miles, with only one slight turn. The water along the site of this part of the channel varied from 3 to 5 ft. in depth before excavation was started; the excavation was made through mud and sand with large dipper dredges, the excavated materials being loaded on scows, in which they were hauled to shallow water along the shore line and dumped. The lower reach of the new channel in a distance of some two miles between the downstream end of the rock section and the original river channel had 22 ft. or more water, so no work was required in this length. From the lower end of this natural deep channel to Mud Lake a new channel, approximately three miles long, was dug through the sand, clay and mud which formed the bed of the river. This three-mile section has only one turn, and its channel is widened at this turn to permit easy navigation, as is done at all turns in artificial channels. This section of the channel was also made with dipper dredges from which the material was carried on scows to dumping grounds.



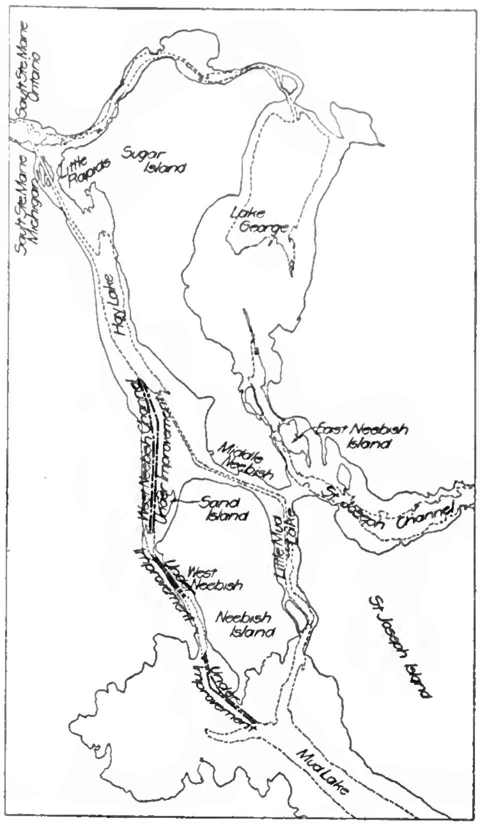
Upstream End of Canal Showing Two 1,000-Foot Cableways.

The water in the West Neebish Rapids of the St. Mary's River through which the rock section had to be built, varied from a few inches to several feet in depth and had a current with a velocity of 4 to 7 miles an hour. The bed of the river was a solid ledge of hard Niagara limestone for 8,600 ft. of the 13,300-ft. section included in the contract for this work. This limestone ledge was covered with scattered boulders, varying from small stones to those containing 2 cu. yd. or more. The specifications under which the contract for this work was awarded required that cofferdams should be constructed which would unwater these rapids over a length of about 6,000 ft. of the channel; and that the remainder of the work could be done by dredges. These conditions were changed, however, to permit the construction of cofferdams which would unwater a length of 8,800 ft. of the river through the rapids, the remainder of the work to be done by dredging.

The contract for the construction of the 2.5-mile section of the channel through the West Neebish Rapids was awarded to MacArthur Bros. Co., of Chicago, on April 7, 1904. This

company built the large cofferdams required to unwater the portion of the excavation to be done in the dry, and then sub-let that portion of the work, involving approximately 1,700,000 cu. yd. of rock excavation to Messrs. Grant, Smith & Co., of Chicago, of which company Mr. C. H. Locher, associate partner, is manager in charge of the work, and Mr. G. P. Locher is superintendent. The contract for the portion of the excavation to be done outside of the cofferdam with dredges was let to Edward Bros., of Sault Ste. Marie. A preliminary description of the work on this rock section was printed in The Engineering Record for March 2, 1906.

Construction Plant and Methods.—The first work of the construction was to build two temporary cofferdams about midway between the two main cofferdams. These temporary dams were about 1,000 ft. apart at the site of the channel and extended across the river from the mainland to the island, varying in direction to suit the contours of the river bed. They were built in 2 to 7 ft. of water flowing 3 to 6 miles an hour. The construction of these dams stopped the flow of water in the West Neebish Channel of the river, so the main cofferdams could be built in still water, and also laid bare a part of the site of the channel about 1,000 ft. long. In building these temporary dams, which varied from 4 to 10 ft. in height, broken stone and rock were dumped from scows on the line of the dams until the force of the current was



The West Neebish Channel.

ice. The rock that had been taken from the portion of the channel on which work was already in progress was hauled on sleds on the ice to a point over the part of the dam already built. This haul was from 4,000 to 4,500 ft., and as much as three cords of stone were carried on a sled at a load. A channel was cut through the ice over the dams in order that the stone could be dumped on top of the bank already built. This dumping was done in such manner as to form a small bank along each side of the top of this base. When these two parallel banks had been carried up to the water surface in this manner, the space between them was filled with sandy clay which contained a considerable quantity of gravel and small boulders, taken from a borrow pit on the mainland. After the space between the two small banks of rock on each side of the top of the lower section of the dam had been filled with the material from the borrow pit the same material was used to top out the dam to its full height of 6 ft. above the water level. The material was hauled from the borrow pit to the dam in boxes on sleds and dumped into place through the ice. After the dam was about finished, a narrow-gauge light railway was laid the full length of it and extended to the borrow pit in order to have it available in an emergency. This dam was completed in April, 1905, and the last part of the area between the two main cofferdams was unwatered soon after.

Only one accident of any moment occurred to

Upstream End of Excavation, Showing Part of Upstream Main Cofferdam and Compressor Plant.

broken and the rock-fill carried above the water. Sandy clay was then brought in and dumped on the upstream side of these rock embankments in order to silt up the openings in the latter and produce water tight dams. The dams were completed in July, 1904, after which the water was immediately pumped out of the area enclosed between them and work started on the rock excavation. Two of the four cableways which have been employed in the construction of the rock section of the channel had been installed meanwhile and were placed in service to hoist the excavated material out of the cut and convey it to spoil banks along the channel.

Main Cofferdams.—The two main cofferdams which unwater the 8,600-ft. section of the work that is being excavated in the dry, are structures of unusual magnitude. The upstream dam is L-shaped, and is built in water from 2 to 18 ft. deep; the stem of the ell extends from the mainland across the river at right angles to the channel for 1,200 ft., the leg of the ell continuing down-stream 700 ft. from the outer end of the stem to the shore of the island, making the total length of the dam 1,900 ft. This cofferdam has a minimum width of 8 ft. at its top, which is 7 ft. above the water, and has side slopes on the water side of about 1 on 1½, and of about 1 on 2 on the other side. The other main cofferdam is 8,600 ft. downstream from this one. It has a total length of 2,600 ft., and in plan is arched slightly downstream against the water on that side of it. This cofferdam was built in water from nothing to 26 ft. deep; it has a minimum width of 12 ft. at the top, which is 6 ft. above the water; its side on the water side is built on an average slope of 1 on 2, and the one the other side of 1 on 2½.

The construction of the upstream main cofferdam was started soon after the current of the river had been broken by the temporary dams. Sandy clay and mud excavated by the dredges at work on the adjacent sections of the channel were brought to the site in bottom-dump scows and deposited in place. When the banks thus formed had been carried up until the bottom-dump scows would operate no longer, the materials were loaded on flat deck scows, and handled from these to place in the embankment by a clam-shell bucket on a derrick scow. The final trimming and finishing of the portion of the dam above the water was done with wheelbarrows and by hand. This dam was finished November 1, 1904, after which the water covering the area between it and the upstream temporary dam was pumped out.

The downstream main cofferdam was also built from scows up to within 5 to 6 ft. of the water surface, with materials excavated by the dredges. Soon after this part of the work was finished in the fall of 1904 the river froze over, and the cofferdam was completed through the either of the two main cofferdams after they were built. In February, 1905, the upper part of a 250-ft. length of the leg of the upstream dam, near the shore where the dam section was light became detached from the remainder of that dam and was carried over into the area which had been unwatered, with the result that that area was flooded. The cause of this accident has never been certainly determined. It is believed, however, to have been brought about by the formation of a line of cleavage in the dam by freezing, followed by a change in the river level which lifted the detached portion and floated it away. This break was soon repaired and since then an open channel maintained in the ice on the water outside the dam has avoided further similar difficulty. This channel was kept open by simply piling brush on it and covering this brush with loose snow; the top and slopes of the dams were also covered with brush to collect snow which prevents freezing and the formation of cleavage planes. Although temperatures of 20° below zero, Fahr., are common in the locality where the work is in progress, this simple expedient forms a line of separation between the main body of the ice and that attached to the slopes of the dam.

Pumping Plants.—The quantity of water which leaks through the cofferdams is very slight when compered with the great length and height of these dams. At the same time, a large amount

t pumping capacity was required to remove the water which covered the area enclosed by the dams. The total capacity of the pumps installed is about 40,000,000 gal. per 24 hours. This capacity is required only a small portion of the year, however, but is all necessary in the spring when the snow is melting, or during excessive rains. A berm ditch on each side of the river, extending the full length of the work on the island side and two-thirds the length on the mainland side, diverts the drainage from the land into the river and prevents it reaching the area between the cofferdams. A 12-in. centrifugal pump on the upstream cofferdam handles the principal part of the water in that end of the area enclosed. Two 6-in. reciprocating pumps in this end of the channel cut are capable of removing the water from the latter. Two centrifugal pumps, one a 12-in. and the other a double section 18-in. are installed in a pump house on the downstream main cofferdam to pump the water from that end of the work. Two reciprocating pumps, an 8-in. and a 12-in., are placed in a house on the edge of the channel cut, about midway between the main cofferdams, and pump from the cut into a flume leading to one of the berm ditches. A 12-in. centrifugal pump in a house on the opposite side of the channel near this point is also used while the snow is melting and during heavy rains. The water in the downstream end of the channel cut is removed by three 8-in. reciprocating pumps.

General Features of Construction Plant.—The controlling feature of the extensive construction plant which has been installed by Messrs. Grant, Smith & Co., is the adaptability and arrangement of the various parts of this plant to be operated day and night, six days a week, throughout the year. The long and extremely cold winters of the locality in which the work is being carried on required unusually careful precautions in the choice of the equipment to be installed. At the same time, the continued low temperature of the long winters, the large amount of snow-fall which occurs and the great quantity of ice that forms in a work of this character interfered seriously with the progress of the construction. In fact, it is believed that the cost of handling work during the winter months has been 25 per cent. greater than it is during the remainder of the year.

An idea of the climatic conditions in this locality may be obtained from the records of the station of the United States Weather Bureau at Sault Ste Marie. The mean average temperature throughout the year for a long series of years, as given by those records was 39° Fahr. During four months of the year, December, January, February and March, the average monthly temperature for the same series of years was considerably below 32° Fahr., with frequent temperatures as low as 25° below zero, Fahr. Ice forms on open water six months in the average year, reaching a thickness of 30 in., or more during the winter. Added to these conditions some snow falls nearly every day in the winter and the annual snowfall is quite heavy, the ground generally being covered with from two to three feet of snow during the winter. Notwithstanding these extreme climatic conditions the construction work has been handled day and night, practically without interruption, except for Sundays, since its inception. During 1906 the government engineers credited the contractor with 290 working days and nights, without including seven holidays on which work was in progress. This record does not mean, either, that part of a day was counted as a full one, because all of the men are provided with rubber clothing, so work is rarely stopped by rain or snow, the rock bottom of the cut always providing a good working foundation.

The various equipment and plant connected with the work is operated, with a few exceptions, on air furnished from a central compressor plant. Air-driven rock drills are employed in making the large number of blast holes in which the channel cut is excavated. The loosened rock is loaded into large skips by steam shovels, the skips being hoisted out of the cut, conveyed to spoil banks along the side of the channel and dumped in these banks by long-span cableways with traveling head and tail towers. All of this equipment was selected largely on account of its adaptability to work continuously under the trying climatic conditions, which become particularly strenuous at night during the winter.

Compressor Plant.—The equipment in the central compressor plant is as complete as that in most permanent plants of this kind, and was installed with as great care. The plant may, in fact, be considered a permanent one, since it has been operated continuously for over three years. It is in a tight frame building, 40x108 ft. in plan, which is divided by a transverse partition wall into a boiler room and an engine room. The boiler room contains three 200-h.-p. Erie City sectional water-tube boilers placed in brick settings on concrete footings. These boilers are operated at 150 lb. pressure and are each served by an 80-ft. stack. They are supplied with feed-water by either of two Snow boiler-feed pumps, which draw from a Kelly-Berryman feed-water heater. This heater operates on exhaust steam from the auxiliary units in the plant.

The engine room contains two cross-compound two-stage Rand compressors; one of these has 40 and 23-in. air cylinders and a 48-in. stroke, producing a capacity of 4,527 cu. ft. of free air a minute at 90 lb. pressure; the other machine has 17 and 30-in. air cylinders and a 30-in. stroke and produces 1,900 cu. ft. of free air a minute at 90 lb. pressure. The larger compressor is driven by a cross-compound 700-h.-p. Newburg Corliss engine, and the smaller one by a cross-compound 325 h.-p. Hamilton Corliss engine. These engines are operated condensing, each of them being equipped with a Dean jet condenser. Circulating water for the condensers is supplied by any one of three pumps in the basement of the engine room. These pumps also supply water to the feed-water heater from the condenser hot well, or from the river.

All of the various units in the plant are on heavy concrete foundations, which were built with special care. The bed plates of the two main units are placed directly on the concrete, without any cap stones. No trouble from vibration of the engines or compressors has ever been experienced, however, although both compressors are in service 23 hr. a day for at least six days a week.

The compressors deliver to an air receiver, 4 ft. in diameter and 18 ft. long, just outside the building, from which air is piped to various parts of the work. An 8-in. pipe line, 6,000 ft. in length, extends along the main-land bank of the

General View of the Construction Work in Progress, Viewed from Upstream End.

river, and is continued an additional 2,000 ft. as a 6-in. line. This 8,000-ft. line is provided with several L-shape vertical joints to provide for expansion and contraction. The line is also laid to drain to drip cocks placed at convenient intervals, in order that the condensation may be removed readily. A second receiver of the same size as the first is placed on the 8-in. line 3,650 ft. from the compressor plant, to provide for sudden demands for air. Taps are made in the main line so branches can be carried to the various plants at any point along the work. A 6-in. main line is also laid to opposite side of the work to deliver air to the engines of two cableways on that side. In all, 35,000 ft. of pipe is required to convey air from the central plant to the different parts of the work. This large amount of pipe is entirely exposed to the weather, but the whole air distributing system has been operated during the coldest weather. Reheaters have to be used on all air-consuming units, however, and in the winter fires are maintained at different points along the supply lines to prevent the water of condensation from freezing and stopping the pipes.

(To be Continued.)

A NEW RAILROAD STATION designed for handling a large number of people in a short time was completed at East Pittsburg by the Pennsylvania R. R. last spring. It is located at the shops of the Westinghouse Electric and Manufacturing Co., and separated from the latter by Turtle Creek. During the rush hours the railroad carries between 5,000 and 6,000 people, mostly employees of the various Westinghouse companies, who live in Pittsburg and its suburbs. The platforms of the new station have in consequence been made especially wide, and since the passengers as a rule have but a few minutes to wait, the station building has been made small, but the main platforms have been covered throughout their length. The passenger trains are operated on four tracks, the two outside ones being devoted to local trains, which carry the bulk of the traffic. The main platforms are on the outside of these local tracks, and an island platform is located between the express tracks. A bridge over the creek leads to the north local platform, from which stairways descend to a subway leading under the tracks to the other platforms. A masonry retaining wall about 30 ft high forms the bank of Turtle Creek, and in order to get the desired width of platform the station building was built out beyond the face of the wall, overhanging the creek 8 ft. and resting on cantilever I beams.

The Hydro-Electric Plant of the Huronian Co.

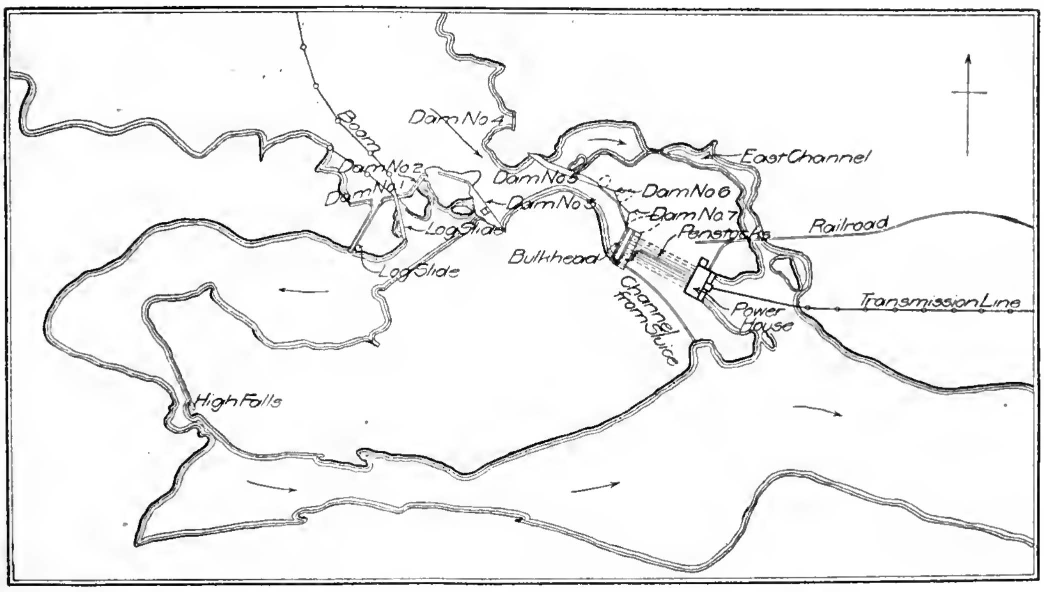
The Canadian Copper Co. operates numerous nickel and copper mines, in the Sudbury District of Ontario, Canada, all of which are located on a strip about 28 miles long and not far from the Soo Branch of the Canadian Pacific Ry. The high cost of coal for operating these mines and the smelting plant which is located at Copper Cliff, resulted in the organization of the Huronian Co., in order to acquire the property known as High Falls, on the Spanish River about 28 miles west of Sudbury, and in the spring of 1904 work was begun upon the development of this water power. The plant is located in western Ontario, north of the Georgian Bay.

The Spanish River above High Falls drains an area of 2,150 square miles, over which the annual average rainfall does not exceed 30 in. The minimum gauged discharge from the river is 1,600 cu. ft. per second, which occurred during a season when the average rainfall did not exceed 24 in. Owing, however, to the nature of the covering of the watershed and to the numerous lakes in the upper reaches, the minimum flow is high, being 0.71 cu. ft. per second per square mile.

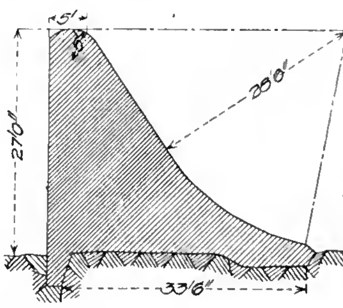
Above High Falls for a distance of 6 miles the river is a succession of rapids, and it was considered necessary that these should be drowned so as to prevent the formation of frazil, and also to form as much of a reservoir as possible. For these reasons the river level above the falls was raised 18 ft., thus providing a storage basin about 6 miles long and increasing the head from 67 to 85 ft. Immediately above the falls are many rocky islands which break the stream into several channels and finally at the falls themselves an island divides the river into two channels which unite again a short distance below the falls.

On account of the number of small channels between these rocky islands, quite an extensive system of dams was necessary. Three of these were needed to close the west channel, two to close the east channel and two others, joining on to the bulkhead, form the forebay. As the river is much used for lumbering purposes and as large numbers of logs come down each year, provision for their passage was made in dams 1 and 2 by means of a chute to which the logs are guided by a system of booms in the upper river. In order to insure a constant flow over these two dams the other dam in the western channel, No. 3, was made 18 in. higher than the overflow dam in the other or eastern channel. Sluices have been built in two of the dams at an elevation 11 ft. below the bottom of the forebay so that by opening them the water can be lowered if necessary, so as to allow of repairs to the racks and bulkhead. These sluices are also intended to be used to relieve the overflow at high water and are accessible by bridges from the shore end of the dam.

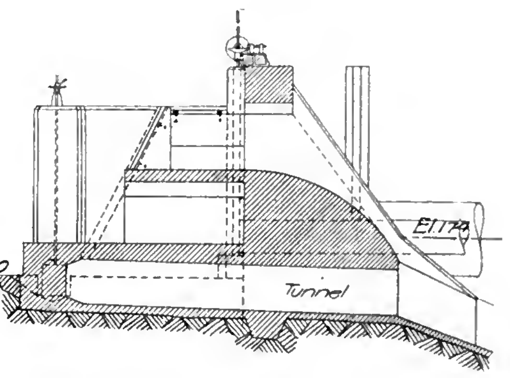
The first work in the actual development was



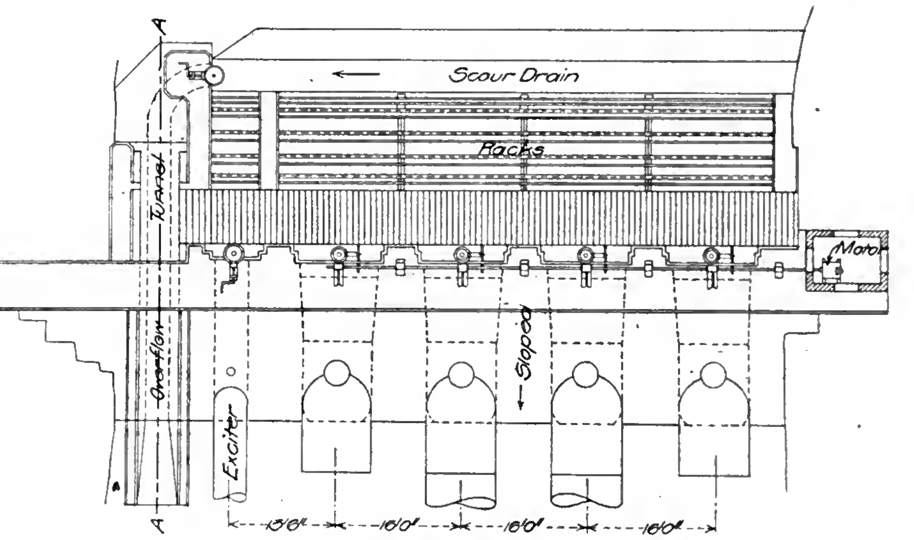
Plan Showing Dams and Power House, Huronian Company.



DAM No.3



SECTION A-A



Dam, Bulkhead and Penstock Inlets.

the construction of the dams, and this was started in September, 1904. The preliminary work had been begun in the Spring of the same year and consisted of the construction of a spur from the Canadian Pacific Ry., and the erection of buildings for housing the workmen and storing material. Dams 1, 2 and 4 were started first and work on them was carried on continuously to completion notwithstanding the severe Winter of 1904 and 1905. About the same time the concrete foundations of the power house were built up above the level of high water so as to avoid delay in the following spring. A log slide and two temporary openings were left in dams 1 and 2, so as to pass the water when it became necessary to stop the flow in the east channel of the river. The latter channel was then closed up by a crib cofferdam against the head of 32 ft. of water. The plan of this cofferdam was in the form of a letter V, each leg abutting on the rocky bank and projecting outward and up-stream. The ends of these legs were finished square leaving a key-shaped space between the channel ends. Accurate measurements were made of this space and a crib of these dimensions was built up-stream, loaded and then lowered with heavy tackle to within a short distance of the proposed location. Its construction was continued until it sank within a few inches of the bottom of the river, and its position was then carefully adjusted so that the current would carry it into the opening between the ends of the two legs. When this had been done the tackle securing it were quickly slacked and the crib slid in place and closed the cofferdam. The face of the entire structure was then double-sheeted and made as tight as the bottom formation would allow and the flow of the river was diverted to the openings in dams 1 and 2. The power house is located on the down-stream side of High Falls Island and in order to carry the water to it a forebay was blasted on the island and enclosed by the bulkhead and dams 6 and 7.

All of the dams are founded on solid rock, ample trenches being cut for anchorages, both in the foundation and in the end walls. The rock was carefully cleaned of all dust and dirt and cement sprinkled dry over the bottom. Over this was placed a layer of 1:3 mortar having a minimum depth of 4 in., and the regular concreting begun. The concrete mixture was 1:3:5 well mixed and deposited very wet. Larger stones were freely used, some measuring over 2 cu. yd., and were placed so that none of them were closer than 9 in. to the face of the work, nor nearer to each other than 12 in. All of them were carefully washed and scrubbed before placing, carefully bedded and so disposed as to form as effective a bond as possible.

Although a large part of the concrete both in the dams and power house foundations was dug in winter with the temperature varying from a few degrees below freezing to 15° below zero (Fahr.), no difficulty was found in securing good concrete work, the only precaution taken being to heat the water by turning a ¾-in. steam pipe into the water barrel supplying the mixer, and during the mixing to use a jet of live steam in the mixer, keeping the cylinders closed by wooden coverings. No attempt was made to heat the sand or stone. In all the winter work care was taken to use only cement which would attain its initial set in not more than 65 min., and the results obtained have been absolutely satisfactory. Even the thin walls used in the sub-station and the blowing engine house were constructed in the winter without impairing the quality of the work.

The dams vary somewhat in height according to the elevations of the rock foundations but are all in the neighborhood of 27 to 30 ft. They vary in length from less than 100 to about 300 ft. in length. The front face in all cases is vertical while the back face in the spilling sections has a ogee curve, and in the remainder of the work a sloped profile having two different ratios.

The steelwork supporting the racks and the entrance cones of the penstocks is built into the bulkhead wall, being carefully bedded and covered with wet mortar. The inlet for the exciter penstocks is separated from the main unit inlet by a concrete pier, and is placed to one side of the four intakes instead of in the center, its usual position. Since the exciter units are placed in the center of the power house with the main units on either side of them the exciter penstock was curved, back of the bulkhead, and carried over the main unit pipes into its relative position in the power house. The bulkhead was housed in so as to protect the operators in severe winter weather. The gates are of steel and may be operated by hand or by a direct current motor driven from the exciters.

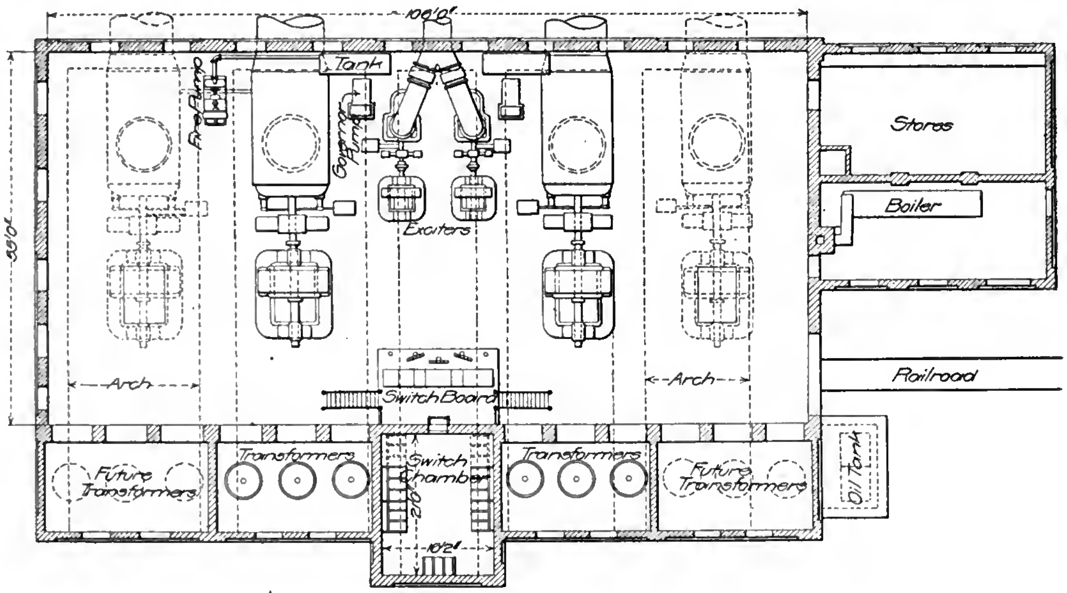
The entrance cones of the penstocks are 10 ft. in diameter at the upper end in the front face of the bulkhead wall and 9 ft. in diameter at the back face. From this point a diameter of 9 ft. is maintained to the wheel cases. The tubes are of steel plate resting on concrete saddles, spaced 18 ft. on centers, equal to two diameters of the penstock, and are anchored in the center of their length, an expansion joint being provided in each tube near the bulkhead wall and also one near the power house. To prevent the formation of ice in the penstocks they are covered with a wooden structure made as nearly air-tight as possible, an arrangement that is quite effective. Such protection is quite necessary in a plant operating in this locality where the temperature sometimes reaches 45° Fahr. The maximum speed of water in the penstocks at full overload is 7.2 ft. per second. Air pipes of ample capacity protected from freezing are provided at the upper end of the penstocks.

The power house is carried on five arches running the entire width of the building, one being beneath each of the main units and the fifth beneath the exciters. The foundations were carried down to rock which dipped to the north and east at a depth of about 30 ft. below the floor level of the building. The overlying material was soft clay and quicksand which gave a good deal of trouble in excavating, though the low temperature at which most of the work was done tended rather to facilitate than retard progress as every opportunity was given the frost to penetrate the earth beyond the limits of the excavation, thus rendering the standing wall secure and enabling the excavation to be carried down about plumb.

The floor arrangement of the power house provides for two exciters in the middle of the room each capable of serving four generators. Both of them are furnished with water from one penstock and each is provided with a hydraulically operated gate valve. The power units, of which there will eventually be four, are arranged two on each side of the exciters. The switchboard is in the center of the building, in front of the exciters, and back of it is the tower in which the high-tension switches are housed. On either side of the latter are the transformer compartments separated from the main room by steel doors. A railway track leads into the power house and an overhead crane commands all the machinery, the transformers being mounted on trucks so that they can be pushed forward under the crane.

The main turbine wheels are designed for a maximum of 3,550 h.-p., and are connected with 2,000-kw. generators, the wheels thus having a capacity sufficient for operating the generators at 33 per cent. overload. The effective head is 85 ft. and the speed 375 r. p. m. The wheels are of the horizontal shaft type and are enclosed in steel cases, which are split horizontally so as to give quick access to the moving parts in case repairs are necessary. There are two wheels to a unit, each 34 in. in diameter. The runners are of bronze. The thrust bearing which is of the marine type, is located between the wheel case and the generator. The bronze gates are of wicket type being as nearly as possible balanced and are operated by a governor of the Sturgess type. The exciter turbines are similar in design to the main units and are also controlled by Sturgess governors. All of the governors are electrically controlled so that the operator on duty at the controlling desk can start up any or all of the machines. The total full load capacity of the plant is 8,000 kw. The exciters each have a capacity of 200 kw. and are operated at 550 r. p. m.

In testing the generators already installed the loads were obtained by connecting one generator up as a motor, reversed in the direction of rotation, and operating it from the other machine running as a generator. Both machines for the purpose of the test were brought up to full excitation and switched together before starting. The gates on the generator wheel being opened up gradually, both machines came up to speed, the motor, of course, driving its wheel in the opposite direction to normal rotation. When both machines were at full speed the gates on the wheels connected to the motor were gradually opened, thus obtaining practically a water brake load. It was possible by this scheme to get any load required and also to reach any power factor by over or under exciting the synchronous motor, thus determining the regulation of the generators at any power factor. This scheme



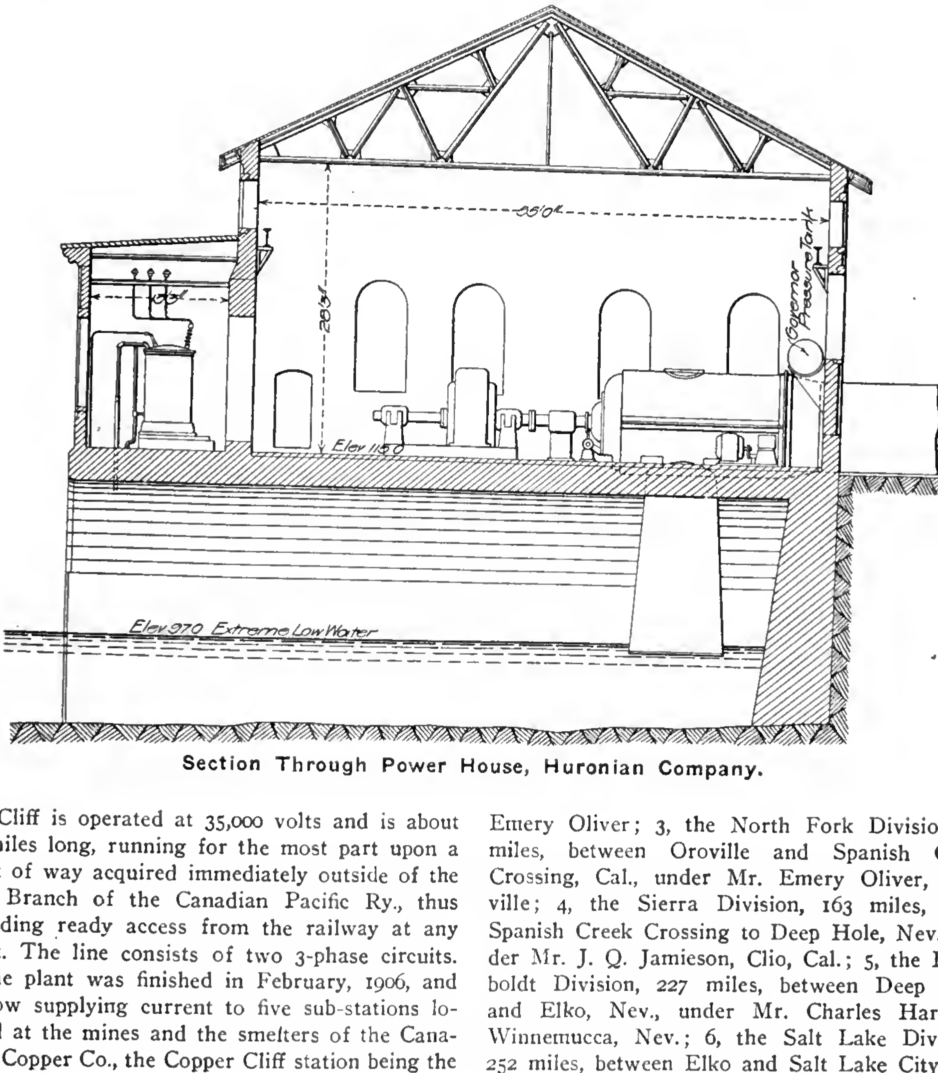
Plan of Power House, Huronian Company.

proves decidedly superior to a water rheostat load which gives only a fixed power factor.

The marble bench board from which the operation of the station is controlled in every particular, including the speeding of the water wheels, was placed on a gallery to give the operator a clear view of the power station and also of the switching apparatus in the tower back of the board. The main switches and all connections between the main units, transformers and transmission lines are distantly controlled so that the only voltages on the bench board are those from the exciter and the operating voltages from the switch control. In other words nothing higher than 125 volts is admitted to the main power station except within the generators themselves which have no exposed parts and the current from which is carried by cables in ducts to the low voltage chamber in the switch tower.

There is a group of three transformers to each main unit, each group being housed separately. The transmission line from High Falls to Copper Cliff is operated at 35,000 volts and is about 29 miles long, running for the most part upon a right of way acquired immediately outside of the Soo Branch of the Canadian Pacific Ry., thus affording ready access from the railway at any point. The line consists of two 3-phase circuits.

The plant was finished in February, 1906, and is now supplying current to five sub-stations located at the mines and the smelters of the Canadian Copper Co., the Copper Cliff station being the farthest from High Falls. The plant was designed by Messrs. Ross & Holgate, consulting engineers of Montreal, Canada, and described by them in a paper before the Canadian Society of Civil Engineers, from which this article has been taken.



Section Through Power House, Huronian Company.

A Curtis Turbine Test was made by the engineers of the Boston Edison Co. on Jan. 29 of this year, the machine being one of 5,000 kw. rating. Under the normal operating conditions the test showed a steam economy of 13.586 lb. of steam per kilowatt-hour. On Feb. 25 of this year one of the four 8,000-kw. turbines at the Fiske St. station of the Chicago Edison Co. was unofficially tested under regular operating conditions, and showed a steam economy of less than 13 lb. per kilowatt-hour. This test, moreover, showed the remarkable result that from 5,000 to 14,000 kw. output the steam consumption varied less than 1 lb. per kilowatt-hour.

The Engineering Organization of the Western Pacific Railway Company.

By George P. Low.

The Western Pacific Ry. is now being constructed from Salt Lake City to San Francisco, its engineering and construction department being under the direction of Virgil G. Bogue, first vice-president and chief engineer of the company. That the construction work may be handled to the best advantage, the line has been divided into six sections in charge of division engineers with headquarters as follows: 1, The San Francisco Division of 93 miles, between San Francisco and Stockton, in charge of Mr. John T. Williams, Oakland, Cal.; 2, the Sacramento Division, 113 miles, between Stockton and Oroville, Cal., subdivided into two sections, the first of 87 miles, between Stockton and Yuba River, under Mr. John T. Williams, and the second of 26 miles, between Yuba River and Oroville, under Mr. Emery Oliver; 3, the North Fork Division, 76 miles, between Oroville and Spanish Creek Crossing, Cal., under Mr. Emery Oliver, Oroville; 4, the Sierra Division, 163 miles, from Spanish Creek Crossing to Deep Hole, Nev., under Mr. J. Q. Jamieson, Clio, Cal.; 5, the Humboldt Division, 227 miles, between Deep Hole and Elko, Nev., under Mr. Charles Harlowe, Winnemucca, Nev.; 6, the Salt Lake Division, 252 miles, between Elko and Salt Lake City, under Mr. T. J. Wyche, Salt Lake City.

The North Fork Division is one of the heaviest pieces of railway building ever undertaken, and it is the purpose of this article to describe the engineering organization under which its construction by The Utah Construction Co., of Ogden, Utah, is being directed. For practically the entire length of the division, the route of the railroad follows up the tortuous canyon of the Feather River, first along the main stream to the junction of its North and Middle forks, which is at a point about 7½ miles by way of the grade northeast of Oroville, thence along the North Fork for 57 miles to its confluence with the East Branch of the North Fork which it follows for approximately 17 miles. It then enters the canyons of Spanish and Spring Garden Creeks respectively and, leaving them by tunneling through the main ridge, reaches the Middle Fork of the Feather River, which it follows through Sierra Valley until reaching Beckwourth Pass.

The North Fork Division is divided into residencies, each about five miles in length, each being in charge of a resident engineer who reports to an assistant engineer. The latter has direction of the engineering work on two or more residencies through various resident engineers, and is responsible to the division engineer. In some cases the work of the engineers is so arranged that assistant engineers are given two instrument men with parties working from the same camp, the men being rated as resident engineers only when they are in charge of a camp. Resident engineers are usually allowed a party consisting of a leveler, chainman, rodman, stakeman, axeman and a cook, but assistant engineers have authority to increase or reduce the number of assistants employed. Where a camp is maintained by the company, expenditures for board elsewhere are discouraged, but when assistant or resident engineers do not wish to board at the company camps, upon application to the division engineer they are allowed $25 per month for board in lieu of subsistence, with proper deduction from this amount for meals which may be taken in company camps. Engineers are not allowed to board their wives and families at company camps, although occasional meals to them are not prohibted.

Assistant engineers are given general supervision of the work to which they are assigned and are responsible for its proper execution. They receive such reports from the resident engineers as are necessary, and these reports, after being consolidated and approved, are forwarded to the division engineer. Assistant engineers are furnished with an advance account with which to defray current expenses which cannot be vouchered. All time rolls, bills of material and estimates made out by resident engineers are sent to the assistant engineers, but to save time weekly progress reports and requisitions for camp supplies are generally sent to the division engineer direct.

Assistant engineers are instructed to give as much personal attention to the details of construction work, where supervision is assigned to them, as is possible, and they are required to assist and direct the resident engineers in every way necessary, as they are held responsible for the proper execution of the work of the resident engineers and their assistants. When necessary, assistant engineers accompany their force reports with letters to the division engineer calling attention to any lack of energy on the part of the contractors or to any disposition to slight or neglect work.

Diaries are furnished to assistant and resident engineers in which all special data pertaining to the work are kept, such as dates of beginning and completing special structures, notes on classified materials, the manner in which contractors handle various kinds of materials and the like. The condition of the weather is also noted, and where camps are convenient to the river, gauges are established and readings taken during floods, these readings being turned in with the final records. The engineers are required to furnish all necessary assistance and information to inspectors detailed to look after special structures and to work in harmony with all other engineers and their assistants. As friction between employees is prejudicial to the company's interests, it is not tolerated.

The following reports are required by the division engineer:

Progress Report.—Every Sunday the resident engineer mails to the division engineer a progress report giving any and all information pertinent to the work which he has in charge.

Contractors' Force Report.—On the 8th, 15th, 22d and last days of each month, assistant engi-

neers are required to make up from data received from resident engineers, a report of the forces of every character employed by the contractors. These forces are counted at least once a day by a time-keeper, who is checked by the assistant and resident engineers as they go over the work from time to time.

Financial Estimates.—Data for financial estimates are compiled and forwarded early enough in the month so that approximately the amount of money necessary to meet pay rolls and vouchers can be provided and forwarded to the division engineers before the last day of the month.

Property Reports.—A complete inventory of all company property in charge of assistant and resident engineers is made in duplicate and forwarded to the division engineer on the last day of each month, and engineers in charge of such property are held responsible for its safe-keeping and care. All camp equipage and instruments received during the month from all sources are entered in the property reports, and reports are also made of the date chiefs of party leave the service or are transferred, and certified to by both outgoing and incoming engineers. If it should happen that the incoming engineer is not present when the outgoing engineer leaves, then the report is signed by the employee temporarily in charge. The new appointee, when assuming charge, also signs it, with any necessary endorsement, and then forwards it to the division engineer.

Time Rolls.—In making out time rolls, the blanks furnished must account for each day worked, as well as for the month's aggregate. In figuring for fractional parts of a month the valuation for a day's labor is figured to the nearest five cents. If time certificates have been issued, the number of the certificate is entered in the proper column opposite the name on the roll. The number of time voucher is also entered by the division engineer or the assistant engineer issuing it. Engineers certifying to time certificates and time vouchers are held responsible for the correctness of the same and their proper notation on the time rolls. Time certificates are not issued unless the employee is leaving the company's service, but when doing so after the rolls have been sent to the division engineer, suitable identification certificates are furnished.

In transferring a man from one party to another, a letter is written by the transferring engineer to the receiving engineer indicating the last day on which time is allowed. In addition to this, a letter of advice is sent to the division engineer's office with the same information, and any failure to do so imposes the penalty of any resultant loss to the company on the party at fault.

Itemized Statements.—The division engineer cautions his subordinates to be systematic in the keeping of accounts, and to call for bills from dealers a few days before the end of the month so they can have these accounts rendered promptly. The practice of having bills sent to the division engineer's office weeks or even days after they should be, is discouraged. Bills for which discount for cash can be obtained are called for when the purchase is made and are sent in at once. All bills must be in duplicate; one being in copying ink or copying pencil. They must show the amount of purchase, the unit price, and calculations checked to the nearest five cents. They are then certified by the resident engineers and forward to the division engineer either preceding or accompanying the subsistence report for the month in which incurred. Receipts are not dated after the last day of the month to which they belong. Board bills must show the name of each man and the dates on or between which the board was furnished. The rate per day or week is also shown, as well as the work upon which the party was engaged during the time. All payments made to contractors are vouchered, and under no circumstances paid directly or entered on pay rolls.

Requisitions.—Where engineering camps are reached by team, the resident engineer, on or about the 20th of the month, makes out a requisition for such supplies as are necessary to last during the following month. The supplies so requisitioned are sent to the storekeeper, after approval by the division engineer. These requisitions do not include farm products, which can be bought near the camp, and standard packages only are sent by the storekeeper, even if a single package will last several months.

Subsistence Report.—This report is made up monthly by the chief of each engineering party subsisted by the company immediately after all bills for supplies furnished during the month have been certified and submitted through the proper channels. An inventory of food supplies on hand after the last meal at the end of the month is taken and entered at actual cost. After deducting this inventory from the total debit, the difference shows the total cost of meals furnished. An accurate account of the total number of meals furnished during the month is kept and the debit divided by this number shows the average cost per meal. A copy of the summary for all camps for the month is sent to the resident engineers that they may see the relative cost of meals at the different camps and correct any waste or extravagance.

Estimates.—The estimates rendered are of two kinds: main contractors' estimates and sub-contractors' estimates, both of which are made out in ink. The main estimates are sent so that they will be received by the division engineer not later than the third day of each month. All the section numbers of the work in charge of any assistant engineer are shown on the sheets in consecutive order, with the limiting stations for each, even if work is being done in but one section; the idea for so doing being to have each quantity which is estimated appear in its proper place in the sheet each month, thus providing the utmost facility in comparing and checking. If only the second page of the estimate sheet shows quantities, the headings on both pages are filled in and both sides are signed by the assistant engineer. Inasmuch as all of the route of the line within the North Fork Division traverses a section of the mountains never before covered by a wagon road, it has been necessary for the company to build one to enable the contractors to carry in materials and supplies. Where work on this wagon road is being carried on adjacent to the line of the railroad, the section numbers corresponding to the main line are shown so as to indicate the portion of the line to which the wagon road is opposite; but, conversely, the station numbers of the wagon road are independent of those of the railroad.

Sub-contractors' estimates are also prepared in duplicate and sent to the division engineer with the main contractors' estimates. They show the work done by The Utah Construction Company as well as by the sub-contractors, and the estimates divide at the section limits in order that they may be checked against the main estimate sheets. The sub-contractors' estimate sheets are complete statements of all work done and are handed to The Utah Construction Co. for its use in settling with its sub-contractors. Station men are not shown thereon.

In estimating quantitites for the monthly estimate, the nearest even 10 cu. yds. is taken when the unit price is $1.00 or less per cubic yard, and fractions of a unit are not used for any material for which the unit price is less than $5.00 per cubic yard. Material for which $5.00 or more is paid per unit is carried out to the nearest hundredths of a unit.

Extra Work.—Any work that it is possible to measure, or which can be covered by the specifications at the contract price, must be shown on the estimate sheets, but when it is necessary to have any extra work done by the contractor's forces, it is carefully looked over and, if sufficient in amount, a time-keeper is kept on the work all the time. A force of half-a-dozen men employed on extra work is considered to be sufficient to justify keeping a time-keeper.

Bills for extra work are made out by the contractor in duplicate and, when approved by the assistant engineer, are sent to the division engineer. These bills are sent in with the estimate at the end of the month in which the work was done, and are not allowed to run along until it is necessary to include more than one month's work on the bill. If the bills, as made out by the contractor, are not in proper form, the engineer in charge must make up the bills, using the contractor's bills as memoranda, the latter being attached to the respective bills and both being sent to the division engineer. All bills rendered by the contractor for extra work which, for some reason, have been disallowed, are sent to the division engineer with a letter giving particulars and the reason for rejection. Bills for extra work show the dates on which the work was done, the number of days work, the rate per day, and the stations between which the work was done, also the distribution and account to which it is to be charged. If in doubt as to the account to which it should be charged, the engineer makes a brief statement on the face of the bill showing of what the work consisted.

Progress Profiles.—These are made on plate "A" profile paper, showing all possible information with reference to the progress of the work. To begin with, the profile shows the ground line, grade line, grade elevation, rate of grade, and alignment. Where revisions of the center line are made, the elevations are shown in dotted lines with new alignment and grades. As the work progresses, the amount of excavation moved and embankment placed are shown in color in their proper places, different colors being used for the respective months. All surfaces are tinted uniformly by mixing enough color at one time to cover all surfaces. The space to be occupied by bridges is left blank until such time as work begins upon them, when the average depth to which piles are driven is shown, and mud sills of framed bents, by short, heavy lines. The stations at each end of the bridge, culverts in place, retaining walls and cribs are shown, care being exercised to color only the portions upon which work has actually been done because of the fact that these profiles are checked with engineers' force reports and estimates. Where the face of a cut is being worked but the center line is not reached, a strip along the ground line proportionate with the amount of work actually done is shown, and where a cut is entirely taken out except for trimming slopes and finishing a small strip is left above the grade line to show that the work is not entirely completed. Fills are not shown completed to grade unless they are of full width.

Standard Progress Drawings.—The division engineer requires that the reports of subordinate engineers shall be uniform in character, and to facilitate the compilation of them in such uniformity, sample sheets in colors are issued to assistant and resident engineers in exemplification of methods to be followed in making calculations and reports upon excavations, fills, grades, tunnels, and, in brief, all features of the work. Excavations, for instance, are classified under three heads, namely: 1, Solid rock, which includes all rock found in ledges or masses of more than one cubic yard and which, in the judgment of the engineer, can be removed only by blasting; 2, loose rock, which includes all bowlders and detached masses of rock measuring more than one cubic foot and less than one cubic yard

in bulk, also all slate, hard shale, soft sandstone, disintegrated rock and soapstone that can be removed without blasting, and such hardpan, gravel and bowlder deposits of such consistency as to prevent being ploughed with a ten-inch grading plough behind a team of six horses; 3, common excavation, including all materials not classified as loose or solid rock.

In the sample cross section furnished to the men, solid rock is outlined in brown, loose rock in green and common excavation in yellow, the sectional areas of each being shown with the dimensions from which the calculations are made. Preparatory to making these sections, of course, the work is cross-sectioned, the quantities are calculated and the results then placed on profiles in order to determine where the cuts are to be hauled and where it is safe to borrow, putting doubtful borrow off until the cuts are out. Waste and borrow are not allowed where they will be detrimental to the completed road, and when allowed the borrowed material is not estimated, but any overhaul which might become due had the cuts been hauled, is estimated.

All classified excavation material is measured, and percentages are resorted to only when conditions preclude actual measurements, but solid rock is always actually measured, the results being positively shown. In cross-sectioning the work sections are taken at every station, and wherever any breaks occur in the center or side lines of the excavation, grade points are set on either side of the roadbed where it enters the cut, taking cross sections to each point. The distance out from the center is marked on all grade points and the full station number is given on the back of every cross section stake. On curves, the cross sections are not more than 50 ft. apart.

All work of every character, including ditches, changes of channels, width of clearing, and culvert and trestle excavations, is staked out. As fast as the work is cross-sectioned, the notes are copied into a record book and the original is sent to the chief engineer's office. The cross sections of the work are platted on cross section paper, all figures being put on and classified materials shown in colors as above detailed. The method of average end areas is used in determining quantities.

Construction.—All excavations for retaining walls, cribs, or masonry structures are sunk to a solid foundation, which must receive the approval of the assistant engineer before the structure is started. Where practicable and within the limit of haul, material excavated from foundation pits is placed in embankments in order to reduce borrow quantities accordingly. All loose or dangerous rocks are removed from rock bluffs beyond the regular excavations before commencing to grade the cuts opposite them, this work being paid for by force account.

Embankments are made so as to be full 16 ft. in width after they have become thoroughly settled, and to secure this result, shrinkage is provided for by adding to their height or width as follows: Casting or wheelbarrow work in earth, 12 to 15 per cent.; cars in earth, 10 to 12 per cent.; cars in gravel, or fine rock, 5 to 10 per cent.; wagon work, 7 per cent; scraper work, 5 per cent, and rock fills, 3 per cent. The contractor is informed of the amount of shrinkage which he will be required to put on before he completes roughing-in the embankment. Where the embankments are short or are side fills so that the profile grade must be maintained, the shrinkage is provided for by widening the embankment from the slope stakes up, the shrinkage being made up in the ballast wherever necessary.

The contractor is required to bear the cost of the entire excavation and removal expenses, including loading, unloading, transportation and deposit, provided the haul does not exceed 600 ft.; for excess of this haul, he is paid an additional price per cubic yard per 100 ft. up to the limit of 2,000 ft., or an overhaul of 1,400 ft. All overhaul in excess of the last distance is subject to additional compensation for the additional distance.

Mass Diagrams.—To secure uniformity in estimating overhaul on excavated material, mass diagrams are used in accordance with a sample form. These are made on plate "A" profile paper, laid out to the horizontal scale of 200 to 400 ft. to the inch, the vertical scale being 200 to 2,000 cu. yds. to the inch. In the sample diagram given the men, one cubic yard of solid rock is taken as equal to 1.6 cubic yards in embankment, but the amount of swell or shrinkage is determined on the ground by observation, the points between which cuts and fills actually balance and the ratio of shrinkage or swell determined being noted. It is found that earth placed in embankments under the blows of horses' hoofs usually shrinks so that 100 cu. yds. of cut will make about 90 cu. yds. of fill, and that rock taken from cuts usually swells 50 or 60 per cent. The quantities used are taken from the cross section notes as they appear in the record book, but when cut and fill both occur within the limits of a station, only the net quantity is used. As shrinkage and expansion affect the distances but not the yardage hauled, the latter is always measured and estimated in excavation.

In making the overhaul diagram, the total yardage, both in cuts and in fills, both ways from grade points is summed up to the various cross section stations within the limits of haul. These stations are platted on a horizontal line to the scale chosen. The total yardage from the grade point to each station is then platted vertically at that station to the yardage scale chosen and connecting lines are drawn. Then a straight edge is moved upward until it measures between the cut and fill lines the proper yardage above 600 ft., at which points horizontal lines are ruled in and the quantities picked off on the vertical scale.

The haul diagrams from which final estimates are made are turned in with the final cross section notes and become a part of the permanent records. The haul is estimated separately for each cut and is paid for on the section from which the excavation is made. A record of the work is kept in ink in a special book provided for the purpose. It shows the station, ground and grade, elevation, cross section, areas, cubic yards, and classification. Surface elevations are shown across bridge openings so that all the necessary information for making a profile may be included. The cross-sections of solid rock or other classified material that can be shown by cross section notes, also all measurements of borrow pits, foundation pits, clearing or riprap, are shown at the end of each section. The measurement for side ditches are given in the remark column, as well as the quantity placed, with the cut to which it belongs. Each section is kept complete by itself and shows at the end a summary of all the quantities for which payments are to be made. The final estimates are made from these summaries. Diagrams for the overhaul from each cut, showing the estimated amount of overhaul for which payment must be made, are attached, as are also diagrams of all special structures, such as cribs, retaining walls, bridge piers, and the like, and bills of material for all culverts with the station at which they were constructed.

Another typical instruction sheet describes in outline the methods to be followed in computing and reporting upon the excavation areas of standard tunnels, as well as of determining the quantities of material necessary for their proper lining. In reality, this sample sheet presents a 63 ft. length of the 806-ft. tunnel known as Tunnel No. 4, which pierces Cape Horn, on the Feather River, about 2½ miles above Oroville. In it the neat section is outlined in red; its enlargement necessary to admit timbering is represented in the space included between red and yellow lines; the overbreakage consequent upon this enlargement is included between yellow and black lines, while the dry packing includes all packing material which is placed by hand outside between the lining or lagging and the line of overbreakage.

Organization Chart.—An organization chart has been prepared, primarily for the information and guidance of clerical forces, which has proved to be of such general utility that its form has been almost universally adopted by the division engineers of the system. In it the engineering organization of the North Fork Division, so far as officials are concerned, is shown at the left, with Mr. Oliver as division engineer; Messrs. H. P. Gradon, A. C. Koogle, Geo. S. Kopp, W. F. Webb, J. A. Hutchinson and A. H. Thomas as assistant engineers, and Messrs. J. F. Miller, C. E. Zeigler, J. R. Howell, W. A. Rowe, C. C. Derby, H. V. Klippel, R. C. Clifford, B. B. Boyd, W. W. Joliffe, R. L. Bryant, and John Tarish as resident engineers. The chart shows the rank of each engineer on the division, with the residencies or residency, or stations to which he is assigned. In the next column appears the numbers of the surveying stations along the route, opposite which are the respective mile posts as surveyed from San Francisco, and between these columns is a double line indicating the wagon road and its bridges, its finished portion being colored red. Following the mile post figures, is a column showing the locations of the various tunnels with their designating numbers and comparative lengths, after which is a line indicating the railroad as sectioned off by contracts, the work opened up by the main contractor and each sub-contractor being given a distinctive color. The scope of each of the four main contracts into which the construction of the North Fork Division has been divided is then shown on the chart, following which the boundary line of the two counties traversed is indicated. Geographical names of points, bars, creeks, etc., occupy the ensuing column, which is followed by a line on which is delineated the rate of grade for the finished road. The locations of water tanks and fuel oil stations are projected from this grade line by means of open circles and black discs respectively. For convenience, the various residencies are again shown, as is the line of the road on which are located the various bridges, tunnels and sidings, with specific information concerning each. The river with its tributaries, the locations of steel bridges and river crossings, together with an indication of the particular side of the river upon which the road runs, are shown with precision. Finally, the width of the right of way at every point is indicated, as is the name of the owner from whom each particular piece of right of way was purchased.

THE SEWAGE PUMPING ENGINES at the Ward St. station of the Metropolitan works at Boston are each rated at 50,000,000 gal. daily capacity against a head of about 40 ft. They are of the Allis-Chalmers vertical triple-expansion type, with standard steam ends. Each engine has three single-acting outside-packed plungers, and six suction and six delivery valve chambers. In each chamber there are 36 specially designed valves of the flap type, with rubber and canvas seats bolted to brass plates. They are hinged and swing on manganese bronze hinge bolts. A modification of the barometric type of condenser, adapted for using sewage for cooling, is used, the passages through it being larger than those employed with clear water in order to avoid any clogging of them.

The Slipping Resistance of Steel and Brass in Concrete.

By H. Burchartz, Gross-Lichterfelde.

Numerous authors have reported on the adhesive strength or the slipping resistance of iron in concrete, for instance Bauschinger, de Tedesco, Mörsch, Féret and von Bach. Dr. O. Meyer has recently made tests relating to this subject and reports on the results of his tests in the "Oesterr. Wochenschrift für den oeffentlichen Baudienst" substantially as follows:

The objects of the tests in question were: (*a*) Dependence of the slipping resistance of the metal rod in concrete on the condition of surface of the rods embedded in the concrete. (*b*) Relation between the slipping resistance and the kind of material of the reinforcement, whether steel or brass. (*c*) Relation between the slipping resistance and the composition of concrete. (*d*) Influence of the form of the rods on the slipping resistance, 1, when the rod was bent to a hook, and 2, when the rod was split to a fork.

All concrete test-pieces were of prismatic shape and square section measuring 20x20x30 cm. or 8x8x12 in. The rods were placed in the specimens in a longitudinal direction, the embedded length amounting to 20 cm. or 8 in.; the ends of the rods were turned off to a 2½-cm. conical shape, so that the tangential adhesion to the concrete was only fully acting on a length of 17½ cm., or 7 in. When calculating the slipping resistance, the cylindrical part of the rod only was considered, for the influence of the cone can hardly be determined numerically in a suitable manner. For this reason the calculated specific slipping resistance may be taken a little too high.

With the rods bent to a hook at the ends the reinforcement was only about 17½ cm., 7 in., in the concrete, and with those shaped like a fork, the end of the fork was found in this length. It is natural that the values for slipping resistance which were found with these latter tests did not at all correspond with the pure adhesive strength, but can merely be used for comparison with the values found with straight bars. Those values are correct standards, however, which indicate the strain per square inch of the sectional surface of the round rods. The latter figures were calculated in order to get the ratio of load to the tensile and breaking strength of the steel.

The materials used in preparing the specimens were: (*a*) Portland cement purchased without knowledge of the origin, but of a quality already approved for concrete buildings; (*b*) Pit-sand with grains passing a sieve with 4-mm. meshes; (*c*) Gravel from the Danube with grains passing a sieve with 10-mm. meshes; (*d*) Round steel bars; (*e*) Yellow metal with a tensile strength of about 30 kg. per square millimeter, and 14 per cent. extension when breaking; (*f*) well water.

The materials were mixed in parts by weight and the mixtures gauged with 10 per cent. of water.

The concrete samples were tamped with the rod in a vertical position.

The specimens in Table 1 were made on November 10, 1900, at about 90° C., the samples of Table 2 on March 29, 1901, at about 6° C. for air and water. The test-pieces were kept dry and for about a month in a shop and then until testing in a laboratory.

The average results of Table 1 are given in Table 3 and the quotient of the average figures of the slipping resistance of rods with rolling skin and with finished surface are also calculated; it fluctuates between 1.5 and 4.8 so that the rough round steel in comparison with the finished one with smoothed surface shows the slipping resistance to be 1½ to 5 times greater.

This result is in good accordance with that obtained by von Bach, who says in "Baumaterialienkunde," 1905: "If the prismatic shape of the rod embedded in concrete is perfect, the slipping resistance depends on the condition of the surface, and if the prismatic shape changes the same is also true. With turned and smoothed rods the slipping resistance is half of that determined for rods with rolling skin." Our differences are therefore still greater. The average of the proportionate values is 2.7 with our tests. The difference in question seems to be generally greater with small steel bars than with large ones; with mixtures of 1:4 and 1:6 the result is, with 12-mm. iron, 2.3 and 3.4 compared with 1.5 and 1.7 with 25-mm. bars.

The strength of concrete seems to influence the slipping resistance, for the richer mixtures of concrete give greater values than the poor ones. It must be borne in mind that the values obtained with 25-mm. steel bars for a 1:6 mixture do not seem to be entirely free from objection, as several test-pieces were already damaged before the test. Even if the results with this mixture are excluded the relation seems to remain true. In the case of the steel bars with the rolling skin left on them, the slipping resistances are, with decreasing richness of the mixture, 697, 514, 426 lbs. per square inch, respectively, for 25-mm. steel bars, while the 12-mm. bars show a decrease from 900 to 740 lbs. per square inch.

The same difference may also be perceived with finished material, though not with the same clearness. These observations are somewhat in contradiction with those made by von Bach, who says: "Alterations in the proportion of the admixture of sand within certain limits do not considerably influence the slipping resistance."

The influence of the thickness of rod has not been distinctly indicated by our tests. Of course the smaller round rods gave more favorable results than the larger ones; but it is the contrary with yellow metal. The observations made with steel contradict those made by von Bach, who found that the slipping resistance decreases with the decrease of thickness of rod. On the other hand, von Bach's remark that with finished rods there are smaller differences, agrees with our results. Yellow metal seems to have greater slipping resistances than steel, which is no doubt due to the softness of the material. This would allow the surface to be roughened more easily and consequently a greater resistance against slipping would result. The finished yellow metal (brass) and steel rods showed equally smooth surfaces at the portion not covered by concrete, so that the finish of the two could be called uniform.

The figures of practical value obtained with the steel bars with rolling skin show on the average a slipping resistance of 651 lb. per square inch; i. e., a value which is somewhat higher than that indicated by Bauschinger. The tests with steel bars bent to a hook and those shaped like a fork showed that the loads required to draw out these rods, are far greater than with straight steel bars with rolling skin. In all cases the concrete body cracked before the rods could be drawn out. With all steel rods the the loads measured, which should properly be called the breaking or bursting loads of the concrete, are so high that, referred to the unit of section of the respective steel bars, they fluctuate between the stretching and breaking load of the steel; in most cases they approach more the latter. The 25-mm. bars form the only exception, which is due to the fact that the surface and section of the rod are as the bases to the squares, the result of which is, with the constant specific resistance, a decrease of the load referred to the section.

The bars split to a fork gave higher figures than those bent to a hook, which result is explained by the fact that the hook-shaped bars when under tension exert only a bursting action on the concrete, whereas the fork also presses the concrete between its two poles thus reducing somewhat the bursting action.

TABLE 1.—RESULTS OF ADHESION TESTS WITH STEEL AND BRASS RODS IN CONCRETE.

	Rod			Adhesion per sq. in.			
Mixture.	Material.	Diameter.	Surface.	Age.	Maximum.	Average.	Tension in Rod.
1:1:2	Steel	1 in.	Smoothed	3m. 24d.	62 lb.	......	1,732 lb. per sq. in.

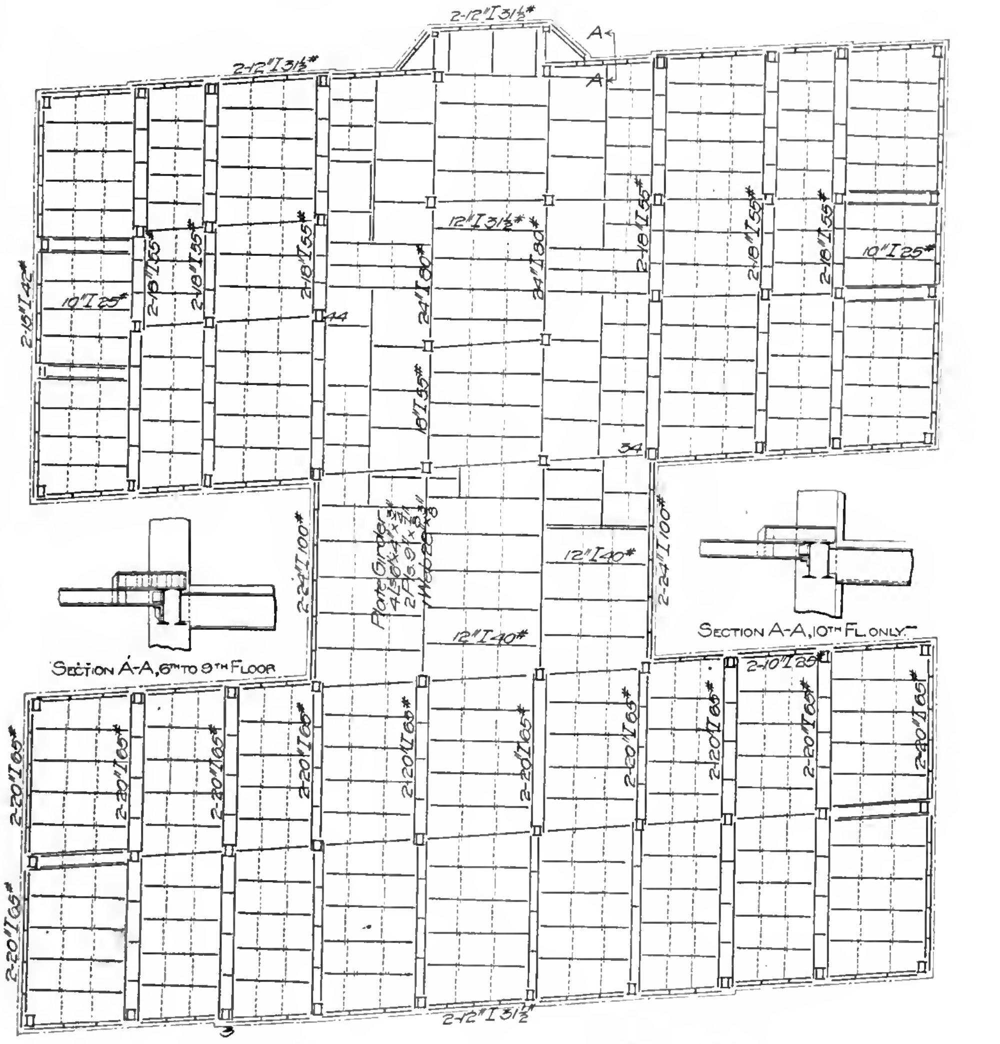
The Hudson Companies' Building, New York.

The terminal station of the Hudson & Manhattan R. R. Co., occupies two city blocks in the congested down-town financial district of New York City, extending from Cortlandt to Fulton Sts., on Church St. It is the terminus of two tunnels under the Hudson River, affording connections with the terminals in New Jersey of the Pennsylvania, the Erie and the Lackawanna R. R., and of all the trolley lines in Jersey City and Hoboken, the passengers from which can enter the subway and elevated lines in New York directly from this station. The station proper has extreme dimensions of about 210x435 ft. and is constructed entirely below the surface of the street in an excavation about 76 ft. deep to the floor of the sub-station.

The massive concrete foundation walls are carried down by the pneumatic caisson process to solid rock at maximum and average depths of about 95 ft. and 80 ft. below the curb and serve to support not only the station but the terminal buildings 275 ft. 9 in. high from the curb to the top of the main roof and 304 ft. high to the tops of the towers. All footings for the interior columns are carried by the same process to rock or hard pan. Below the street, the construction is uninterrupted across the line of Dey St., but above street level it is divided into two large 21-story structures, used as independent office buildings, one on each side of Dey St., which are harmonious in appearance and of the same type of construction and will be operated under the same management and by the same equipment of mechanical installation. The massive sub-structure below street level was separately designed and constructed and may be considered as an independent base on which the fire-proof steel cage superstructures of the terminal buildings will be erected similar to ordinary office buildings.

The two 21-story steel cage fire-proof buildings have brick walls, faced up to the 5th floor with polished granite and Indiana limestone and trimmed above that level to the 16th floor with terra cotta. Above the 16th floor the entire facade is of terra cotta ashlar with brick backing. Together they will contain about 25,000 tons of structural steel, fabricated at the Pencoyd and Trenton plants of the American Bridge Co., about 5,000 tons of terra cotta furnished by the Atlantic Terra Cotta Co., and about 15,000,000 W. A. U. red brick. The floors will generally be reinforced concrete slabs with cinder concrete fill and yellow pine finish. All steel will be enclosed in terra cotta tile, brick or concrete and all wood-work will be fire-proofed. Metal sash and window frames and wire glass will be treely used. The approximate weight of the combined superstructures including the estimated live load is about 165,000 tons.



Typical Beam Plan, 6th to 10th Floors Inclusive.

The dead and live loads per square foot of floor surface are as follows: In the Cortlandt Building dead 85, live 75, total 160 and total roof load 150. In the Fulton Building, dead 95, live 105, total 200 and total roof load 150. Total first and lower mezzanine floor load, both buildings, 250. Stairs and runways, total load both buildings, 270 lb. per square foot. Wind stresses are computed for a uniform pressure of 30 lb. per square foot on the entire exposed vertical surface of the building and the columns loads are calculated with the 5 per cent. allowance taken off from the maximum floor loads at each of the upper floors in accordance with the New York building laws. The maximum unit stress in columns is 13,000 lb. and the minimum stress is about 11,500 lb. The maximum column load is 1,700 tons and the corresponding maximum cross section is 268 sq. in. Above the second floor all columns are made in two-story lengths and the heaviest section of a column in the building from basement to concourse floor weighs about 25 tons. The heaviest girder is in the concourse floor and weighs about 20 tons.

The 213x170-ft. Cortlandt Building, bounded by Cortlandt, Church and Dey Sts., is H-shaped in plan with two symmetrical 32x76-ft. light courts separating wings of 57 ft. and 78 ft. width respectively, which are joined by a connecting structure 65 ft. wide. It contains about 26,000 sq. ft. of rentable area on each of the upper floors. The 156x154-ft. Fulton building is bounded by Fulton, Church and Dey Sts., and is of similar construction with two 48x32-ft. light courts and has about 18,000 sq. ft. of rentable area on each floor. Both buildings are substantially alike and in general symmetrical, but owing to the lack of exact perpendicularity of the intersecting streets on which they are built, none of the angles are right angles and as all of the streets have different grades, great complications in the design and details of the steel work were unavoidable. These, however, related chiefly to the details of connections and are disregarded in the following descriptions.

In the Fulton Building, the first tier of beams in the superstructure is that provided for the pipe gallery at a level of about 13 ft. above the concourse floor and about 8 ft. below the intersection of the Dey and Church St. curb, which has been assumed as datum for all levels referred to in this article. The pipe gallery forms a platform from about 8 to 18 ft. wide extending around two sides of the building under Church and Dey Streets with a floor carried by 6, 12 and 18-in. I-beams supported at one end on the concrete foundation piers and at the other end on beams and channel girders carried by the columns. The main stairway at Dey Street and an inclined runway at Fulton Street, provide entrance and exit respectively from street level to concourse. The concrete slabs of the runway floor are carried on I-beams inclined 1:12½ and supported by plate girders.

In order to provide proper clearance for trains passing through the station, several of the columns have been spaced at wider intervals, below the concurse floor than in the superstructure This arrangement necessitates the employment of heavy triple distributing girders in the Concourse floor to support the 22 upper stories. Some of these girders are supported at one end by distributing and grillage beams on top of the wall column caissons; all of them are encased in concrete and have concrete filling in the interstices between their webs.

The floor designated as the "Lower Mezzanine" is mainly at the street level. It covers the entire area of the building west of the stairway and runway, and is intermediate between the concourse and first floors.

The first floor covers the entire area of the building except where runway and main stairway emerge and a few bays where a greater story height was desirable. East of the runway it is in general at the street level. West of the runway the first floor is intermediate between the lower mezzanine and the second floor, and contains the main elevator hall. In general the above remarks regarding pipe gallery, runway and stairway, lower mezzanine floor and first floor of the Fulton Building, apply also to the Cortlandt Building.

Dey Street roadway between curb lines, including a back fill of about 5 ft., the pavements and the constant traffic of heavily loaded trucks and wagons, is carried on a system of plate girders and I-beams, which form a skeleton platform about 180 ft. long, and about 27 ft. wide, supported on 14 2-story columns, about 18-ft. apart,

in longitudinal rows parallel to the wall columns in both buildings.

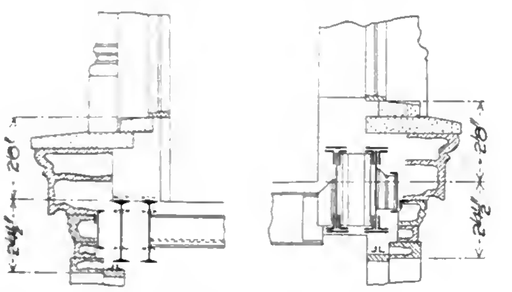
The platform is proportioned for a total load of 1400 lb. per square foot and in the widest panels has 24-in. 90-lb. I-beams about 4 ft. apart, 17 ft. 10 in. long that are web connected to plate girders and carry concrete arches about 18 in. thick.

Two lines of longitudinal girders outside of the ones just described form supports for a portion of the roadway, the sidewalks and several lines of heavy pipes, and are connected to transverse girders. The latter are connected directly to the main columns at one end and to the short columns and main longitudinal girders under Dey Street at the other end. This arrangement keeps the sizes of the girders within reasonable dimensions and provides for the distribution of a part of the weight of the street betwen the street columns and the building columns without involving oblique connections, notwithstanding the fact that the spacing of the columns is irregular and that those in the buildings are not in many cases in the same lines as those in the street.

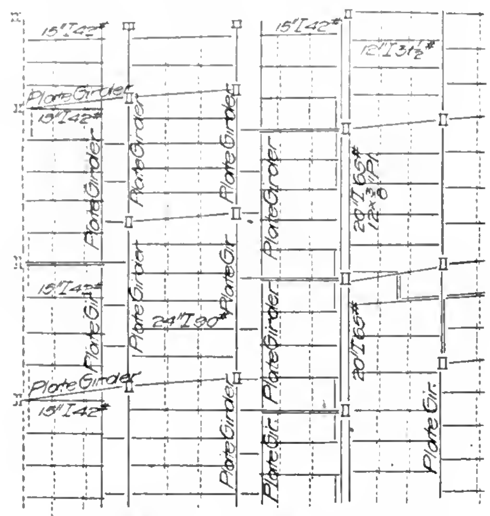
In the building the floor construction is complete and the 12-in. and 15-in. I-beams are carried directly from the columns and on 24-in. I-beam girders or plate girders. The grade of Dey St., the different levels in the floors, and the irregularity necessitated by the wide stair-ways and their framing of these floors is therefore special in that particular and in a few other minor details, otherwise it corresponds in general to the framing of the 6th, 7th, 8th, 9th and 10th floors, which varies from those above up to the 18th story only in minor details around the bay windows, walls and elevator shafts. In all of these floors the girders are in most cases pairs of 18-in. 55-lb. or 20-in. 65-lb. I-beams symmetrically arranged to give balanced loads on the columns, although where the latter are out of alignment, the variation is provided for in a number of cases by continuing girders of adjacent spans across the opposite faces of the columns and making the other girders of each pair engage the sides of the columns as shown in the diagram.

Above the 13th floor the bay windows disappear and all of the exterior walls carried on pairs of I-beams from 9 to 24 in. deep. The 18th floor framing is special, chiefly in the wall girders which provide for a heavy projecting belt course carried by I-beams or plate girders as indicated in the spandrel sections. In the upper stories of the beams and girders are reinforced by the milled upper ends of vertical distributing angles which transmit the girder loads to the columns.

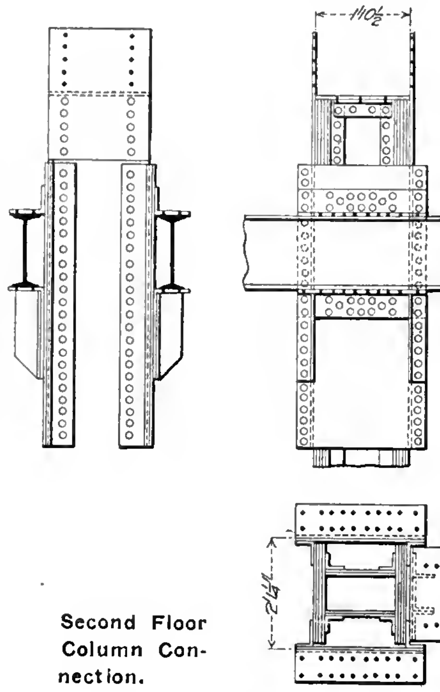
In order to avoid wind braces which would obstruct the panels between wall columns and floor beams or would interfere with the requirements of the architectural design, special provision was made to connect both upper and lower flanges of all beams and girders to horizontal angles shop riveted to the columns and thus provide a moment of stiffness equal or somewhat superior to the depth of the girder and insuring a considerable degree of stiffness in the frame work independent of the wall masonry. This construction together with the great mass and inertia derived from the weight and dimensions of the building is considered ample to provide



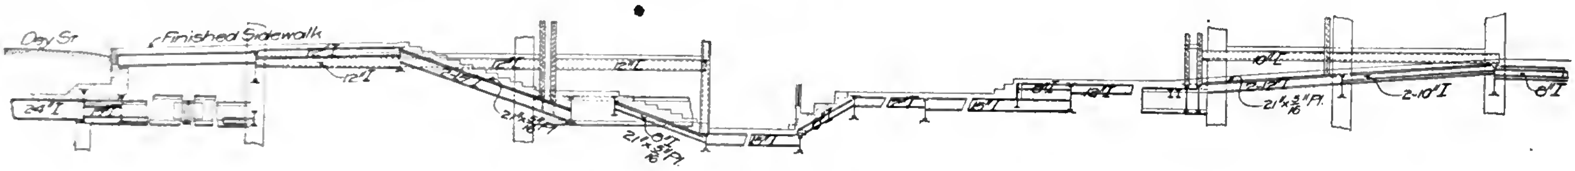
Spandrel Details.



Beams and Girders under Dey St.



Second Floor Column Connection.



Section of Lower Mezzanine Floor Parallel to Church Street.

landings make the framing of this tier very complicated.

There are in the lower mezzanine floor of Fulton Building, 58 different girders, of 30 different patterns from 24½ to 40½ in. deep. The web plates are from ¾-in. to ⅞-in. thick and in some cases are made with double 9/16-in. plates. All flanges are made with 6x6 or with 6x4-in. angles reinforced in many cases with 14x¾-in. cover plates. The girders have reactions of from 40,000 to 285,000 lb.

The location of columns and girders in the first floor corresponds essentially with the location in the upper floors, but the floor loads are so heavy that special provision is required for them and the 12 and 15-in. I-beams are carried in most instances by plate girders of which there are 3 types, nearly all of them 30½ in. deep with 6x6-in. flange angles. Owing to the irregularity of the column spacing and the diverging of the column rows there are many offsets in the lines of girders and I-beams and their connections are in many cases necessarily eccentric and irregular. Except on the rear side and in the light courts the outer walls are carried on pairs of 15, 20 and 24-in. I-beams. The full size light courts are open to the street at both ends of the building, but at the 2d, 3d and 4th floors the beam tiers are extended across the courts covering the entire rectangle enclosed by the outer walls of the building. The the Fulton building there are 70 main columns from 12 to 36 ft. apart in longitudinal and transverse rows. All of them, up to the 8th floor, have standard rectangular closed cross sections made with web and cover plates and four angles. At the 8th floor the construction changes to rolled channels diminishing from 15 in., to 10 in. in the attic where the minimum size has 12x⅜-in. cover plates. The web plates of the built channels are 16 in. wide in all cases and have cover plates, increasing from 20 in. at the 7th floor to 24 in. in the lower story. All columns have reinforced shelf angles which carry the beams and girders, and are spliced 24 in. above the floor line with horizontal connection angles, a horizontal diaphragm, and a pair of short cover plates, the latter shop riveted to the top of one column and field riveted to the bottom of the succeeding column.

I-beam girders parallel to the column webs are connected by special shelf angles, plates and vertical angles riveted to the cover plates. Those at right angles to the webs are usually riveted to the east and west girders with short connection angles. Girders offset beyond the faces of the columns are carried on projecting cantilever plates properly stiffened. Deep plate girders are additionally connected to the columns and stiffened by auxiliary diaphragms shop riveted to the columns and field riveted to the webs of the girders. The shelf angles which receive the bottom flanges for all wind stresses. The heaviest column in the building is the lower section of No. 44 in the Cortlandt St. Building, which carries 1,700 tons. It is made with four 16x¾-in. web plates, two 24x⅞-in. two 24x½ and two 24x13/16-in. full length cover plates, besides two half-length 24x⅞-in. cover plates and four 6x6x¾-in. flange angles. It is 53 ft. 8 in. long and weighs about 900 lb. per lineal foot. Another very heavy column is in the basement section of No. 34 of the Fulton Building, which carries two deep plate girders in the sub-structure of the building besides the heavy loads from the upper stories. It has four 6x6x¾-in. flange angles, six 16x½ and ⅝-in. web plates and eight 24x¾ and ⅞-in. cover plates.

Column 3 between the concourse and the 2nd floor is typical of the upper story columns and the accompanying details show the numerous field rivets through the girder planes and the column connections to provide for the wind stress. The section of column 34 between the concourse and 2nd floors is made with 4x4x¾-in. flange angles, two 16x¾-in. web plates, four 24x11/16-in., and four 24x⅝-in. cover plates, is about 40 ft. long and weighs about 700 lb. per lineal foot. The connections at the upper ends are typical for those of beams and girders throughout the floor and are designed for a maximum stress of 7,500 lb. per square inch on the field driven rivets.

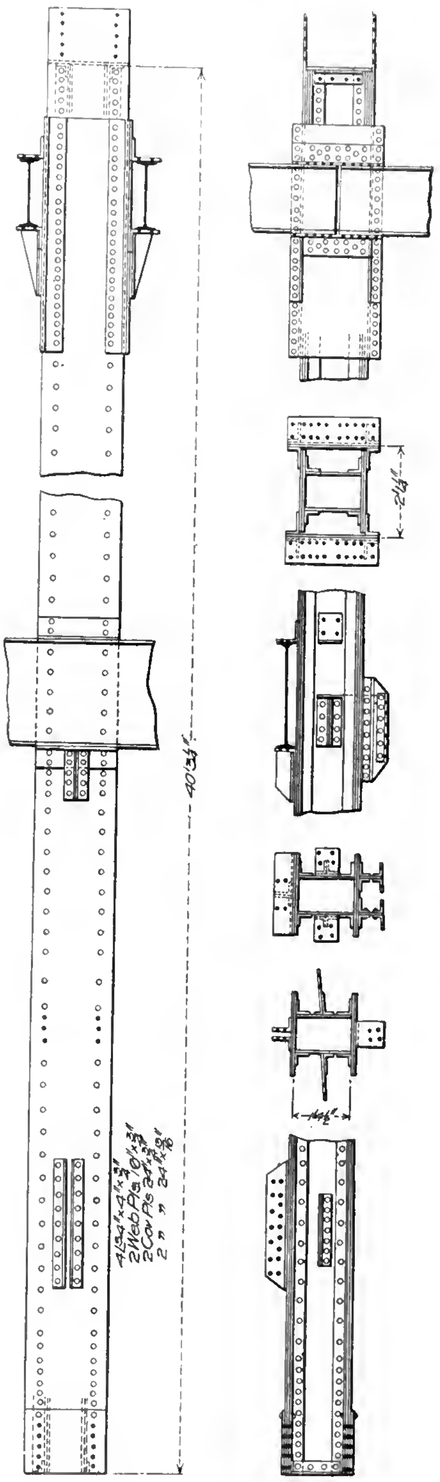
WEED DESTRUCTION by the use of salt water from Great Salt Lake is being tried by the Oregon Short Line.

A Study of a Ground-Water Supply.

In connection with an investigation of the sources of water supply for Muscatine, Ia., Mr. Wynkoop Kiersted, of Kansas City, who was retained by the city as consulting engineer, prepared a report, which, while it deals with a special problem, is of value to those who have to secure water supplies from gravel strata. Muscatine Island is several miles in width. Its surface is in general above high water and undulates slightly in a direction perpendicular to the course of the Mississippi River. The surface slopes permit little run-off of storm water, hence the rainfall, not evaporated or absorbed by vegeta-



Column 3 A, Hudson Co. Building.

tion, reaches the river by flowing through a gravelly substratum. The surface soil is light and porous and readily permits the passage of water.

About 2½ miles below the business portion of Muscatine nine wells were sunk into the gravel down to bed rock or some other impervious material. These were on a line perpendicular to the course of the river. The well nearest the river, termed No. 1, was about 300 ft. from the bank and the others were at distances of 100, 200, 350, 500, 700, 1,000, 1,500 and 3,000 ft. from No. 1, and were numbered consecutively from 2 to 9. No. 1 was 8 in. in diameter, 2, 8 and 9 were 5 in. and the others 2 in. The depth of the wells below the ground surface varied from 46.0 to 57.25 ft. and averaged about 49.5 ft. and the variation in the elevation of the top of the wells was from 115.65 to 120.69, with an averge of 117.82, datum being approximately 100 ft. below low water of the river. The strata through which the wells passed were practically the same in every case and about as follows: 3 ft. of sandy top soil; 5 ft. of clay; 10 ft. of red sand and fine gravel; 10 ft. of coarse gravel; 15 ft. of coarse sand and gravel; 6 ft. of gravelly sand; 2 ft. of sand and coarse gravel; 5 ft. of blue clay; 3 ft. of shaley clay; 6 ft. of sand rock.

A series of observations, taken at intervals of one to five days and extending over a period of nearly two months, was made of the static level of the ground water in the wells and at the same time the stages of the river and the rainfall were noted. During the month of August and the first half of September the river fluctuations were small and there was a correspondingly stable condition of the ground water surface as shown in the wells. The average slope of the surface of the ground water toward the river during this period was 0.8 ft. in 1,000 ft., clearly indicating an under flow toward the river. From Sept. 13 to 21 the river rose a little over 2 ft. and a rise of 2.1 ft. in well No. 1 resulted. A corresponding rise occurred in the other wells, gradually decreasing as the distance from the river increased, until at well No. 9 the rise was only 0.3 ft. The slope of the ground water surface toward the river, though considerably reduced, was still evident, showing that the river water was not flowing into the gravel beds but simply acting as a dam and causing the ground water in the beds to rise and fill the wedge of gravel included between the water table of Sept. 13 and that of Sept. 21. In order for this to happen it was necessary for the water in the gravel to advance toward the river as well as to rise. This advance was estimated by Mr. Kiersted to be at the rate of at least 2½ ft. per day, and it necessarily occurred throughout the entire depth of the gravel bed, about 43.5 ft.

From Sept. 21 to 27 the river rose over 4 ft. and the slope of the ground water surface was completely reversed, so that on Sept. 30 it sloped inland at the rate of 1.13 ft. per 1,000. It was computed that from Sept. 27 to 30 the river water advanced into the gravel beds at the rate of 4.63 ft. per day. From Sept. 27 to Oct. 9 the water table maintained an average slope inland of 0.84 ft. per 1,000 and the computed average rate of advance of the river water for the same period is 2.3 ft. per day. In the accompanying table the results of the computations, involving slope and velocity of flow, are given, v, i and k being the symbols used in the Dupuit formula, $v = k\,i$, where v = velocity in feet per day, i = fall of ground water surface in a given distance divided by that distance, and k = a factor depending on the porosity of material through which the underflow passes.

RESULTS OF UNDERFLOW COMPUTATIONS.

Interval	v	i	k
Sept. 13 to 21.......	2.5	0.0005	5000
Sept. 20 to 21.......	1.55	0.000273	5680
Sept. 27 to 30.......	4.63	0.00113	4100

The average value of k is nearly 5,000, or the average rate of travel of the underflow of Muscatine Island per day is five times the fall of the ground water per 1,000 ft., indicating a very porous sub-soil.

To secure further information concerning the porosity and continuity of the gravel deposits

a pumping test was run at well No. 1, during which readings of the ground water level were taken at the nine wells. The water discharged from the pump was conveyed directly to the river in a wooden trough. The quantity of water pumped was only roughly estimated since it would have been of little use in determining the value of the beds as a source of water supply. A 6-in. centrifugal pump, operated at the rate of about 1½ million gallons per 24 hours, was used. The test was begun in the morning of Sept. 21 and continued for 125½ hours. Between the mornings of Sept. 21 and 26 the river rose over 3 ft. and notwithstanding the steady operation of the pump the level in the wells showed a simultaneous rise. The zone affected by the pumping seemed to extend about 700 ft. from No. 1. The conclusion drawn was that the gravel beds under that part of the island where the wells were driven are practically continuous and so porous as to be favorable for the operation of tubular wells.

The method of development of the gravel beds as a source of water supply depends on the rainfall, the catchment area, the rate of water consumption, the available velocity of ground water flow up to a limit safe for efficient filtration, the depth of the water-bearing gravels, and, it might be said, upon the permissible rate of infiltration from the river were it not for the possible choking of the beds with particles of silt. Although the river will always contribute somewhat to the flow of ground water, the rainfall upon the catchment area is usually considered the main reliance of a ground water supply. At the same time, there should be a large capacity for permanent storage in the gravel bed. The water stored above the low-water mark of the river is an uncertain quantity. If the average stage of the river is low the amount of water in the gravel beds above the low-water line will be small and vice versa. Below the low-water level the beds are sure to be always saturated and will yield water as long as the river and rainfall replenish it.

The amount of rainfall which is available in the run-off by underflow is a larger percentage of the total rainfall in a year of excessive or average precipitation than it is in a year of low precipitation, ranging approximately 50, 45 and 35 per cent., respectively, according to Mr. Kiersted. Taking 45 per cent. of the rainfall for an average year gives 17 in. per year or 813,500 gal. per day per square mile, as the available rainfall at Muscatine. The catchment area supplying the underflow will be on both sides of a line of development and may extend a mile or more on either side of it. For a development having a total width of 2 miles the daily yield per lineal foot is 308 gal. and the velocity 235 ft. per day. When the total width is 3 miles the quantities are 462 gal. and 3.52 ft., and when the development is 4 miles wide 616 and 4.7 are the corresponding daily yield and velocity. The length of the development is not necessarily the same as the length of the constructed work because, as shown by the pumping test, the affected zone may extend upwards of 700 ft. beyond the actual construction.

The computed velocities of ground water flow are based on an available depth of saturated gravel of 35 ft. and an available void space of 25 per cent. of the bulk of the gravel.

Mr. Kiersted recommended that, at Muscatine, the development should be laid out approximately parallel to the river and far enough back from it to insure thorough filtration, probably about 650 to 800 ft. from the bank. The development should be extended enough to insure a slow average rate of percolation. Either the gallery or tubular well system is reported to be feasible at Muscatine, but wells are recommended.

The Reconstruction of the East St. Louis & Suburban Ry. Power Station.

The power station of the East St. Louis & Suburban Railway in East St. Louis, Ill., was built in 1902, with an electrical generating equipment, capable of producing 3,100 kw. Since then this equipment has been augmented from time to time to supply increasing demands for power, and early in 1906 an 80 ft. addition, containing two 1,000 kw. engine-driven generators and 2,000 h. p. in boilers was erected at one end of the original building, the rearrangement of the interior of the latter having been commenced prior to the installation of other new generators.

The original station was built to supply power for the street railway lines in East St. Louis and interburan electric lines in the vicinity of that city. The station building is of brick and is divided by a brick wall into a boiler room, 52 ft. 5 in. wide and 280 ft. long, and a generator room, 56 ft. 9 in. in width and 262 ft. in length. The generator room originally contained two 750 kw. three-phase 25-cycle 13,200 volt alternating current General Electric generators, each direct-connected to a 1,150 h.p. non-condensing St. Louis Iron & Machine Co. Corliss engine; a 1,600 kw. 575-volt direct-current General Electric generator direct-connected to a 2,500 h. p. twin non-condensing Fulton Iron Works' engine, and the necessary auxiliary machines and switch boards. Soon after the station was completed demands were made for power at different voltages from that of the current generated by the units installed, and at present current is being supplied from the station for the following purposes: 575-volt direct-current for street railway service; 500-volt direct-current, over nongrounded double-wire circuits, for power; 2,300-volt 3-phase 60-cycle alternating current for commercial lighting and power; 13,200 volt 3-phase 25-cycle alternating current, which is transmitted to six railway substations and in these transformed to direct current at 550 volts. The power supplied by the original generators was utilized as it came from the latter, transformed to alternating current, or employed to drive motor-generator sets producing current at the desired voltages.

Steam for driving the units in the generator room was furnished by twenty 250 h. p. Heine water-tube boilers. These boilers were set in batteries of four each and were equipped with Green automatic traveling-chain-grate stokers, 12 ft. wide, one grate serving each pair of boilers. Coal was fed to the stokers from elevated bunkers supplied by a gravity overlapping-bucket conveyor that delivered from a hopper under a switch track along one end of the building. Eight additional 250 h. p. Heine water-tube boilers in two batteries have been installed in the addition to the boiler room, and the settings of the existing boilers are being reconstructed. The coal handling equipment will be retained and the new boilers will have grates of the same general design as the existing ones.

When the non-condensing engines driving the three original generating units were purchased they were to be installed in a power house at coal mines about eight miles east of the city, but when the city railway and lighting plants in East St. Louis were acquired by the interests which were erecting the power house, this proposed site of the station was abandoned and the latter was built at the edge of the city. At that time coal could be delivered to the station over the company's tracks from the mines at such a low figure that the non-condensing engines were installed at the new site. Since then the price of coal has increased considerably in the territory in which the station is located, so that in adding

Fans, Stacks and Fan Engine House.

to and re-arranging the station, provisions have been made for utilizing the exhaust steam from these non-condensing engines by passing it through low-pressure turbines.

Two new 1,000 kw. engine-driven units have also just been installed, and are designed to operate condensing. In addition to these engine-driven units, two turbo-generator units, one of 800 kw. and the other of 1,000 kw. capacity which operate on exhaust steam, and a 500 kw. link steam turbo-generator have been added to the equipment.

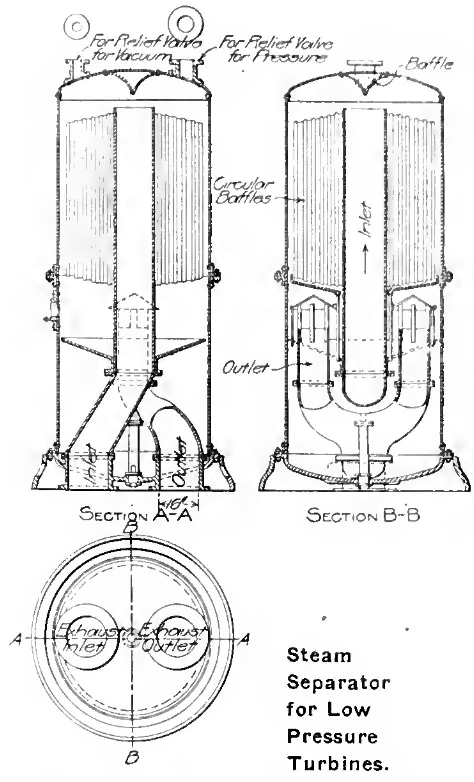
The site on which the station is built afforded such poor foundations that brick smoke stacks could not be erected at a reasonable cost, so five steel stacks, each 6 ft. in diameter and 180 ft. high, were built. These stacks were once partially wrecked by one of the windstorms to which the territory is subject. When the addition to the station was determined on, it was decided to equip the boiler room with an induced draft installation which would provide for the entire plant and to abandon and remove the stacks. This induced-draft apparatus taking care as it does of 7,000 h. p. in boilers, is of unusually large size, and is being built at the same time the other reconstruction work is in progress.

The exhaust steam from the engines driving the 1,600 kw. and the two 750 kw. units is utilized in the low pressure turbines operating on steam at 1-lb. gauge pressure; these turbines are operated

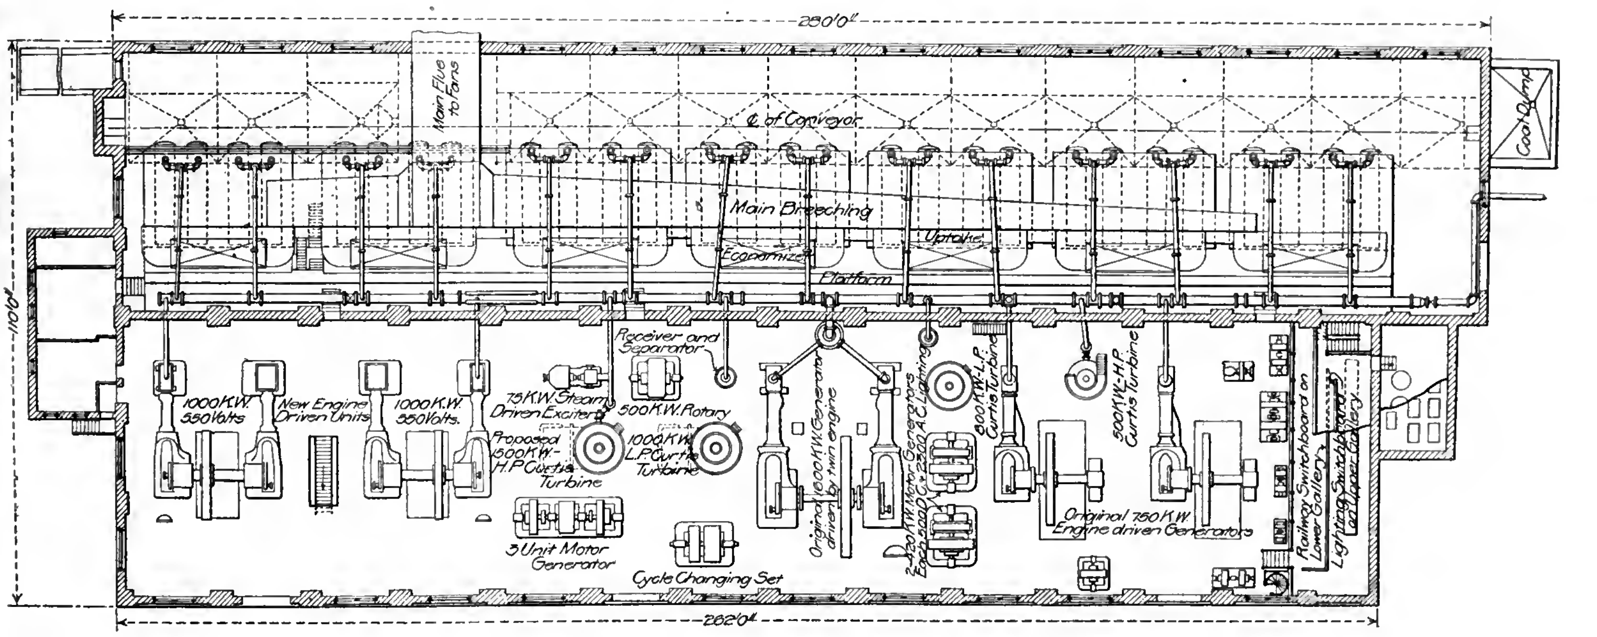
condensing, and as about 27 in. of vacuum are obtained, normally, the turbines operate at approximately 14 lb. pressure. An exhaust main 30 in. in diameter is placed in the basement of the engine room and extends the length of the building on the side next to the boiler room. The exhausts of the various reciprocating units are connected to this main and the low-pressure turbines are supplied from it. An 800 kw. 25-cycle 13,200-volt three-phase alternating-current General Electric generator, direct-connected to a vertical low-pressure self-governing Curtis turbine, is placed between the engine of the 1,600-kw. unit and the engine of one of the 750-kw. units, as shown on the accompanying plan. This turbine is supplied with steam from the exhaust main and can be operated independently on the exhaust from the engines of the two 750-kw. units. A 1,000-kw. 60-cycle 2,300-volt alternating-current General Electric three-phase generator, direct-connected to a vertical low-pressure self-governing Curtis turbine, is placed on the opposite side of the 1,600-kw. unit. The turbine of this unit is also connected with the exhaust main, and it is arranged so it can be supplied with exhaust steam from any of the five reciprocating engines. Both of these turbines also have live-steam connections through reducing valves from the main steam header of the station.

The engines driving the two 1,000-kw. units which have recently been installed are equipped with a single Wheeler surface condenser having 3,000 sq. ft. of area; space is also provided for a second condenser of the same size for these two units. One or both of the latter can be operated non-condensing, however, when the exhaust from the three non-condensing units is not sufficient to supply power for the low-pressure turbines.

A specially-designed separator is placed in the connection between the exhaust main and each of the low-pressure turbines, in order to remove the oil and water from the exhaust steam as fully as possible, and to act as a reservoir so that a steady steam pressure may be maintained. The details of these separators are shown in an accompanying illustration. Each separator is inclosed in a cylindrical steel shell, 5 ft. in diameter and about 12 ft. high, which stands on a base on the floor of the generator room. A 16-in. inlet connection from the exhaust main enters this shell at the bottom and extends nearly to the top of the latter, with which it is concentric. The steam is discharged from this inlet against a curved baffle plate in the top of the shell, which baffle directs it downward through a series of cylindrical baffle plates placed concentric with the inlet pipe. These plates retain the impurities and deposit them on an annular diaphragm which is drained to the outside through a blow-off pipe. The steam passes through a narrow space between the outer edge of this diaphragm and the shell of the separator, and then through twin 12-in. outlets into the connection leading to the turbine. The tops of these outlets are capped to prevent any impurities entering with the steam.



Steam Separator for Low Pressure Turbines.



Plan of East St. Louis & Suburban Railway Co. Power Station.

Connections are made to the separators which will maintain the pressure in the latter, between certain limits, automatically. A relief valve which will prevent the pressure in the separator rising above a pre-determined amount is placed on a connection in the top of the separator. A second relief valve which will prevent a vacuum occurring in the separator is also placed on a connection in the top of the separator. Live steam may be supplied to the separator through an inlet in the side of the latter.

A 500-kw. 60-cycle 2,300-volt alternating-current General Electric generator direct-connected to a vertical Curtis turbine has also been erected, and space for a 1,500-kw. 25-cycle 13,200-volt alternating-current General Electric generator, direct-connected to a vertical Curtis turbine has been reserved in the generator room of the station. These units both operate on steam at about 150 lb. pressure. The 500-kw. unit furnishes power for a commercial lighting and power circuit; the 1,500-kw. unit will supply power for transmission to the street railway sub-stations.

The high and low-pressure turbines are each equipped with a surface condenser. These and the surface condenser for the engines of the two 1,000-kw. units are also supplied with cooling water from the same source, namely, six large cooling towers.

Two of these cooling towers are of the Alberger sprinkler type and the other four are of the Wheeler trough type. The six towers are in a row along one side of the building, each one being on a separate footing. They are built of steel plates and are 19 ft. in diameter to a height of 33 ft. and then 10 ft. in diameter to the top of the tower, 60 ft. above the footing. The cooling water is drawn from the base of each tower, circulated through the condensers and forced back to the top of the towers by centrifugal pumps in the basement of the generator room of the station. A pump is provided for each condenser, each pump being direct-connected to a motor. The two sprinkler-type towers are each equipped with two 8-ft. fans while the four trough-type towers each have two 10-ft. fans. Each pair of fans is connected through a shaft to a motor in the generator room of the station. Each tower is connected to a supply pipe from the city main, these connections being fitted with valves by which the make-up water is supplied automatically.

The condensed steam is pumped from the condensers to a 6x17.5x5-ft. closed hot-water tank in the basement of the boiler room. This tank is arranged with vertical baffles, placed 1 ft. apart, which are open alternately at the top and bottom of the tank. The water is admitted at one end of this tank and passes in a circuitous up-and-down route around the baffles to reach an outlet at the opposite end. The oil and other floating impurities are thus caused to rise to the surface between the alternate pairs of baffles, which alternate baffles are attached to the top of the tank. A blow-off pipe is placed in each of these spaces for removing the impurities from the surface of the water.

The induced-draft system which will replace the stacks that now serve the boilers has a main breeching extending the length of the row of boilers over the tops of the latter and connecting

in a space between the old and new boilers to a main flue leading to a fan house that has been built on a separate footing at the side of the main building. Two fans, having impellers 20 ft. in diameter and 10 ft. wide are placed along the side of this house, in steel-plate volutes 32 ft. in diameter.

Each of the batteries of two boilers has been equipped with a Green economizer, which is placed over the boiler setting in a by-pass between the boilers and the main breeching, the various economizers being a part of the induced-draft system. The different main parts of the latter have been designed to provide for draft for an eventual installation of six additional boilers, or twenty in all, sufficient for expansion for a considerable time.

The breechings, flues and connections have all been designed so that any part of the induced-draft system may be cut out of service without interfering with the operation of the other parts. The connection between each boiler furnace and the main breeching is fitted with a damper that is operated by hand from the firing floor in front of the boiler, so the amount of draft in each furnace can easily be regulated separately from the others. The by-pass in which the economizer for each battery of boilers is placed is connected at both ends with the main breeching. These two connections can be shut off either separately, or together by dampers, while a balanced damper in the main breeching at each economizer by-pass permits all the gases to be diverted through the latter if desired.

The main breeching over the boilers increases in size at a uniform rate to a cross-section of 10.5x12 ft. at the main flue. The latter is 14x14 ft. in cross-section for its full length from the junction of the breechings to the connections leading to the volutes of the fans in the house at the side of the building. The breechings and flue are suspended from the roof trusses of the building, while the economizers are carried by a steel frame in the boiler settings. In all cases ⅜-in. plates reinforced with channels and angles were used for the ducts carrying the waste gases from the furnaces to the fans. The limited head room over the boilers makes the installation of the ducts particularly difficult and necessitated the rearrangement of the piping connections by which the steam is led off from the boilers.

Engines which drive the fans are placed in the brick fan house outside of the power station building. Two smoke boxes, 11 ft. wide, are placed along the side of this house, one at each side of the end of the main flue leading from the boiler room and to these the volutes of the fans are connected. Dampers make it possible to cut each of these boxes out of service separately.

The two 20-ft. fans which furnish draft for the system are driven by two 12x30-in. Fulton Corliss engines in the fan house. Each fan is on the end of a shaft direct-connected to one of these engines, a double water-cooled bearing, each part of which is 48 in. long, being placed between the fan and the engine which drives it. The fans will normally be run at 80 r.p.m., but are designed to operate at from 70 to 150 r.p.m., depending on the amount of draft desired and on local conditions. Each fan is served by a self-supporting steel stack 10.5 ft. in diameter and 70 ft. high above the footing, which is integral with those of the fan house.

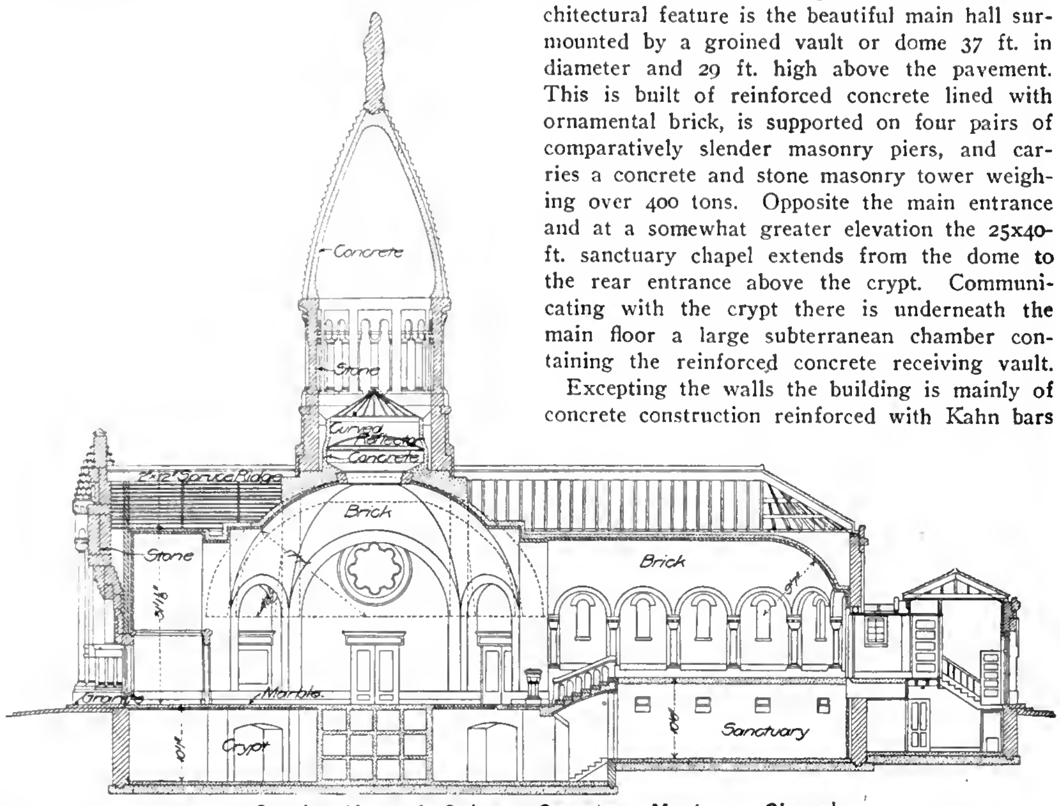
The additions to and the rearrangement of the power station are being made under the direction of Messrs. Lichter and Jens, consulting engineers, of St. Louis, who prepared the plans for and supervised the construction of the original station.

Combined Forced and Natural Draft Cooling Towers.

The Calvary Cemetery Mortuary Chapel.

The Mortuary Chapel now being completed in Calvary Cemetery, New York, at a total cost of about $200,000, is a 64x124 ft. structure about 32 ft. high to the top of the main roof and 92 ft. to the top of the tower, which is surmounted by a 5-ton stone figure 10 ft. high. The general elevation and the symmetrical plan are indicated by the vertical longitudinal sections and by the foundation diagram. The central architectural feature is the beautiful main hall surmounted by a groined vault or dome 37 ft. in diameter and 29 ft. high above the pavement. This is built of reinforced concrete lined with ornamental brick, is supported on four pairs of comparatively slender masonry piers, and carries a concrete and stone masonry tower weighing over 400 tons. Opposite the main entrance and at a somewhat greater elevation the 25x40-ft. sanctuary chapel extends from the dome to the rear entrance above the crypt. Communicating with the crypt there is underneath the main floor a large subterranean chamber containing the reinforced concrete receiving vault.

Excepting the walls the building is mainly of concrete construction reinforced with Kahn bars



Section through Calvary Cemetery Mortuary Chapel.

which make monolithic construction for all floors, roofs and dome. The walls are faced on the exterior with Indiana limestone above a granite base and the interior of the superstructure is faced with light brick and pink Minnesota sandstone. The main floor is paved with marble and that of the crypt and subterranean receiving chamber has a granolithic surface on a bed of cinder concrete. The doors and windows have stone lintels and the dome has at the crown a cut stone curb about 6 ft. in diameter, covered with a concave skylight of ornamental stained glass. Above the skylight there is a curved Frink reflector and a conical skylight roof at the base of the open colonade forming the lower part of the tower.

The vaulted roof over the chapel is a full centered arch surmounted by an exterior shell of timber framework covered with Celladon tile to give the Gothic appearance required for the exterior elevation. The foundations for the wall have continuous footings. Those for the 8 piers carrying the dome and tower are isolated. The dome piers are virtually segments of an octagonal ring taken at the vertices and their footings, 26 in. thick, are reinforced by cross layers of ¾-in. Kahn bars 12 in. apart on centers and 4 in. clear of the lower surface of the pier. The footings for the main walls are of the same thickness and are reinforced with single transverse bars of the same size. Under the crypt the footings are only 12 in. thick and are reinforced by 1½-in. transverse bars.

The reinforced concrete dome construction consists essentially of two pairs of arches at right angles to each other supported on piers. The tops of the piers are connected in pairs to arches of 9 ft. diameter of intrados and four 1x3-in. vertical anchor bars project above the

top of each to secure the arches which were built separately after the completion of the piers. The thickness of the arches diminishes from 3 ft. on a horizontal line at the base to 2 ft. at tion details and have offset footings on the upper side to receive the stone masonry of the tower.

The arches and groins of the 4-in. brick lining for the domes spring from so many points of intersection with the piers that the stability of by Morse anchors to the monolithic concrete dome above, from which it is actually suspended, although in construction the concrete dome was built on the brick arch.

In order to support the compound structure during erection and to provide for extreme accuracy of the complicated curved surfaces, great pains were taken with the centering. The main

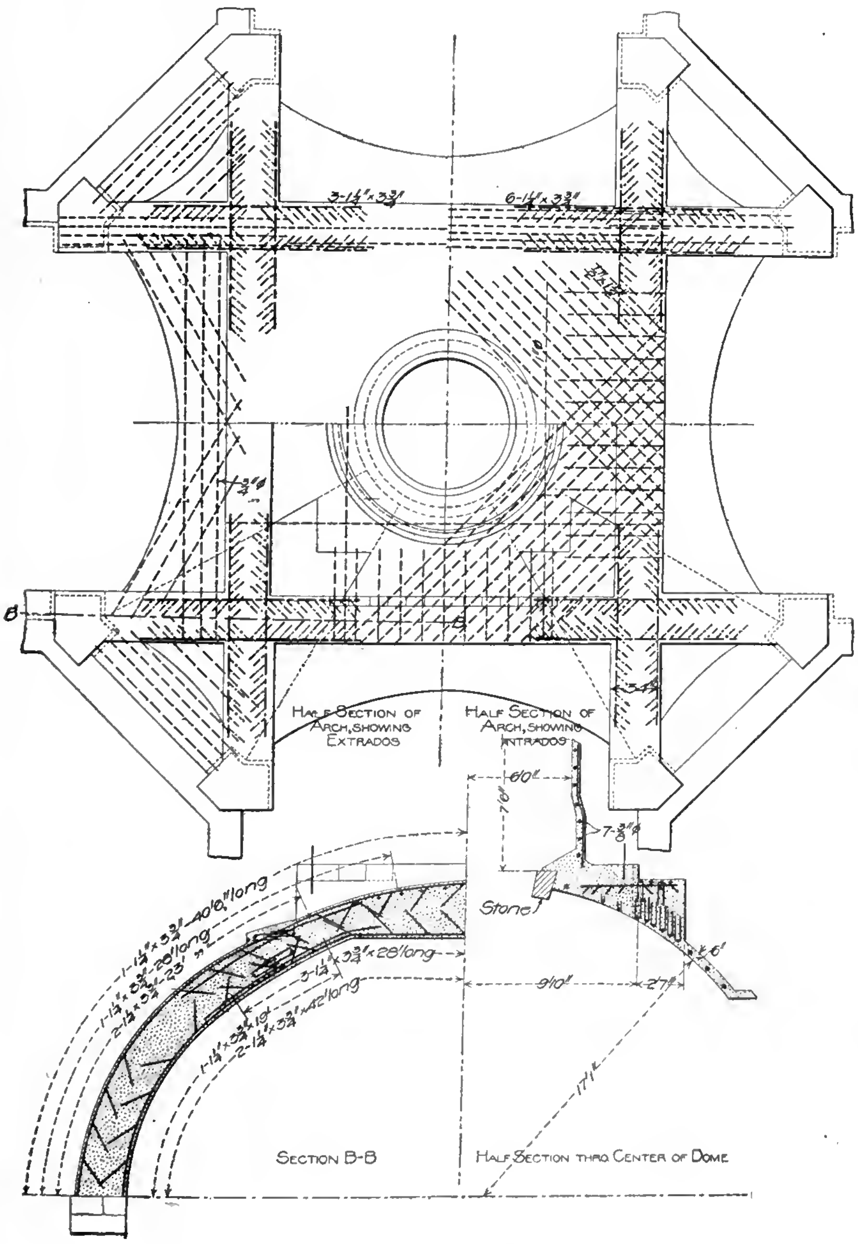
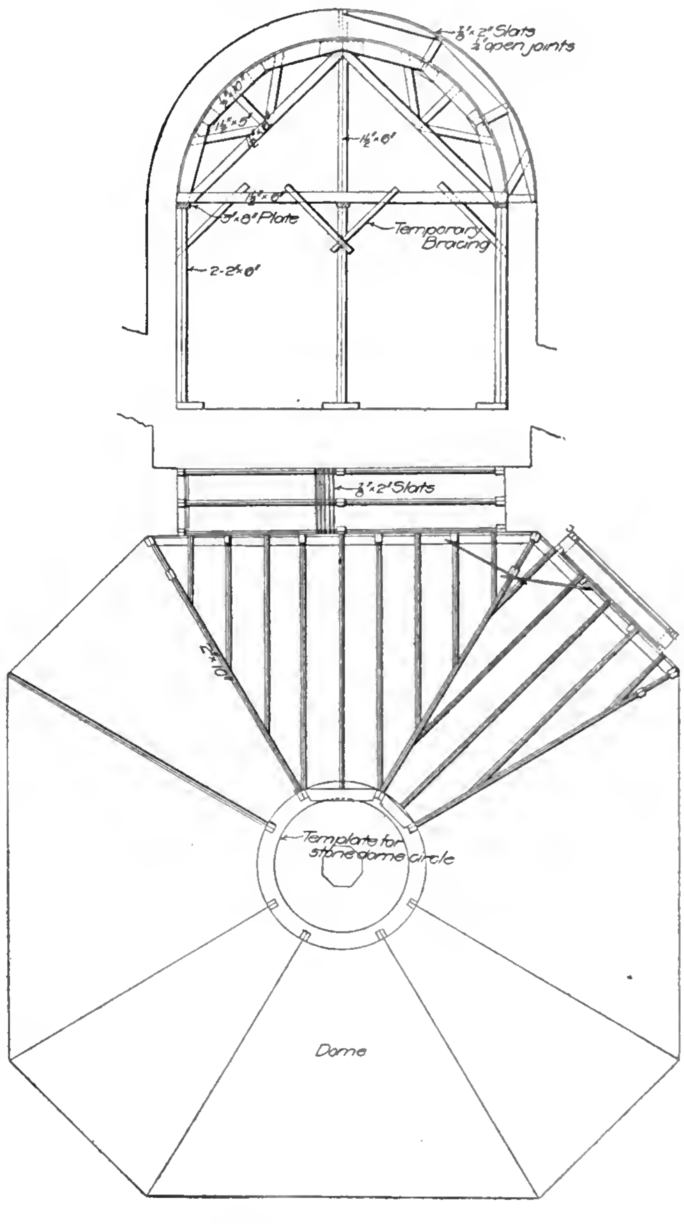
Plan of Chapel Showing Footing Reinforcement.



Reinforcement of the Dome.



Dome Falsework and Arch Centering.

the haunches where the thickness is a minimum at the intersection with the curves and horizontal intrados. They are reinforced with crossed layers of radial and horizontal bars near the intrados and extrados, as shown in the cross section the latter is very much decreased and the concentrated thrust would be so great that unless other supports were provided for them than is given by the skewbacks stability could not be secured. The brick lining is therefore connected framework was built with 8 radial sections or sectors symmetrical about their center line and symmetrically arranged alternately in pairs corresponding with the long and short side of the octagon formed by the piers. Vertical posts con-

sisting of pairs of 2x6-in. timbers were placed in the openings between the piers and in a circle under the crown of the arch. The former carried centering for the relieving arches and the latter carried segmental caps fitting the intrados of the dome. The ends of the caps and centers were connected by radial trussed ribs, like hip rafters, into which were framed transverse scarf boards at right angles to the separate elements of the dome arches and afforded support for the lagging which was very carefully cut and laid. The radial ribs were in reality wooden trusses with curved top chords made from the scarf boards and with 2x8-in. straight inclined bottom chords connected to them with 6x½-in. zig-zag web members spliced to both chords. The intermediate ribs were of similar construction but lighter and were proportioned to be supported at both ends without intermediate columns.

In order to make the courses of the brickwork exact and their alignment perfect, a full-sized quarter section model or negative of the intrados of the dome was made of plaster paris on which the courses of the brick work were marked and then transferred to the lagging. Every brick in the lining was applied to it and was cut and rubbed in two directions, namely, concave on the exposed face, concave on the lower bed, and convex on the upper bed so that the brick would be truly horizontal when laid. This work was done with great care and resulted in such precision that all of the lines are perfectly regular and no imperfections can be observed in the finished work. It is believed that this method of constructing brick work and suspending it from reinforced concrete above has never before been followed in this country, and so far as shown only once recorded abroad.

After the completion of the brick lining, forms were built above it and in them the concrete arches were made. After they were set the thin interior concrete walls for the sides of the lantern frame were built continuous with the dome concrete. Later the stone masonry walls for the base of the tower were laid in the usual manner on a footing provided by the offset upper surface of the dome, the concrete columns of the colonnade were set on it. Finally the reinforced concrete shell of the top of the tower 18½ ft. in diameter and 24 ft. high were built on it with sectional inside and outside wooden forms of ordinary construction. This concrete shell is reinforced by 12 horizontal rings of 1-in. round iron and by curved bars in vertical radial planes. The latter are made in two varying lengths. The base of the structure is reinforced by a ring of 6x6x⅜-in. angle iron secured to the sub-structure by eight 1¼-in. vertical anchor bolts through its horizontal flange. The vertical flange of this angle is bolted to the flattened lower ends of the radial reinforcement bars.

The stairway descending to the crypt is made with an inclined slab of solid reinforced concrete 12 in. in minimum thickness and provided on the upper surface with triangular offsets to engage the rectangular solid marble steps placed on it. The vaults in the crypt are contained in a monolithic rectangular concrete structure 14 ft. 4 in. wide, 17 ft. 8 in. long and 10 ft. high with horizontal and vertical partition slabs dividing it into 24 compartments each 30 in. square. The main walls are 8 in. thick and are reinforced with Kahn bars, all the partition slabs are reinforced with ⅜-in. round bars.

Mr. Raymond F. Almirall is the architect and P. J. Carlin Construction Co. is the general contractor. The reinforced concrete work was designed under the supervision of Mr. John Hawksworth, assistant engineer of the architect, by the Trussed Concrete Steel Co., Detroit, Mr. B. J. Greenhood, engineer, and was constructed by the Concrete Steel & Tile Construction Co., Detroit.

The New Water Supply of Mexico.

Heretofore the water supply for Mexico City has been of rather limited quantity and poor quality, but there is now in an advanced stage of construction a new system which will remove both objections. The new system comprises works for taking the water of several springs, a conduit to convey the water to the limits, receiving and distributing reservoirs, pumping plants, and a new system of distributing pipes in the city.

The new supply comes from four different groups of large springs at La Noria, Nativitas, Santa Cruz and San Luis, situated along the southwestern shore of Lake Xochimilco.

This lake is one of the ancient and historically interesting bodies of water in the valley of Mexico and lies on the southerly side of the city, the springs being from 20 to 30 kilometers from the reservoirs, which are located on high ground about 10 kilometers from the center of the city near to and westerly from Chapultepec.

The valley of Mexico, in which the city lies, is a great basin 7,000 ft. above sea level and entirely surrounded by high mountains. Of the latter, the Ajusco Mountains lie to the south of Lake Xochimilco, and their formation is so porous and their capacity for absorption so great that they appear to yield the underground flow from which the springs mentioned, as well as many others on the south side of the valley or basin, are supplied.

The water, as it comes from the springs, is as clear as crystal, and, analyses show it to be of a high degree of purity.

The four groups of springs yield a total of 700 gal. per second. The new works are designed to take and deliver 562.5 gal. per second, or 48,600,000 gal. per day. The population of Mexico City is about 400,000, from which it appears that the new supply provides about 125 gal. per capita.

To collect the water, reinforced concrete wells or caissons of rectangular and octagonal forms, with necessary partition walls, openings and valves, are sunk into and around the springs to depths of 20 to 30 ft. and with horizontal dimensions from 10 to 30 ft. The pumps are located in or over these wells.

To convey the water from the source of supply to the distributing reservoirs west of Chapultepec, a reinforced concrete conduit to have a total length of 30 kilometers (18.75 miles) is under construction. It runs across the level valley with a hydraulic grade of 0.0003. Its cross-section is oval, the maximum horizontal and vertical diameters being about 6.60 ft. The invert is flat, while the crown is, approximately, a parabola.

Along the conduit and spaced 333 meters apart, open concrete stand pipes about 20 ft. high and about 30 in. in diameter are built on the conduit with a manhole in the top of the latter on either side of the stand pipe, and a gate in the conduit between the standpipe and the manhole on the upstream side. The bases and tops of the stand pipes are handsomely finished in cut stone trimming.

The conduit will work under a normal head of 5 to 10 ft. Its shell above the invert is about 5 in. thick and the entire section is reinforced by expanded metal. The concrete is a 1:3:3 mixture, using Portland cement. Owing to the level country, the conduit has a covering of earth rarely exceeding 3 ft. except in approaching the reservoirs. It is laid but a few feet below and approximately parallel to the hydraulic grade.

The conduit terminates near and about 50 meters below the receiving and distributing reservoirs. As previously stated, the latter are situated westerly from the city and Chapultepec and adjacent to the west end of Chapultepec Park. The reservoirs are four in number and are at an elevation of 50 meters (164 ft.) above the streets of the city. Each one is circular and 100 meters in diameter and deep enough to hold 50,000 cubic meters, the combined capacity being equal to 30 hours' supply for the entire city.

For a depth of about 10 ft. the circular wall of the reservoirs is vertical, and from there to the bottom it slopes 1 on 1. The bottom is covered with a heavy floor of concrete. Each reservoir is covered with a heavy concrete roof of girders and slabs carried on concrete columns set on circles concentric around the central octagonal chamber about 18 ft. in diameter, which rises from the bottom to the roof of the reservoirs and terminates in an ornamental tower about 10 ft. in diameter above the roof.

This chamber has openings in each face inside the reservoir and is connected to a central gate chamber centrally located outside the reservoirs by a concrete tunnel having a diameter of 1.5 meters. The only office of this large central chamber in the center of each reservoir appears to be to permit the flow into and out of the reservoir, there being no gates or other means of control in it.

The roofs of the reservoirs are approximately level with the ground and, when finished, the reservoirs will be covered with earth and sodded, it being the intention to grade the reservoir site and convert it into an extension of Chapultepec Park.

Outside of and conveniently located near the reservoirs, one large controlling gate chamber, surmounted above ground by an ornamental tower, will be constructed. The tunnels above described will run from each reservoir to this chamber and deliver the water to it for distribution to the city.

All concrete in this construction is very heavily reinforced in all directions by Johnson bars, and the dimensions of the concrete are heavier than theoretical requirements dictate. The mixture is 1:3:3.

From the controlling gate chamber 60-in. cast-iron pipes will lead to the city and an entirely new network of pipes for the latter will be laid. This part of the work is not yet under way.

At each of the four groups of springs and wells the water must be lifted from 6 to 12 meters to get it into the conduit and give it necessary head. At the terminus of the conduit at the reservoirs, the lift will be 50 meters to get the water into the latter.

Single stage centrifugal pumps will be used for all this work, there being two 24-in. pumps at each of the four groups of wells, and one plant of three pumps at the reservoirs and having a capacity equal to the sum of the other four. These pumps are being constructed by I. P. Morris Co., Philadelphia, and will be run by electric power. The lift of 50 meters in single stage appears abnormal for this class of pump, but the data are taken from the official statement of the Water Works Board of Mexico City. Handsome stone buildings will house the pumps.

The work as a whole, which is being carried out in an admirable, permanent character, was designed and is being directed by Sr. Manuel Marroquin y Rivera, Chief Engineer to the Board.

IMPROVEMENTS IN MANILA HARBOR and the Pasig River, which were completed during the past year, cost $4,483,000. The work consisted in dredging channels and constructing breakwaters, and has resulted in making the harbor the safest in the Orient. Two covered steel and concrete docks, one measuring 600 by 70 ft. and the other 650 by 110 ft., are now being built. The mud dredged from the harbor and the river has been pumped to shore, and used in filling in along the water front, at the points recommended by Mr. D. H. Burnham, who visited the islands some years ago in order to plan broad improvements for Manila.

The Effect of Stress on the Corrosion of Iron.

It is doubtless known to a number of readers of this journal that Prof. William H. Walker and Mr. Colby Dill have been conducting some important investigations of the effect of stress on the corrosion of iron at the research laboratory of technical chemistry at the Massachusetts Institute of Technology. They presented a paper on the subject at the recent convention of the American Electrochemical Society, and were on the program for a similar paper before the convention of the American Society for Testing Materials, which was unfortunately read by title only. The substance of the information they have made public in these papers is an important contribution to our knowledge of the corrosion of iron. The authors consider that a definite relation exists between electromotive force and corrosion, and that the corrosion of iron in water depends essentially upon three factors, the electrolytic solution pressure of the iron, the electrolytic solution pressure of hydrogen, and the condition of surface of the iron or metal in contact with the iron, in so far as it affects the ease with which molecular hydrogen may be liberated on it. In an experiment, the last two factors may be held practically constant, and the electromotive force of the system made to depend for the greater part on the solution pressure of the iron. In the paper read before the American Electrochemical Society, the authors deal with a single one of the conditions which affect the electromotive force of iron, the effect of stress on the metal. The particular problem investigated was the determination of the sign and magnitude of the potential changes caused by straining a piece of iron, particularly below the elastic limit.

The magnitude of the increase of potential which one would expect to be produced can be easily computed on the assumption that the energy stored in the specimen below the elastic limit is available as potential. Some very pure Swedish charcoal iron was tested in the usual manner to determine the modulus of elasticity and the elastic limit. From these data the maximum amount of work which it is possible to do on 1 cu. in. of soft iron by stretching it to its elastic limit was calculated to be 5.16 in.-lb., which is equal to 5.83 joules. One cubic inch of soft iron weighs approximately 126 grams, the specific gravity being 1.7. The work done in joules per equivalent is therefore 1.30, and the change in elctromotive force which would be expected is 1.30 joules divided by 96,540 coulombs, or 0.0000134 volt. The magnitude of this change is, therefore, very small; its direction should be positive, because it is the manifestation of energy stored up in the metal.

The paper gives the results of experimental measurements by the Poggendorf method, using a cadmium cell as standard electromotive force. The specimens of iron tested were made from two lots of exceptionally pure Swedish charcoal iron. One lot was hard-drawn wire about 0.25 in. in diameter, and the other was bar iron about 0.5 in. in diameter. The bars were cut in lengths of about 18 in., and the central portion reduced in a lathe for a distance of about 1 in. until a zone of bright new metal was exposed. This band was smoothed in the lathe first with a file and finally with emery cloth. With the exception of a narrow zone about 0.25 in. wide at the middle, the bars were covered with several waterproof coatings of ordinary shellac to insulate the metal from the solution except at the desired point.

The cell consisted of a central tube about 3 in. long and 1 in. internal diameter, open at both ends. To this were bound by means of adhesive tape three smaller tubes of the same length closed at the bottom. The bottom of the central tube was closed by a rubber stopper, carefully cleaned, through which the iron part projected, so that the reduced portion came at the middle of the tube. The central tube containing the specimen was filled with ferrous sulphate and then the three outer tubes were filled, one with ferrous sulphate and two with potassium chloride. All four tubes were then connected by syphons. The syphon of the normal calomel electrode dipped into the last potassium chloride tube. These precautions were successful in preventing the diffusion of the $FeSo_4$ into the tube containing the normal electrode. The $FeSo_4$ solution was protected from air by a layer of paraffine oil carefully washed to remove traces of alkali or acid. The loads were applied with a testing machine operated by hand, as a power machine rendered potential measurements out of the question.

Tests were made with a large number of pieces of iron which were subjected to increasing stress up to the breaking point; a typical test was as follows: The stress was applied uniformly and gradually increased. The potential dropped simultaneously very slowly until at a stress of about 31,000 lb. per square inch of original section, the electromotive force had decreased 0.9 millivolts. When the machine was stopped at this point the beam of the machine sagged. When stress was again applied the potential rose suddenly 3.9 millivolts, and when the machine was stopped it dropped to its former value in 15 seconds, then sank more slowly to a minimum and then started slowly to rise again. When load was put on a second time the character of the change was similar to the first, there being first a sharp rise of electromotive force while the load was increasing, followed by an abrupt fall when the machine was stopped, then a slower fall, then a rise to a constant value. The magnitude of the sudden rise depended upon the rate at which the stress was applied. The final value after fracture was about 8 millivolts higher than the initial value.

The cause of the abnormal rise observed at high stresses was next investigated. Change in temperature suggested itself as the most probable cause, although iron under these conditions has shown itself to have a negative temperature coefficient. In order to duplicate as nearly as possible the thermal conditions which obtain in the iron electrode, a device was used whereby there was a continual flow of heat from the electrode to the solution. A hole about 1/8 in. in diameter was drilled throughout the length of one of the electrodes. The upper end was joined by a rubber tube to a reservoir directly above, holding about 2 liters. A copper-nickel thermopile was soldered to the surface of the electrode where it was in contact with the liquid. The copper, nickel and solder were insulated from the solution by means of shellac. Hot water was placed in the reservoir and allowed to flow down through the electrode, the rate being regulated by a screw pinchcock. The test showed that a rise in temperature produced a decided decrease of electromotive force. The experiment was repeated with additional precautions and entirely concordant results were obtained.

If the sudden rise in potential above the elastic limit is caused by temperature changes in the electrode, then, since iron has a negative temperature coefficient, the specimen must cool off as the breaking load is approached. Such a phenomenon, though highly improbable, is perhaps conceivable. Experiment showed, however, that there is a continuous rise in temperature from the elastic limit to the breaking load. The rise in temperature in this test was determined by means of the copper-nickel thermopile previously used.

An experiment was also made with normal ferric chloride as electrolyte to see if this change in potential below the elastic limit also occurred. The specimen was prepared in identically the same manner as the previous ones. Soon after immersion in ferric chloride it became coated with bubbles of hydrogen and the surface lost its metallic lustre and grew black. The potential rose rapidly during the first and second days. On the third and fourth days the potential was not measured. On the fifth day it had risen from 0.5279 to 0.6638 volt and was very constant. Scraping the specimen by means of a sharp wire produced a decrease of 0.0031 volt. On the sixth day the bar was pulled nearly to fracture. The potential decreased gradually 0.0006 volt from 1,200 to 32,600 lb. (yield point), per square inch. Here the potential rose as in all previous cases, but the subsequent behaviour was irregular. This experiment confirmed the previous ones with ferrous sulphate as electrolyte.

If there is any permanent difference in electromotive force between a strained and an unstrained piece of metal, it should be apparent in the case of hard-drawn wire when compared with the same wire annealed. A number of specimens of steel wire in its strained condition were obtained and portions of each specimen carefully annealed in a vacuum. In almost every case a difference of potential was observed between the annealed and unannealed specimen; but further investigation showed that as great, and frequently greater, differences existed between the different portions of the same wire, both in the strained and the annealed condition.

The results of the experiments are summarized by the authors of the paper as follows:

1. The magnitude of the potential changes suffered by soft iron when tested in a tension machine below the elastic limit is exceedingly small. In the majority of cases it was less than 0.0001 volt. The maximum change was 0.0004 volt.

2. The change, when great enough to be measured, was negative, *i. e.*, the strained metal had a slightly lower potential than the same metal unstrained.

3. Somewhere above the elastic limit the potential rises suddenly several hundredths of a volt. The magnitude of the increase depends on the rate of straining and ceases abruptly when the straining ceases.

4. Measurements on specimens under tortional stress give results similar to those obtained from tension tests.

5. Out of a considerable number of specimens strained to breaking, the potential of six reached a constant value shortly after fracture. The difference between the initial and final potentials varied from —0.00019 to +0.0077 volt, and the single potential of unstrained metal was found to be 0.156 volt.

Electrolysis of Pipes.

Electrolysis of pipes is receiving careful attention from the Metropolitan Water & Sewerage Board of Massachusetts, which states in its last annual report that the districts in which such damage occurs seem to be extending. In general, the injury has not proceeded so far as to require immediate repairs, but the examinations show that the corrosive action is advancing. The pipe lines crossing Chelsea Creek between Chelsea and East Boston were found to be particularly subject to disturbance, and at one point it was found that a hole had been eaten through a pipe. The examinations were made over the greater part of the system, records being made of the conditions for future use in caring for the mains. Efforts are being made to devise means of checking the action of the current, and as an experiment insulating joints have been inserted at several points in Cambridge.

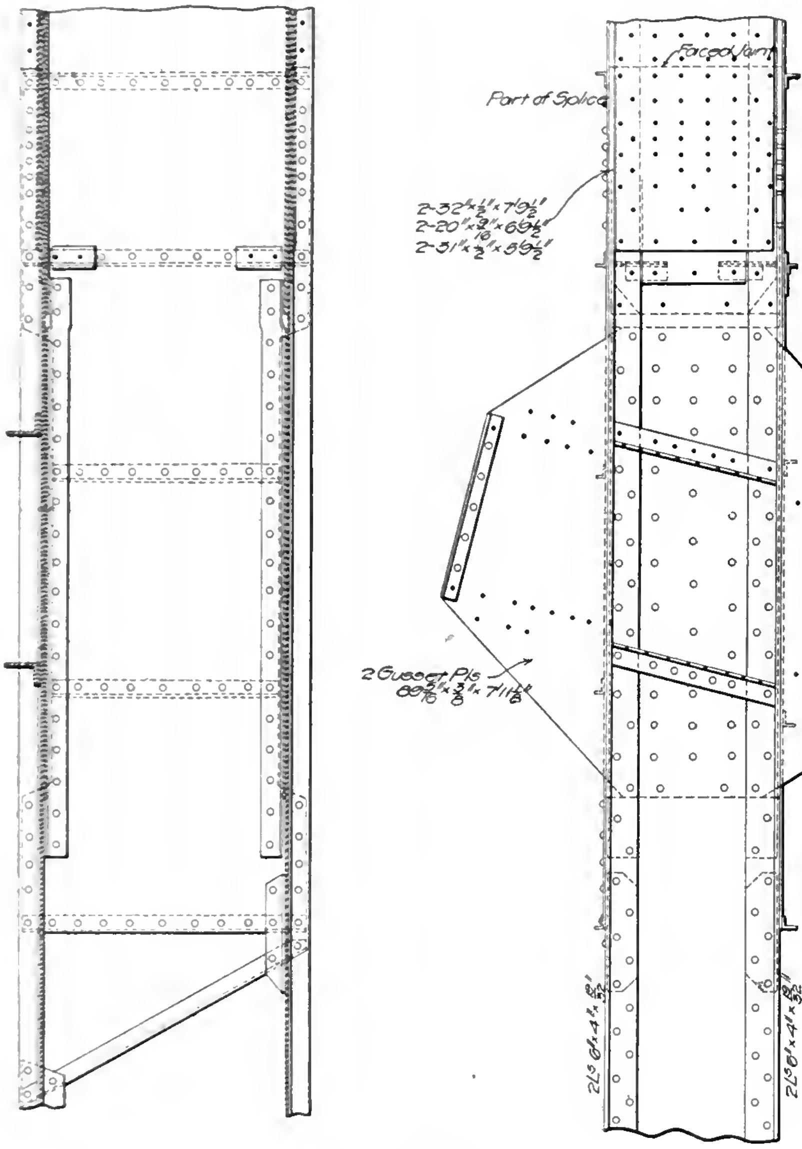
The Quebec Bridge Superstructure Details; Part VI.

Diagonal Members.—The main diagonal in the panel at the river end of the anchor span is a pin-connected strut 273 ft. long on centers and weighs 268,000 lbs. It has a 38½x48½-in. rectangular cross section and was shipped and erected in four pieces with field riveted web and flange cover plate splices. At the lower end it has a cross section of 158.4 sq. in. gross, or 144.15 in. net proportioned for a total maximum static stress of 1,312,000 lb. tension or 554,000 lb., compression and a wind stress of 1,990,000 lb. in either tension or compression. At the upper end the gross and net cross sections are respectively 226.9 and 208.9 sq. in. proportioned for maximum stresses, of 1,123,000 lb. static, and 2,350,000 lb. wind pressure in tension or 1,046,000 lb. static, and 2,350,000 lb. wind in compression.

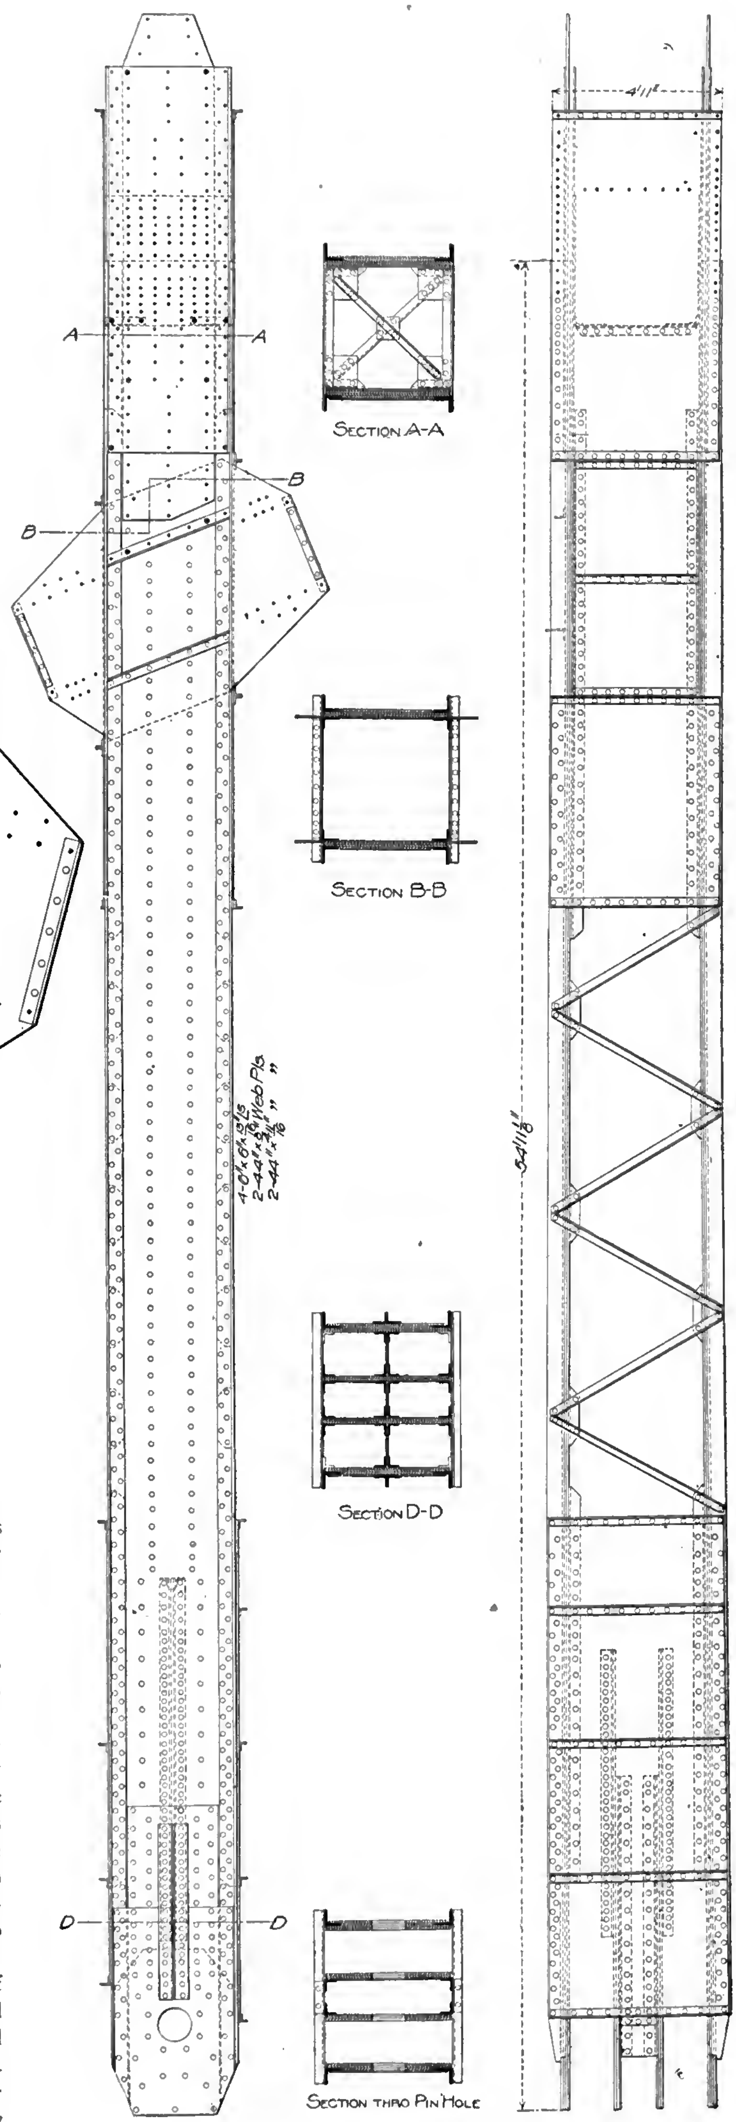
The lower section of the member is about 55 ft. long over all and weighs 66,000 lb. It is made with two built channels having their flanges turned outward and latticed with 3x3-in. angles each of which has one rivet at each end through the channel flange and a second rivet through an auxiliary connection angle riveted to the inside of the channel web. The channels are each made with one ¾-in. and one 11/16-in. plates 44 in. wide and two 6x6x13/16-in. flange angles at the lower end. Additional pin bearing is providing by two intermediate webs about 13½ ft. long riveted between a center transverse diaphragm about 8½ ft. long and two flange cover plates.

For about 19½ ft. at the upper end of this section of the strut the cross section is closed by flange cover plates ½-in. thick, riveted on in three lengths and stiffened with transverse angles. The center lengths of these cover plates are 43 in. wide and 7 ft. 2½ in long and do not engage the flanges of the post channels, but are riveted on each long end to connection angles riveted in their turn to the webs of the post channels, thus connecting the latter rigidly together and still allowing transverse jaw plates to be riveted across their inner faces and project beyond both flanges to receive the field driven connections of the horizontal strut which intersects the diagonal strut at this point. The splice between this section of the strut and the adjacent one is made with long multiple cover plates on the webs and single cover plates on the flanges which were shipped bolted in position with 10 shop rivets driven and finally connected with 1,100 steel field driven ⅞-in. rivets.

The next upper section of the strut is 87½ ft. long and weighs 80,000 lbs. with field riveted splices at both ends. Near the upper end a pair of 111x¾-in. wing plates 17 ft. 11 in. long are riveted to the backs of the channels and pro-



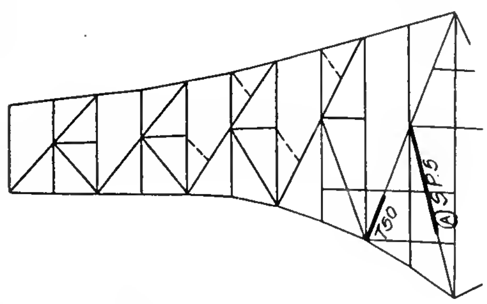
Part of Diagonal A S P_5.



Lower of Main Diagonal T_{50}.

ject 67 in. beyond the flange on one side to form jaws for the field riveted connection of a sub-vertical, sub-diagonal and horizontal strut intersecting the main member at this point. The sub-vertical is continuous and passes between the webs of the diagonal strut to which it is field riveted. The outer edges of the plates are stiffened and connected by a diaphragm 7 ft. 9½ in. long field riveted in position after the connection has been made to the vertical post. During shipment the wing plates were additionally secured by thorough bracing and wedging with sub-units. The webs and flanges are stiffened and set in accurate position so as to maintain the rectangular cross section by interior X-braced frames or diagonals made up with angles such as are used for similar purposes in the outer vertical and sub-vertical posts.

The sub-diagonal strut in the river-end panel of the anchor arm has a riveted connection at both ends and is 195 ft. long over all with a total weight of 63,000 lbs. It is proportioned with a cross sectional area of 59.52 sq. in. designed for a total maximum static and wind pressure of 1,201,000 lb. It is made in three sections spliced together with inside and outside field riveted web cover plates. It is made with two built channels having a 32x9/16-in. web and two 6x4x19/32-in. flange angles turned outward and latticed with 3x3-in. angle bars each having two rivets at each



Anchor Arm, Quebec Bridge.

end, one rivet being directly through connection plates interposed between the lattice bars and the channel flanges. A pair of 8½x⅜-in. x 8-ft. gusset plates are riveted to the backs of the channel webs at the intersection of this strut with a horizontal strut and project beyond both flanges to form jaws field riveted to the latter. Between these jaws the channel webs of each column are connected by transverse diaphragms in the planes of the flange angles cut to clear the latter and the jaw plates, and riveted to short connection angles on the inner faces of the jaw plates. At this point the flanges of the channels are connected by a pair of 54-⅜-in. batten plates about 10½ ft. long stiffened by transverse angles and cut to clear the projecting wing plates to which, however, they are connected by inside angles riveted through them to the webs of the main channel.

(To be Continued.)

A Ganz Steam Motor Car is being tested by the Erie R. R. The car is divided into a motor compartment, a baggage-room, smoking-room, and general passenger compartment.. It is 58 ft. long, weighs 45 tons and has seats for 50 passengers. The motive power consists of two compound inclosed steam motors of 60 h.-p. each, with cylinders 4.7 and 6.7 in. in diameter, and 5½ in. stroke. The steam generator is 42 in. in diameter and 5 ft. high, and produces superheated steam at 270 lb. pressure. Anthracite coal is used for fuel. The speed of the car is 40 miles per hour on level track. The car is being used in regular service out of the Jersey City terminal of the Erie. Cars of this general type have been used in Europe, and a western road sometime ago secured one for experimental purposes.

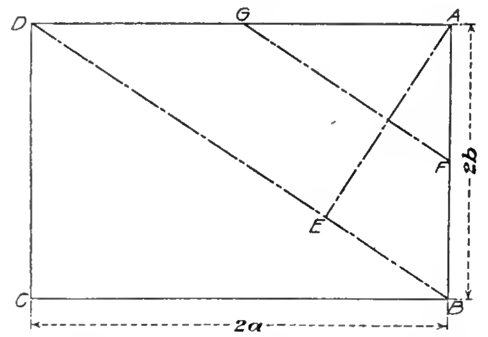
Notes on Reinforced Concrete Designing.

Accompanying the report of the Joint Committee on Reinforced Concrete, which was printed in this journal on July 27, were a number of appendices explaining the reasons for certain requirements suggested by the Committee. As these are of general interest in connection with the report, a number of them are reproduced below.

Bach's Slab Theory.—The first appendix was a discussion of Bach's theory of the resistance of flat slabs supported on all edges and uniformly loaded. It was written by Prof. A. C. Unwin and reads as follows:

The experiments of Professor Bach show that a flat square slab supported all round fractures along a diagonal, and the greatest stress is therefore on the diagonal section. It is the same apparently with rectangular slabs, though the evidence is not quite so clear. But if a diagonal fracture is assumed a very simple theory gives the stress.

Let the figure represent a rectangular slab with sides $2a$ and $2b$ in inches. Let the diagonal $B\ D = d$; the thickness of the slab $= h$; the perpendicular on the diagonal $A\ E = c$; draw $F\ G$ bisecting the sides and let p be the load per square inch. Consider the left-hand half of the rectangle. The total load on it is $2pab$ acting



at the centre of gravity of $A\ B\ D$ or at $c/3$ from the diagonal. Whatever the distribution of the reactions of the supports, from symmetry, the reaction on $A\ B$ must act at the centre F of $A\ B$ and the reaction on $A\ D$ must act at the centre G of $A\ D$. Hence the resultant of the reactions on $A\ B$, $A\ D = 2pab$ must act at some point on the line $F\ G$ or at a distance $c/2$ from the diagonal. Hence the bending moment on the diagonal section is

$$M = 2pab\left(\frac{c}{2} - \frac{c}{3}\right) = \frac{pabc}{3},$$

the stress at the diagonal section is

$$f = \frac{6M}{dh^2} = 2p\frac{abc}{dh^2}.$$

But $cd = 4ab$,

$$d^2 = 4a^2 + 4b^2,$$

$$f = 2p\frac{a^2}{a^2+b^2}\frac{b^2}{h^2}.$$

The following form of the equation is convenient:

$$f = \tfrac{1}{2}\frac{\left(\frac{a}{b}\right)^2}{\left\{1+\left(\frac{a}{b}\right)^2\right\}\frac{a}{b}}\frac{W}{h^2}.$$

Where W is the total load on the slab:

a/b	1	1.5	2
f	$0.25\ W/h^2$	$0.23\ W/h^2$	$0.2W/h^2$

It would seem that if Bach's formula is to be used in calculating slabs, the reinforcing rods should be perpendicular to the diagonals of the rectangle.

Comparison of Slab Formulas.—The second appendix gives a comparison of the results obtained from the use of various rules for the strength of flat rectangular slabs supported on all edges and uniformly loaded. It was written by Mr. William Dunn and reads as follows:

The theories of Professor Grashof and of Professor Rankine assume that the maximum bending stress on the slab is at the centre, where there are two principal stresses on planes normal to each other, these planes coinciding with the major and minor axes of the slab.

The stress on the plane formed by the major axis of the slab (which is the greater of the two principal stresses) may be found in a simple manner as follows:

Let the length of the slab $= a$, and the breadth $= b$ (where a is equal to or greater than b).

Calculate the bending moment on the slab (disregarding the end supports) as a beam supported or fixed at the sides only, of a span b under the total load on the slab. Multiply this bending moment by the factor s in the following table,

When $\frac{a}{b} =$	Grashof's and Rankine's Rule. $s = \frac{a^4}{a^4+b^4}$	Grashof's and Rankine's Rule. $r = \frac{b^4}{a^4+b^4}$	French Government Rule. $s = \frac{1}{1+2\,b^4/a^4}$	French Government Rule. $r = \frac{1}{1+2\,a^4/b^4}$
1.0	0.50	0.50	0.33	0.33
1.5	0.83	0.16	0.71	0.09
2.0	0.94	0.05	0.89	0.03

to allow for the effect of the end supports. The result is the actual bending moment on the long axis of the slab.

The stress on the section formed by the long axis of the slab is found in the usual way by equating this actual bending moment to the moment of resistance of that section.

Similarly the stress on the plane formed by the minor axis of the slab is found by assuming the slab supported or fixed at the ends (disregarding the effect of the side supports), calculating the bending moment as if the slab were a beam of span a under the total load on the slab. Reduce the bending moment so found by the factor r in the table above, and the result is the actual bending moment on the short axis of the slab.

The stress on the section formed by that axis is found as before by equating this moment to the moment of resistance of that section.

The reasoning by which we find the factors s and r is not entirely satisfactory, and other writers give other values. In the Instructions issued by the French Government to the bridge and highway engineers, with the report of the Ministerial Commission on Reinforced Concrete, the factors adopted give a greater importance to the effects of the third and fourth supports. The values of s and r, according to that report, are also given in the table above.

The maximum stresses on the sections as found by the foregoing rules when the slab is supported but not fixed all round are given in the table below, W being the total load uniformly distributed over the slab, h its thickness, and f the minimum stress due to bending.

When $\frac{a}{b} =$	Values of f according to Grashof and Rankine. On L'g Axis.	Values of f according to Grashof and Rankine. On Sh't Axis.	Values of f according to French Government Rule. On L'g Axis	Values of f according to French Government Rule. On Sh't Axis.
1.0	$0.375\ W/h^2$	$0.375\ W/h^2$	$0.250\ W/h^2$	$0.250\ W/h^2$
1.5	$0.416\ W/h^2$	$0.183\ W/h^2$	$0.361\ W/h^2$	$0.101\ W/h^2$
2.0	$0.352\ W/h^2$	$0.088\ W/h^2$	$0.333\ W/h^2$	$0.045\ W/h^2$

These results may be more readily compared by the diagram.

It is implicitly assumed in the foregoing that the strength to resist bending is the same in both directions, so that the reinforcements longitudinal and transverse should be of equal area and at the same depth from the compressed face; they should

be placed parallel to both the ends and sides.

The stresses found by Bach's formula are also plotted on the diagram.

Moments of Inertia.—Prof. Unwin contributed the third appendix, on the moment of inertia of

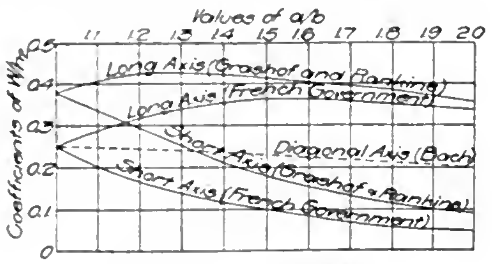


Diagram of Stresses.

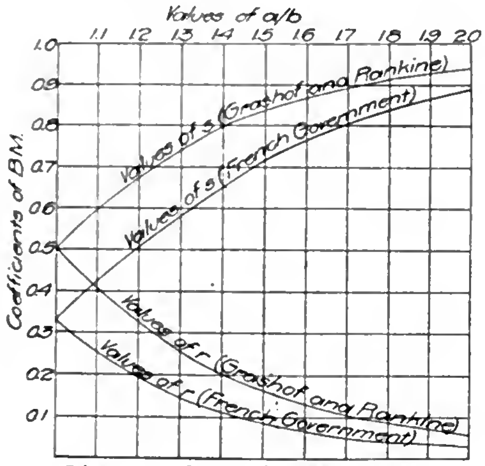

Diagram of Bending Moments.

reinforced concrete, which reads as follows:

If m is the ratio E_s/E_c of the coefficients of elasticity of steel and concrete, then an area A_t of steel is equivalent to resistance to mA_t of concrete. If A_c is the area of a section (including the area of reinforcing bars), and a the area of the reinforcing bars, then the section is equivalent to a section of area $A = A_c + (m - 1)a$ of concrete only. This will be called the equivalent section.

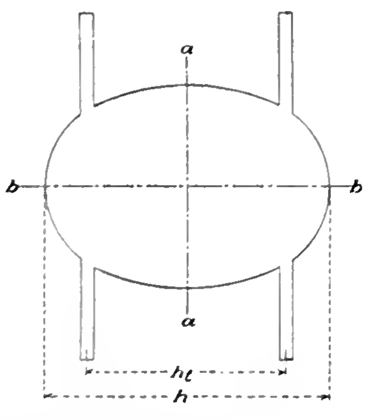
The moment of inertia of a section about its neutral axis can always be put in the form

$$I = nAh^2,$$

where h is the depth at right angles to the neu-axis and n is a constant depending on the form of the section. Thus for a rectangular section $I = {}^1/_{12}\ Ah^2$, and for a circular section $I = {}^1/_{16}\ Ah^2$.

In dealing with reinforced sections, it is convenient in many cases to express the moment of inertia in terms of the equivalent area. The equivalent area is found by adding to the actual area of the section portions of a total area $(m - 1)a$ at the same distance from the neutral axis as the reinforcing bars.

The figure shows a section for which $b\ b$ is the plane of bending, and $a\ a$ the neutral axis pass-



ing through the centre of gravity of the section. The reinforcing bars are supposed symmetrical to the neutral axis. The projecting parts of total area $(m - 1)a$ are the concrete areas equivalent to the steel. If I_c is the moment of inertia of the section without reinforcing bars, the moment of inertia with reinforcing bars is

$$I = I_c + {}^1\!/_4\ (m - 1)ah_t^2.$$

Thus for a rectangular section

$$I = {}^1/_{12}A_ch^2 + {}^1\!/_4\ (m - 1)ah_t^2,$$

and the modulus of the section is

$$Z = {}^1\!/_6A_ch + {}^1\!/_2(m - 1)a\frac{h_t^2}{h}.$$

For a circular section

$$I = {}^1/_{16}A_ch^2 + {}^1\!/_4\ (m - 1)ah_t^2,$$

and the section modulus is

$$Z = {}^1\!/_8A_ch + {}^1\!/_2(m - 1)a\frac{h_t^2}{h}.$$

Example 1, Rectangular Section.—Let $m = 15$, $a = 0.01A_c$, and $h_t = 0.9h$. The equivalent area is $A = A_c + (m - 1)a = A_c + 14a = 1.14A_c$.

$$I = {}^1/_{12}\ A_ch^2 + \frac{14 \times 0.81}{4 \times 100}\ A_ch^2$$
$$= 0.1117A_ch^2$$
$$\text{But } A_c = 0.877A$$
$$I = 0.098Ah^2$$
$$Z = 0.196Ah.$$

In this case in the general expression $I = nAh^2$, $n = 0.098$ when A is the equivalent section.

Example 2, Circular Section.—Let $m = 15$, $a = 0.01A_c$, and $h_t = 0.8h$. The area of the equivalent section is $1.14A_c$, as before.

$$I = {}^1/_{16}A_ch^2 + {}^1\!/_4 \times 14 \times .01A_c \times .64h^2$$
$$= 0.0849\ A_ch^2.$$

$$\text{But } A_c = 0.877A.$$
$$I = 0.0745Ah^2.$$
$$Z = 0.149Ah.$$

Example 3, Circular Section with Reinforcing Bars arranged in a Circle.—The reinforcing bars are nearly equivalent to a ring of steel of the same total area. Let $m = 15$, $a = 0.01A_c$, and let the diameter of the circle of reinforcing bars be $h_t = 0.8h$. The equivalent section is $A = 1.14A_c$, as before.

$$I = {}^1/_{16}\ A_ch^2 + \frac{m - 1}{8}\ ah^2t.$$
$$= 0.0625\ A_ch^2 + 1.75 \times .01A \times .64h^2$$
$$= 0.0737A_ch^2$$
$$= 0.0646Ah^2$$
$$Z = 0.1292Ah.$$

It will be seen that if the value of n in the equation $I = nAh^2$ for simple circular and rectangular sections, and the reinforced sections are compared, the results are as follows:

	Simple Sections.	Reinforced Sections.
Case I	$^1/_{12} = 0.0833$	0.098
Case II	$^1/_{16} = 0.0625$	0.0745
Case III	$^1/_{16} = 0.0625$	0.0646

The differences are not very great, so that while the value of n can always be found exactly when necessary for any proportion of reinforcement, there are cases such as that of columns where the value of n does not much affect the result, and where, from the nature of the calculation, great accuracy is impossible—for which a value of n can be assumed without any practically important error.

Ratio of Moduli of Elasticity.—The fourth appendix, on the ratio of the moduli of elasticity of steel and concrete, was written by Mr. Dunn, and reads as follows:

In the foregoing recommendations, as in the Prussian Government and various other foreign rules, the value of E_s/E_c for concrete of the kind usually employed, of hard stone or gravel mixed 1:2:4, is put at 15.

In reality, it varies with the age of the concrete, the proportions and nature of the materials, the stress at which it is taken, etc. As determined from tests of full-sized columns of concrete, with longitudinal reinforcement only and without transverse binding, it varied from a maximum of 10 at working loads to 15 to 21 at ultimate loads. For cinder concrete of 1:2:4 or 1:3:6 it varied from about 12 at working loads to 26 to 48 at ultimate loads.

This factor E_s/E_c is employed to determined the position of the neutral axis in beams, and it is found that while a variation between 10 and 15 makes no very great difference in the result, a value of 15 fixes the position of that axis nearest to the position found by experiment in singly reinforced beams. In fact, the formula given herein for the position of the neutral axis with $E_s/E_c = 15$ gives a result which agrees well with observed values in beam tests.

As mentioned above, it does not agree so well with the tests on columns: it gives too great an importance to the metal reinforcements, which becomes more noticeable when the percentage of reinforcement is considerable. But these tests were made on columns with longitudinal reinforcement only and without transverse binding, which latter adds greatly to the strength. This binding is explicitly required in the Prussian Government and other proposals where E_s/E_c is taken at 15; and that figure may be taken as making allowance in some degree for it.

We have no satisfactory determination of the increase in strength due to the transverse reinforcement, whether in single bindings or a continuous spiral.

In the Report of the French Commission on Reinforced Concrete, it is stated that where the concrete has spiral binding or transverse or oblique reinforcements, so disposed as to resist swelling under thrust, the safe loads may be increased in some measure, but not in any case to more than $^6/_{10}$ of the crushing strength as determined from tests on cubes of 20 cm. sides at the age of 90 days.

In the explanatory circular accompanying that report the value to be given to E_s/E_c is discussed, and its theoretic value is put at about 10. It is stated, however, that it is preferable to regard that coefficient as the result of experiences on pieces with longitudinal and transverse reinforcements, and not as representing the ratios found from concrete and metal separately. It is to be taken as varying from 8 when the longitudinal reinforcements have a diameter equal to one-tenth of the least dimension of the piece and the bindings are spaced at a distance equal to that least dimension in the direction of the length; up to 15 when the longitudinal bars are one-twentieth of the least dimension and the bindings are spaced one-third of that distance apart. In both cases the bindings are to be near the outer face of the concrete.

Again, it is stated in the circular that it is desirable to encourage the proper use of the metal in both longitudinal and transverse directions. While an exact determination of the increase of strength due to the transverse reinforcement would be difficult, the investigations of the Commission enable it to be admitted, in default of something better, that it is found by multiplying the resistance to crushing of the concrete by a coefficient.

$$1 + m^1V^1/V,$$

V^1 being the volume of the transverse or oblique reinforcement, and V the volume of the concrete, m^1 being a variable coefficient depending on the efficiency of the union between the longitudinal bars. When the union is made by bindings in the usual way, m^1 varies from 8 when these bindings are spaced at a distance equal to the least transverse dimension of the piece to 15 when spaced at one-third that dimension.

When spiral binding is used m^1 varies from 15 to 32, the lower value being taken when the pitch of the spiral is two-fifths of the least transverse dimension, and the higher when the spacing is one-fifth of the dimension under a pressure of 50 kilos per square centimeter, or one-eighth of the dimension under a pressure of 100 kilos per square centimeter.

In no case should the working stress exceed six-tenths of the resistance to crushing as determined on cubes, as before mentioned.

Filtration Experiments at Washington.

The water purification experiments conducted under the direction of Major Spencer Cosby, Corps of Engineers, at Washington, were described at some length in this journal on May 25. They were made with three systems of treatment: A, a rapid sand filter and a slow sand filter; B, a Maignen scrubber and a slow sand filter; C, a settling and coagulating basin and a slow sand filter. In a report recently submitted to the Chief of Engineers by Major Cosby, it is stated that no combination of filters has been found which satisfactorily clarified the Potomac water. "While the preliminary filters remove the greater part of the suspended matter," he says, "and leave comparatively very little work for the slow sand filters to do, the grains of mud remaining in the water after the first filtration are so exceedingly small that they are not entirely removed by either a second or third filtration. In order to arrest these fine grains a layer of very finely powdered animal charcoal was applied to the surface of the slow sand filter of system B, but without any apparent success. The results from system C (the modified slow sand system) show, however, that it has so far been successful in keeping the water free at all times of turbidity by the occasional use of a coagulant and subsequent filtration. The experience thus far gained with this system indicates that it will be found to be the most practical method of clarifying the Potomac water at a reasonable cost, and at the same time utilizing the plant already installed. The bulk of the mud is not only removed by coagulation, but the small amount which remains is so changed in character that it can readily be removed by filtration. It also tends to form a sticky gelatinous mass on the top of the filter sand which assists in arresting particles of mud in the applied water for several days after the use of the coagulant has ceased." The experiments were undertaken in order to find the best means of removing the turbidity which sometimes occurs in times of flood.

The Construction of the Dam of the Nevada-California Power Co.

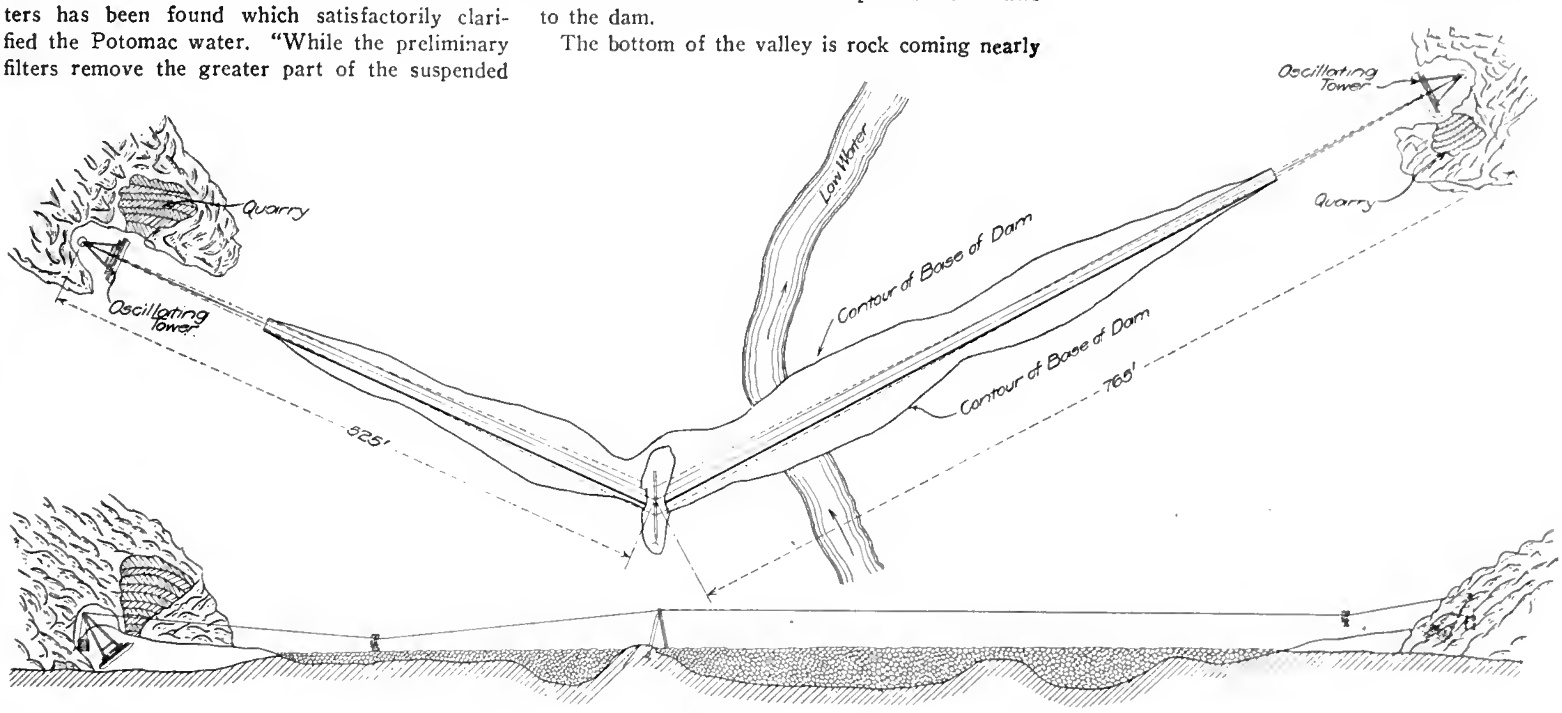
A dam about 1,300 ft. long and 75 ft. high is now under construction by the Nevada-California Power Co., across a narrow valley at a high altitude in the Sierra Nevada Mountains to impound water for supply and power development purposes. It was at first intended to build the dam of stone masonry laid in cement mortar or of concrete, and derricks and other appliances were shipped to Laws, Cal., on a narrow-gauge railway at a cost of 6 cents per pound freight from New York. From this point to the dam site, a distance of about 18 miles, it is necessary to haul all materials by wagon over a very steep, rough road at a cost of $80 per ton. This made the transportation of appliances and materials so costly that the design and method of construction had to be radically changed, and it is now proposed to build the dam entirely of loose rock puddled on the upper side, quarrying it at the site, and handle it by a cable crane system so light that its installation will require the minimum amount of materials to be transported from Laws to the dam.

The bottom of the valley is rock coming nearly or quite to the surface of the ground and rising near the middle of a valley in a ridge extending a little above the crest of the dam and forming a center abutment where the two straight portions of the dam intersect in an angle of about 140 deg. pointing up-stream as indicated in the general plan. On one side of the ridge the dam is about 350 ft. long, 55 ft. wide at the base and 30 ft. high. On the other side it is about 570 ft. long, 75 ft. wide at the base and 35 ft. in maximum height. The crest of the dam has a uniform width of 10 ft.

The axes of the dam produced one or two hundred ft. beyond each end, intersect the faces of steep cliffs of solid rock rising many hundred feet above the crest of the dam. In these cliffs natural recesses occur at the right places to enable them to be utilized for the location of the end towers for the cable crane in positions thoroughly protected from operations in the quarries which will be commenced on the face of the cliff between the recesses and the ends of the dam. In these quarries, carried up to any convenient height above the cable crane, the rock will fall by gravity as blasted to the foot of the cable crane and can be delivered and deposited by it in the required position in the dam, thus obviating the use of all derricks or tracks and reducing the handling of material.

The two-span, cable crane system has been designed and built by the Balanced Cable Crane Co., New York, Mr. W. F. Brothers, president. The plant installed has a single Victor cable 2 in. in diameter with a capacity for a 5-ton load and a breaking strength of 200 tons. It is 1,290 ft. long, and is attached at both ends to oscillating traveling shears which gives it sufficient transverse movement to enable it to command the full width of the dam. It is divided into spans of 525 anad 765 ft. by a telescopic pivoted strut set on the rock at the intersection of the two sides of the dam. The strut bisects the angle between the axes of the dam and is inclined from the vertical toward the stress in the cable and is secured by a tackle anchored to the solid rock. Each tower is inclined away from the center of the dam so as to exert a constant tension on the cable, and has suspended from its apex a 40-ton counterweight exerting a constant tension on the cable and capable of sufficient vertical motion to allow the top of the tower to revolve through an arc sufficient to permit the adjustment of the angle to the position of the load and maintain a constant tension in the cable. These conditions being similar on both sides of the center support the whole system remains in equilibrium while both spans act independently. Both towers are seated on single-track rails perpendicular to the axis of the cable, and when it is necessary to move either one the other can be adjusted until the counterweight is seated with bearing on the solid ground. In the 526-ft. span the deflection due to weight of cable and to maximum load are respectively 2.41 and 23.26 ft. In the 765-ft. span the corresponding deflection was 6.19 and 39.54 ft., the maximum cable tension in both spans being 42 tons.

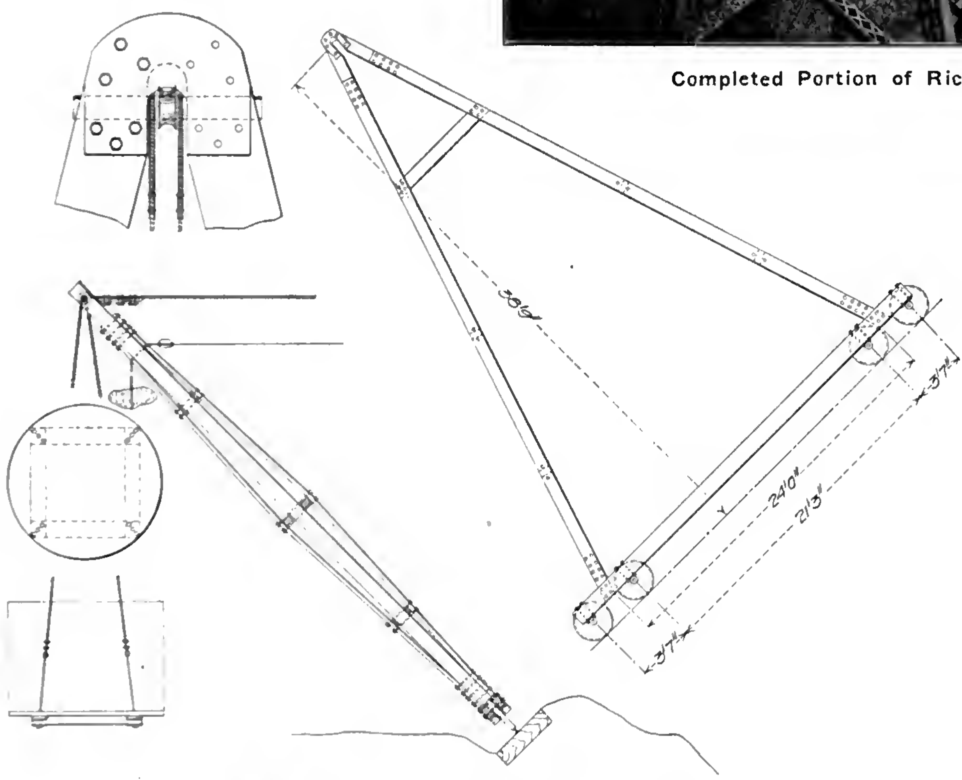
Each of the duplicate towers consists of a triangular wooden frame about 39 ft. high and 31 ft. wide over all, made with single 10x10-in. legs trussed with 10x3-in. planks and with a single 6x12-in. sill. There are four 24-in. wheels with their single flanges set alternately on opposite sides of the rail. The tops of the posts are bolted together through a pair of ⅜-in. plates and have a horizontal transverse pin receiving the clamped loop-eye of the main cable and the bights of two suspender ropes for the counterweight platform. The platform, 10 ft. in diameter, is made of 3-in. planks and is loaded with 40 tons of rubble masonry or concrete. Below it a cushion 2 or 3 ft. deep of soft earth is provided where it can be lowered down to bearing in case it is necessary to temporarily seat it



Two Span Continuous Cable Crane, Nevada-California Dam.

on the ground. The single 80-lb. rails are spiked to short ties perpendicular to the main inclination of the tower.

The hoist carriage is suspended from two deeply grooved wheels with teeth cut in their flanges which mesh with a pinion on a horizontal axle, which, at its outer end, is propelled, released or gripped by the action of a single lever controlling it through friction clutches which directly engage the motor. The pinion can be reversed to propel the carriage in either direction and it is traversed, held stationary or allowed to coast by different positions of the same lever. Each of the two hoist ropes is double with its bight wound on a separate drum and the loose ends provided with clevises for attachment to the bucket or skip. Each drum is supported on four sets of ball-bearings with steel racers about 15 in. in diameter and 5/8-in. hardened steel balls. The hoisting apparatus is controlled by a single lever and clutches much like those for traversing the carriage, and it is so arranged that either drum can be disengaged and run, stopped or overhauled independently of the other, thus enabling the operator to revolve a skip about its horizontal axis to dump it or to operate a clam-shell bucket. The motor shaft is vertically midway between the belt-driven traversing and hoisting pulleys, which run constantly. The 40 h.-p. motor can be run in either direction and normally drive both hoisting and traversing shafts, but can be disengaged instantly from either in order to concentrate all the power on the other if required. The hoisting apparatus is rated at 40 h.-p. and can develop a maximum of 60 h.-p. The speed of operation is 80 ft. per minute for hoisting a 5-ton load and 1,500 ft. per minute for traversing. There is a



Oscillating Tower, Nevada-California Dam.

duplicate carriage on each cable and each carriage has a suspended enclosed cab for the operator who is in entire control of hoisting, traversing and dumping. A 50 h.-p. General Electric dynamo, driven by a 75 h.-p. engine, furnishes the current which is transmitted through a trolley wire attached to both towers and provided at each end with an adjustable counterweight.

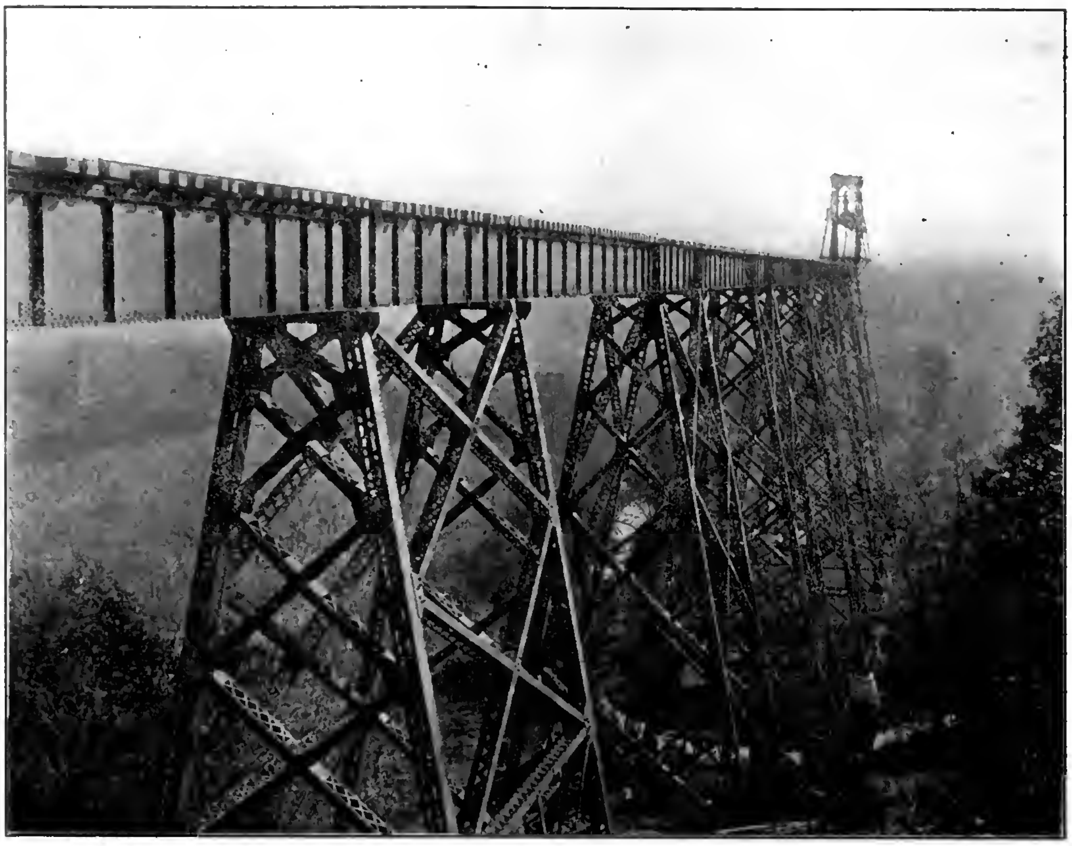
The surface of the rock is being stripped and a concrete foundation prepared for the sluice pipe intended to provide for the dry weather flow through the dam while the latter is under construction. It is expected that the quarry blasts will deliver the broken rocks so close to the cable crane at both ends of the dam that a large proportion of it can be chained in massive pieces and delivered to the required position at an average cost of about 25 cents per yard. This is on the assumption that 1,000 cu. yds. per day can be handled by a small force of laborers at 50 cents each per hour.

Messrs. Manifold & Poole, Los Angeles, Cal., are the engineers of the power plant.

The Specific Heat of Superheated Steam has been under investigation for some six years by Mr. A. R. Dodge, and at the recent meeting of the American Society of Mechanical Engineers he presented a paper describing his methods and summarizing his conclusions. He believes that at constant pressure the specific heat is constant for all ranges of temperature investigated, although it increases with increasing pressure according to the equation $c = 0.4754 + 0.00031\ p$.

Richland Creek Viaduct, Indianapolis Southern Railway.

A single-track viaduct of the Indianapolis Southern Ry. crosses Richland Creek, 7 miles from Bloomfield, Ind., with a steel superstructure 132 ft. in maximum height and 2,215 ft. in length. It has alternate 40 and 75-ft. plate girder spans,



Completed Portion of Richland Creek Viaduct and Traveler.

supported on eighteen 40-ft. towers, besides two 50-ft. spans at one end and two 60-ft. spans at the other end supported on single rocker bents next to the abutment. The girders have a uniform depth of 7 ft. and are spaced 8 ft. apart transversely and connected by the usual vertical transverse sway-brace frames and by zig-zag lateral angles in the planes of the top and bottom flanges.

Each tower is made with two vertical bents 40 ft. apart longitudinally, each vertical bent being composed of two columns battered 2¼ :20 with open rectangular cross-sections made with two built channels composed of pairs of 4x4-in. angles and 21-in. web plates latticed on flanges. The thicknesses of the angles and plates are the same in each column section and vary from 3/8 to 5/8 in.

The longitudinal faces of the columns are divided into two, three or four panels and the transverse faces into four, five or six panels, according to height, and both longitudinal and transverse panels are X-braced with struts, all of which are made with pairs of 10-in., 20-lb. channels latticed, with double 2½x3/8-in. bars. There are no horizontal struts except at the top and bottom of the transverse faces of the columns and where, both bent of the tower being of the same height, the longitudinal struts connecting the feet of the post in both bents happen to be horizontal. All bottom longitudinal and transverse struts are supported at their center point by suspenders made with four angles reaching to the intersection of the diagonals in the panel above.

The feet of opposite diagonal columns in each tower have expansion bearings with a 3/8-in. phosphor bronze plate sliding on a 7/8-in. steel masonry plate. The other columns have fixed bearings on 1¼-in. steel masonry plates. There

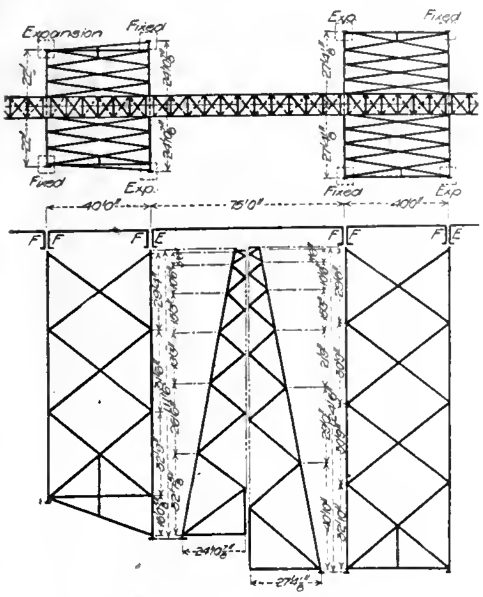
are no transverse girders and the tops of the columns have horizontal cap plates directly receiving the ends of the longitudinal girders with expansion bearings at one end of each 75-ft. span. Cross ties are laid on the top flanges of the longitudinal girders to receive a track on a tangent and at 5 per cent. grade.

The structure was designed for Cooper's E-50 live load and unit stresses of 15,000 lb. and 19,000 lb. were allowed in tension reduced by the impact formula, $I = LL \times \frac{LL}{DL + LL}$.

The maximum unit stresses in compression were

$$\frac{15000}{1 + \frac{l^2}{13500r^2}} \text{ and } \frac{19000}{1 + \frac{l^2}{13500r^2}}$$

and a maximum of 9,000 lb. per square inch was allowed for shear. Unit values for shop-driven rivets were 11,000 lb. shear and 22,000 lb. bearing, and for field-driven rivets 8,800 lb. shear and 17,600-lb. bearing.



Towers and Connecting Span.

The superstructure contains 2,017 tons of steel fabricated at he Detroit plant of the American Bridge Co., of New York and erected, as described in The Engineering Record of February 23, 1907, by the Strobel Steel Construction Co., of Chicago. The design and construction was under the direction of Mr. R. E. Gaut, enginer of bridges of the Illinois Central R. R. Co.

A New Use of Tar.

A new use of tar is reported from East Palestine, Ohio, where a mason erecting a number of brick houses ran short of black mortar color and was unable to get a new supply in the time at his disposal. Accordingly he tried a little partially refined tar, and had no difficulty in getting the right color for the mortar for pointing and beading between the bricks. Fearing defects from this material, the mason watched the houses very carefully, and recently reported that after a lapse of several years he found the color as strong as ever.

Water-Power Developments are being investigated in the southern part of Sweden for furnishing power to operate the State Railways in that part of the country. Estimates have been made which show that five waterfalls which can be developed for about $16,000,000, will furnish sufficient power.

Special Methods of Shaft-Sinking.

A paper read before the Engineering Conference of the Institution of Civil Engineers by Henry Louis.

Under the head of special methods of shaft-sinking, I propose to consider the methods that have to be resorted to when ordinary methods cannot be applied economically on account of an excessive influx of water. Such complications are mostly confined to coal-mining, and arise but rarely in metalliferous-mining, mineral deposits usually lying in the older, less heavily-watered rocks. Year by year, as the coal-seams available within the area of the exposed coal-fields are more extensively drawn upon, it becomes increasingly necessary to sink down to the so-called concealed coal measures, overlain by more recent formations, many of which carry vast quantities of water.

It is a question what quantity of water may be regarded as necessarily involving the use of special methods. The largest amount that I know to have been sunk through successfully was at Horden Colliery, where 9,250 imp. gal. of water per minute at a depth of 540 ft. were dealt with. But in many cases far less than this amount has proved an insuperable obstacle to sinking in an ordinary way. It is possible that in the future ordinary methods of sinking may be found applicable in cases in which they have heretofore been considered impracticable, by the use of suspended tubbings, as introduced by Messrs. Haniel and Lueg of Dusseldorf, a system which has never been tried in this country, although it has been used with much success in several deep sinkings on the Continent.

The special methods to be used will differ, according as the water-bearing strata to be traversed are firm or running ground. In the former case the Kind-Chaudron method is mostly resorted to. This system was first employed about the year 1854, since when about eighty shafts have been sunk by it, of which five have been in this country. A pair of shafts were put down by it in 1876 at the Cannock and Huntington Colliery in Staffordshire, but the operation failed through the breaking away of the ground at the moss-box in each shaft. Sinkings by this method were also commenced, almost simultaneously, in 1877 at the Whitburn Collieries, and were completely successful. Finally, the shaft of the Consolidated Kent Collieries Corporation, Limited, was sunk by this method at Dover in 1904-5. A depth of 1,095 ft. had been reached by ordinary methods of sinking, and there still remained some 90 ft. of Oolitic and Liassic rocks to sink through in order to reach the coal-measures. This was done by the Kind-Chaudron method, and a column of tubbing 1,120 ft. high was put in. The modern continental practice in such cases is not to put in a column of tubbing the full depth of the shaft, but to lower a length of tubbing corresponding only with the depth bored out, and fitted with a false cover as well as a false bottom, the economy being obvious.

Mr. Riemer, one of the leading German authorities on sinking, considers that it will not be possible to execute sinkings by the ordinary Kind-Chaudron method at depths exceeding 2,000 ft. because it would be impracticable to handle cylinders thick enough to withstand the pressure corresponding to that depth, the limit of thickness according to him being about 5 in. Various proposals for modifying the method, so as to render it available at these great depths, have been put forward by Mr. Riemer and Mr. Tomson, but have not yet been put into practice.

When the ground to be sunk through is running as well as water-bearing, the Kind-Chaudron method is no longer applicable. In such cases three groups of methods are recognized, namely (1) driving down annular sheet-piling, (2) forcing down continuous cylinders of brickwork or iron, and (3) the Poetsch freezing process. Annular piling is the oldest method, and is only applicable when the stratum of soft ground to be passed through is not very thick, and is comparatively near the surface. As the piling is usually in lengths of 15 ft. to 20 ft., and as each new ring of piles has to be driven inside the one above, it follows that the original diameter must be taken very much greater than the finished diameter of the shaft. The method is not often seen now, but a good modern example may be quoted, namely, the recent sinking (September, 1906) at Bowburn Colliery, Co. Durham.

It may be here suggested that ferro-concrete sheet-piling might be used. Piles of this material, 60 ft. in length, have been driven, and it has also been found practicable to add fresh lengths to the top of piles already driven, and thus to get down to almost any desired depth. Furthermore, the adjacent sides of ferro-concrete piles can be grooved, and when the piles are down, cement can be run into the spaces thus left, making the piling practically water-tight. As far as I know, this system has never been tried for shaft-sinking, but there appears to be no reason why it should not be perfectly successful.

The method of sinking continuous cylinders, and excavating the ground from inside them, has only been used in this country for moderate depths. There have been several good examples of shallow sinkings by it in Scotland, where sand, mud and silt on the seashore have been sunk through for depths of about 100 ft., the sinkings at Musselburgh (1901-2), and at Bridgeness (1878), being cases in point. In a more recent sinking of a pair of shafts at Ardeer (1905), about 80 ft. of silt had to be traversed, and a similar process was adopted, using, however, the somewhat antiquated device of the air-lock (first used by Triger in 1839) for the actual excavation, the men working in compressed air at the bottom of the cylinder. Modern practice seems generally to favor the use of some form of dredge for excavating the material from the inside of the cylinder.

This principle has reached its greatest development in Germany, where it has been extensively used for sinking down to firm ground through the overlying thick masses of superficial deposits. The modern practice consists in sinking a cylinder, usually of masonry, built upon a massive iron cutting shoe, until skin-friction prevents its further descent. Tie-bolts, attached to the cutting shoe, are built into the brickwork, and by means of these a heavy iron anchor-ring is secured to the upper part of the shaft. A cylinder of iron is then built up beside the first cylinder, and is forced down by powerful hydraulic presses, which work against the anchor-ring. The ground inside the cylinder is excavated by some form of dredge, grab-dredges, bucket-dredges, bag-dredges, and the air lift all having been made use of.

The freezing method was devised by F. H. Poetsch in the year 1883. Although originally intended for sinking through wet quicksands, it has also been applied to sinking in solid but broken strata, carrying much water. Although it had been used repeatedly with success in both France and Germany, the first applications of this method in Britain have been comparatively recent, and have all been confined to the Durham coal-field. The first example was the sinking of a pair of shafts at Washington in 1902.

Freezing was subsequently employed in two very difficult sinkings at Eastington and at Dawdon. At the former place the operation was a failure; the yellow sands here are exceptionally thick, namely, over 100 ft.; they lie at 465 ft. beneath the surface; the water is brackish, and the water-level is affected by tidal movements. At the neighboring colliery of Dawdon, however, the operations, commenced about the same time, were perfectly successful.

Another very interesting sinking by this method

is now in progress at the famous Wearmouth Collieries, originally sunk in 1826. It is now proposed to sink a new shaft close to the site of the old ones. If this were done by the ordinary method, the necessary pumping would relieve the tubbing in the old shafts of the hydrostatic pressure under which it now stands, and when this pressure comes on again, which it would do as soon as the new shaft were tubbed off, the old tubbing would in all probability be destroyed. Hence it has been decided to use the freezing method, which does away with the need of pumping, and therefore does not affect the hydrostatic level of the district.

Finally, reference may be made to a method that has only been used once or twice in the North of France, namely, the forcing of cement slurry through boreholes into soft, fissured strata, and thus forming a wall of concrete within which sinking can be performed; this method was used successfully a few years ago at the Lens Collieries.

Book Notes.

An attractive 26-page pamphlet has just been issued giving a brief description of the general design and construction of the Quebec bridge now under construction across the St. Lawrence River at an estimated cost of about $4,000,000. It gives a very concise resumé of the principal data for the 1,800-ft. channel span, notes the character and magnitude of its members, and describes the large concrete and granite piers. It is illustrated by 12 pages of photo-engravings including progress pictures at different stages of the construction of the south anchor and cantilever arms, the steel false-work, the 1,000-ton steel traveler, and the storage yard at the site. The pictures also include special operations of erection, such as the simultaneous hoisting of 160-ton groups of top chord eye-bars for both trusses, and the driving of 12-in. chord pins nearly 400 ft. above water level. The electrical installations from which all power used in erection is provided and the principal machines and tools used for the erection, most of which are special, are also described or illustrated, thus outlining some of the most important points connected with the building of the bridge. (D. R. Kinloch and N. R. McLure, New Liverpool, P. Q., Canada, 35 cents).

A pamphlet full of useful information to the experienced roadbuilder as well as the young engineer has been issued under the title of "The Construction of Macadam Roads," by the Office of Public Roads of the Department of Agriculture. It is written by Mr. A. B. Fletcher, secretary of the Massachusetts Highway Commission, and gives in some detail what is generally considered the best practice in macadam road construction in the Northeastern States, particularly that followed on the Massachusetts roads. It is particularly useful on account of the detailed information it contains respecting the amounts of materials and the average costs of executing different classes of work. The author is careful to point out that direct comparisons of average costs of roads in one locality with those in another are not likely to be of value, for the reason that the conditions in the two localities are rarely even approximately alike. Even the costs of broken stone surfacings, which at first thought might be considered comparable, often lead to wrong conclusions. The data are often interesting, nevertheless, and when used carefully furnish suggestions that are likely to result in some improvements in the methods followed at places where costs run high. The importance of making allowances for different local conditions is shown by the following extract from the pamphlet: "Road officials in New Jersey are advised to use 2,461 tons of broken stone, exclusive of screenings, to the mile of road 15 ft. wide and 6 in. thick, after thorough rolling. The screenings needed are estimated to weigh 407 tons to the mile, making a total weight of 2,868 tons. Trap rock is used almost exclusively in New Jersey. In Massachusetts in 1906 the 6-in. to 4-in. roads, average depth 5 in., built of trap rock and 15 ft. wide, averaged 2,810 tons to the mile, including the screenings. It would appear from these figures that in Massachusetts nearly as much stone is used in building the 5-in. roads as is required in New Jersey for 6-in. work." In addition to the general description of road-building which the pamphlet contains, it has extracts from specifications used in constructing State-aid roads in Massachusetts, New Jersey, New York, Connecticut, Pennsylvania and Maryland, and reproductions of the drawings of standard structures adopted by the Massachusetts Commission.

Letters to the Editor.

BRICK-BATS FOR CONCRETE AGGREGATE.

Sir:—Do you consider concrete made of brickbats any good for the foundations for a tower of a water-works system, the tower to be of steel and 100 feet high? Do you not think that in time the brick-bats will crumble and allow the tower to settle? CITY CLERK.

This question is asked so many times that the answer is probably worth printing, as a matter of record. The following notes are taken directly from Mr. L. C. Sabin's "Cement and Concrete," which is the standard American authority on the subject. Fragments of brick and other burnt clay products give good results up to the limit of the strength of the pieces, but this limit is not high. Four beams mixed 1:2:5.8 and tested at the age of eleven months showed an average modulus of rupture of 302 lb., the supports being 4 ft. apart, while two beams of the same composition but made with soft limestone shavings from a stone planer showed an average modulus of 413 lb. Eight beams of brick-bat concrete mixed 1:2:5.8 and tested in 20-in. spans at the age of about two years showed an average modulus of 397 lb., while four beams of the same composition and age, tested under like conditions, made with soft limestone shavings, showed a modulus of 604 lb. It will be seen that the strength obtained with broken brick is considerably lower than that obtained with soft limestone. Had a poorer mortar been used, the brick would, doubtless, have given a better comparative result, since with 1:2 mortar, the brick were not strong enough in themselves to utilize the full adhesive strength of the mortar.

The preceding notes from Mr. Sabin's book state the case so clearly that it is only necessary to emphasize the importance of his assertion concerning the effect of the quality of the brick-bats on the concrete made with them. There is such a great difference in brick that it is out of the question to state in a general way whether brickbats should be permitted in the foundations of a water tower. Some brick are dense and hard enough to be perfectly safe, provided the unit pressures imposed on the concrete are not excessive, while other brick are unfitted for such use. In this connection it might be stated that a concrete footing for a water tower in a Southern city, which cracked so as to endanger the structure, was made with brick-bats and the cracking was attributed to their use.

REINFORCEMENT STEEL.

Sir:—I note that in your abstract of the paper submitted by Mr. Shuman at the annual meeting of the American Society for Testing Materials, relative to specifications for steel used in the reinforcement of concrete, you neglected any referNce to the discussion which was offered by the writer at the time the paper was submitted, and as two out of the three parties whose discussion you quote in your issue of the July 20 are directly interested in the manufacture and sale of the material discussed, you may not consider it unfair to refer to some of the statements made by those not so connected. I am, therefore, enclosing a copy of the discussion which was offered at that time, which, though slightly revised, gives in substance what was stated verbally at the meeting of the American Society for Testing Materials. You are at liberty to use this as you see fit, but I do not think that your paper should favor the tendency which exists, to make it appear that almost any kind of material is good enough for the reinforcement of concrete.

Yours truly,
J. B. FRENCH.

MR. FRENCH:—The reading of this paper prompts me to say that as far as my knowledge goes the steel that goes into reinforced concrete is not being tested, and that the purchasers that use it know very little about its properties or quality, and Mr. Shuman being here, he can probably tell us what information he is able to give to purchasers in regard to the physical and chemical properties of the material that is furnished by the company with which he is connected.

It is known that old Bessemer rails are being bought up, twisted hot and furnished to reinforced concrete users, and the people that twist this material cold claim that the hot twisted material is very unreliable, because the phosphorus is excessive, and that it is liable to break and crack in using. Having myself insisted on cold-twisted material, made tests of it and failed to make it bend more than 45° without breaking off short, I have been forced to think that the claims in favor of the cold-twisted material (made from Bessemer stock) may sometimes be very misleading.

If we go back to the manufacturer and ask him for the best information he can furnish us in regard to Bessemer steel that is put into rods for cold-twisting, he gives us what he calls an average analysis. We are not able to find out the extremes between which the results vary, but must be satisfied with the "average." If we try to go a little further and find out how often analyses are made, we are told that an analysis every three or four blows is all that can be furnished.

As far as the statement goes that these average analysis or these analysis of occasional heats or blows represent uniform conditions,— I know, as a matter of fact, from check analyses that have been made within the last two or three months, that we found as high as 13 and 14 points of phosphorus in samples taken from material represented to show less than 10 points, and we have found bars that break before being bent 90°.

I think that in view of the many important uses to which reinforced concrete is now being put, and the failures, many of them involving the loss of human life, which often result from the use of bad material, that steel for the reinforcement of concrete should be as carefully specified, inspected and tested as is considered necessary for structural steel used in bridges and buildings, and if this view is correct, Bessemer steel will be excluded from use in reinforced concrete structures exactly as is already done in the case of important structures built entirely of steel.

SEVENTY-NINE REINFORCED CONCRETE BUILDINGS have been erected or are now under construction in San Francisco, according to Mr. Wm. Ham. Hall. One is a ten-story structure and sixteen are over six stories. Fourteen are stores, thirteen are office buildings, ten are warehouses, six are factories, and two are power stations.

THE ENGINEERING RECORD
PUBLISHED WEEKLY BY THE
McGraw Publishing Company
James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.
MAIN OFFICES:
114 LIBERTY STREET, NEW YORK.
BRANCH OFFICES:
CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.
LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico	$3.00 a year
Canada	$4.50 a year
Foreign subscription	$6.00 a year

25 shillings. 25 marks. 31 francs.
Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGES OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1905, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,250 copies are printed. Total circulation for 1907 to date 465,000 copies, an average of 14,531 copies per week.

TABLE OF LEADING ARTICLES.

An Engineering Potpourri.

Attention is called to the proposed municipal engineering board described in a letter published elsewhere in this issue. The fantastic originality of the suggestion is equalled only by its bright promise of endless confusion. Evidently the engineering work in the city referred to is already so foot-loose and free from direction by a central authority that its further reduction to a state of impotence is not a difficult matter. The situation stated by the writer of the letter has evidently arisen from the exigencies of practical politics. In the multitude of official boards there is multiplication of jobs for all the cohorts of great and small leaders, and consequently in a city where politics is a thrifty business it is customary to see each public works department more or less independent, its affairs being directed by a distinct board which appoints its employees and is responsible only to the mayor. It is usually a wretchedly inefficient system, so far as economical and effective technical management of the different public works is concerned. The various boards fight between themselves for patronage and appropriations, and instead of helping each other as occasion arises, generally do their best to prevent progress. It sometimes happens that for financial or other reasons it becomes necessary for a city to place a certain kind of work in charge of some special board. If this is not done the work cannot be carried out, and a board organized under such circumstances has a real reason for existence. Every condition in ordinary municipal affairs points, however, to the importance of placing all engineering work under the charge of a single city engineer, as has been done for years with marked success in Boston, where the city engineer, as the technical adviser on all engineering matters, directs the work of all the department engineers and harmonizes their differences. His most important function, however, lies in acting as a buffer between the heads of the various engineering departments and the city legislative and administrative officers. The heads of departments are thus free from all annoyance, and the mayor, councilmen and others become accustomed to applying to a single man for the engineering information they require. It is a great deal better in any organization for the work of one general kind to be under a single head, who alone is authorized to say anything about it. This has been demonstrated repeatedly in business affairs, in the management of large railway and manufacturing companies, and in a number of important cities, and consequently only the demands of politics can account for such an organization as is stated to exist in the city mentioned by the writer of the letter.

There are few engineers who have the breadth of view qualifying them to direct the technical affairs of a large city. The average engineering specialist is rarely so qualified, for by training and inclination he is accustomed to regard certain branches in which he is particularly interested as of greater importance than they probably are and is equally inclined to underrate the importance of other branches. Moreover, it is generally the case that a specialist has been so thoroughly concerned with technical matters that he has neglected the business side of engineering. He is an excellent man to give advice regarding details of his specialty, but this is no reason for putting him in a position to criticize the works of other engineers engaged in different lines. In such a municipal organization as that mentioned in the letter, there is bound to be more or less departmental jealousy, and this feeling of dissatisfaction between the politicians directing the different boards will be reflected by their engineering assistants. On account of this jealousy, it is not at all unlikely that excellent engineering suggestions by the technical head of some department would be voted down by the majority of the proposed board of engineers, owing to mere spite. Theoretically, this should not occur, of course, but those who are familiar with the feeling that sometimes exists between different departments of large organizations, public and private, will recognize in the proposed plan an element of danger of the sort indicated.

The writer of the letter suggests that the engineers who form such a board and undertake to criticize work of their associates, of which they know little or nothing, are guilty of unprofessional conduct. This raises a point concerning which there will be marked differences of opinion. If such an engineering board could be organized and its members were to work together harmoniously, criticisms from ignorant or from semi-ignorant members regarding certain projects could not be looked upon as unprofessional but rather as inquiries for purposes of information alone. It hardly seems probable that any engineer would undertake of his own volition to vote against plans prepared by somebody who knows more about the subject than he does. But if jealousy arises, either personal or departmental, it is evident that all hope of efficient progress in any engineering branch will be completely lost. The contrast, therefore, between a properly organized engineering department with a city engineer at the head of the whole force and such a board of probably discordant members as is suggested in the letter, is strongly marked. Even assuming that each member of that board is an expert, it is probable that sooner or later he will feel the necessity of consulting with other specialists concerning some parts of his work. The suggestion that he should refer such matters to the people associated with him on the board, who are less well informed about them than he is, instead of to competent consulting engineers, is a ridiculous attempt to save money in trifles by risking enormous losses in large works.

Comparing Estimates with Construction Costs.

Few duties are more instructive in engineering practice than the comparison of estimates with the actual construction expenses relentlessly added by each day's progress from the beginning to the completion of the work in hand. The task is sure to be a pleasant one if the totals fall below the anticipated amounts, but in so many instances changed conditions or inaccurate forecasts modify the results expected or secured, that an engineer would be more than human if he did not feel the temptation to postpone the rigid comparison of early figures with late experience. In actual work it is almost always necessary to explain increases in grand totals to the financial powers back of the enterprise, but this is not the point at issue. The question which ought to be faced fairly and squarely is, how the results in detail check with the detailed estimates, and what are the causes of discrepancies.

If field notes are kept with sufficient care in explanation of unexpected changes in working conditions the problem ought to be a simple one. Presumably the original estimates and the contract prices will be properly filed at headquarters. When a job diary is posted from day to day with records of all important decisions of the supervisory engineers, agreements modified by consultation with contractors, delays in shipments, unforeseen obstacles in excavation and the like, the comparison of estimates and costs becomes an easy task, as far as explaining discrepancies is concerned. Errors of judgment are liable to occur in the most carefully prepared estimates, and the detection of these by stripping off all other uncertainties in comparison is the most valuable aid toward more accurate judgments in future work. It is decidedly worth while to know the unit costs of every large enterprise and most small construction jobs, even at the expense of a certain amount of clerical work, which at times proves irksome. It is not enough to apprehend the probable limits of a prospective cost range. Excavation, stripping of land, pole erection, blasting, fills and many other constructional

activities all vary in unit costs according to conditions, and it is unquestionably valuable to be able to estimate such work with reasonable accuracy as checked by previous jobs.

If it is important for the engineer to verify his estimates with the actual results in cost details, it is equally essential for the client to appreciate that perfectly legitimate reasons may occur to change the original figures without in the least impairing the reputation of the engineer himself. When a client does not possess the mental breadth to realize the effect of conditions which could not have been foreseen, nothing is to be gained by volunteering explanations of why detailed items varied so widely in the actual costs, while the totals were close to those secured in the work. It is a personal matter for the engineer to determine, of course, how far it may be wise to offer explanations of this kind. Times are when they are asked for and appreciated when presented, but whether they are called for or not, every far-sighted engineer will check up the figures in the privacy of his office and will realize the immense importance of full memoranda as the job progresses.

The Improvements in the St. Mary's River.

The improvement of the West Neebish channel of the St. Mary's River, which is described at length in this and the preceding issue of The Engineering Record, affects a greater total tonnage of shipping than any other similar work that has been undertaken in recent years by the general government. The traffic between Lake Superior and the other Great Lakes has increased at a truly remarkable rate in recent years, the net total of this traffic being nearly 52,000,000 tons in 1906, as compared with a net aggregate of approximately 19,000,000 tons in 1897. This rate of increase has been particularly great since the opening of the iron mines in the Messabe Range at the head of Lake Superior, although the traffic in coal, general merchandise, grain and grain products is proportionately as much heavier each year, due to the rapid development of the vast agricultural region tributary to Lake Superior. Furthermore, it may certainly be expected that the present rate of increase will be maintained, and probably given considerable acceleration during the next few years as the scope of various enterprises at the head of the lakes is broadened and as new industries now under construction in that locality are placed in operation.

The narrow tortuous course of the St. Mary's River, through which this great volume of traffic is required to pass in leaving or in entering Lake Superior, and the rapids in that river, have necessitated some exceedingly broad and expensive improvements. These have been carried on as rapidly as practicable, but, in general, have never kept pace with the increase in traffic sufficiently to permit vessels of the most desirable sizes to be used. The work that has been done at the rapids consists of a lock on the Canadian side and two locks on the American side, together with approaches to these locks. The latter passed 22,155 vessels in the season of 1906, and during June of this year 3,134 vessels were locked through them. While they are capable at present of handling this great traffic, at the existing rate of increase their capacity will soon be entirely inadequate. Plans for a third lock on the American side have been made, and the construction of this lock will be started within a year, but it can scarcely be finished before the traffic becomes greater than can be passed satisfactorily through the existing locks.

The work that has been done in the past in improving the channels of the St. Mary's River below the locks is briefly outlined, and the work now under way on those channels is taken up in detail, in the description to which reference has been made. From this description it is evident that the opening of the West Neebish channel will practically complete such work in the river below the locks until the depth of water in various other channels and harbors of the Great Lakes is increased. Even at that time the improvements which will then be required in the St. Mary's River can readily be carried on without interfering with traffic. The most desirable feature of this new channel on the west side of Neebish Island, however, is that after it is in use a practically double sailing course will be available from the locks at the head of the river to the mouth of the latter in Lake Huron. That is to say, where two channels do not exist the single channel is either naturally wide enough or has been widened and deepened so the upbound and the downbound traffic may be separated entirely. The downbound traffic going with the swift current of fthe river will then be allowed to take the right-hand course, including the straighter route offered by the West Neebish channel, while the upbound traffic will use the more crooked route around the east side of Neebish Island. The value to the heavy traffic in the river of the double sailing course thus made possible by the completion of the West Neebish channel can scarcely be overestimated, and the opening of the latter will certainly be followed by a greatly increased traffic tonnage through St. Mary's River, due as much to the possibility of operating the existing vessels to greater seasonal capacities as to the addition of new vessels to service.

The Superstructure of the Quebec Bridge.

Unusual interest attaches to the articles now appearing in The Engineering Record describing fully the principal details of the Quebec 1,800 ft. cantilever. A detailed account of the structural work of a large steel bridge, or other similar work, is not at the present time, generally speaking, a matter to which it is worth while to call special attention, but the Quebec cantilever is the longest span steel bridge of any type yet constructed, and the arrangements of its details are necessarily unusual in order to meet the extraordinary stress conditions existing in such a great structure. It is sufficiently remarkable to have the main column between the anchor and cantilever arms 315 ft. long, but when it is borne in mind that such a member may have to carry a total load of 10,000,000 lb. or more, chiefly conveyed to it by pins at its upper end, it is easy to realize that provision must be made for extraordinary conditions.

Before giving attention particularly to the main details of this structure, it is worth while to consider some of the principle features of its design. It is now well established that it is in general economical to make the length of the suspended span about one half of the main cantilever opening. In long spans, however, conditions resulting from the erection of a long cantilever arm may render it judicious to decrease the length of the suspended span, and in the present instance it was made three-eighths instead of one-half of the 1,800 ft. opening. It is probable that there would be economy of material with the greater length, but the difficulties of design and manufacture in making provision for the correspondingly increased erection stresses might easily balance or overbalance any small saving of material.

It is interesting to observe that the width of the structure between centers of trusses, 67 ft., is practically one twenty-seventh of the main cantilever span. This width of structure insures a lateral stiffness essentially equivalent to that of a simply supported truss span of the same length and loading, whose transverse width between centers of trusses is one-eighthteenth of the span length. This measure of lateral stability for a cantilever span was first established in connection with the design of the Red Rock cantilever, a structure also built by the Phœnix Bridge Co.

The system of web bracing for this great cantilever structure, 315 ft. deep over the main piers, is a single system with subdivided main panels making the subdivided panel length 56.25 ft. The plan of subdivision makes the secondary members compression and is similar to that used in many of the longer spans designed and built by the Phœnix Bridge Co. It secures a most effective web system in which no ambiguity or statical indetermination exists. Only one serious question arises with this arrangement, and that is, why the entire shear of the cantilever and anchor arms is carried to the top of the great center post, instead of transmitting it down to the bottom of the same post by an inclined compression member meeting the top chord two panel lengths from the top of the center post. The comparatively small depth of truss at the extremities of the anchor and cantilever arms gives an economical angle of inclination to the inclined web members of those portions of the trusses, but the angle becomes far less economical as the main center post is approached.

The massive character of the individual members and of their details can scarcely be realized, even with the comprehensive description given in The Engineering Record, except by those familiar with the corresponding members and details of some of the largest ordinary spans yet constructed. It is obvious that a suitable arrangement of the details at the intersection points of the chords and web members, has been reached only after the most careful consideration of all the ends to be obtained in the design. Central intersections in such a great structure are absolutely essential for the elimination of objectionable secondary stresses, and they could only be secured by a massiveness of details which is unprecedented in bridge construction. The system used can be properly called pin-connected and yet so much extraordinarily massive riveted work is found that an advocate of riveted joints could claim that the trusses are built as much on the riveted type as pin-connected, if not more so. As a matter of fact, the plans show the trusses to be an admirable developement of both pin and riveted work to meet the exigencies of this particular structure. They further conclusively demonstrate that the single web system may be successfully applied in a highly satisfactory manner to the longest span of truss work yet contemplated.

The Quebec Bridge, therefore, is a most interesting exhibition of modern structural design of the most advanced type, in its application to a railway bridge structure of a span so great that it was a question whether the stiffened suspension system should not be employed. The degree of excellence to which shop work of this class has been developed is effectively shown by the fact that these great bridge members were never assembled after fabrication in the shop until they were placed in the actual structure with complete accuracy. This is in marked contrast to the system of construction of the Forth Bridge, for which shops were actually equipped and put in com-

mission at the bridge site in order to accomplish the fabrication, as it were, of each member in its actual place in the completed structure.

Notes and Comments.

THE HELL GATE BRIDGE PLANS for the Pennsylvania R. R. structure connecting Long Island and the Borough of the Bronx have been rejected by the Municipal Art Commission of New York. . This structure as planned was illustrated in The Engineering Record of June 1, and in a later issue it was stated that the Art Commission might request a modification of the architectural treatment. In its report the Commission states that it is quite ready to accept the judgment of the designing engineer on all engineering or structural questions, but the attempt to give decoration to the towers and to the bases of the towers is considered unsatisfactory from an artistic point of view. The report reads: "Your committee cannot approve these decorative features as they would have been ready to approve a strictly utilitarian construction, or, better still, a scheme of ornamentation which would seem to them artistic and appropriate. They, therefore, recommend disapproval of the plans without prejudice to their re-submission with a different treatment of the towers and their bases." In this connection it might be added that the "Builder," the leading British architectural journal, has also found fault with the architectural treatment of the structure.

AN ELECTROLYSIS CONTROVERSY of considerable interest recently took place before a committee of the British House of Commons, which was listening to arguments for and against a bill introduced in favor of the North Metropolitan Electric Supply Co. The Metropolitan Water Board insisted that this bill should in no way exempt the company from responsibility for causing injury to underground conduits and other structures by electrolysis. The electric company produced experts who testified that there was absolutely no danger of electrolysis from works such as the company proposed to construct. The committee finally decided that, this being the case, there was no reason why the Metropolitan Water Board should not be protected in the manner it wished and accordingly inserted the clause desired. It is understood that, in spite of the electric company's assertion that it would cause no harm, the presence of this clause is a source of considerable annoyance. It seems unfortunate that British electrical corporations continue to fight attempts to get a better knowledge of electrolysis and the methods of providing a protection against it. In Germany the contrary is the case. There the Association of Gas and Water Engineers, which has been carrying on an investigation of electrolysis for many years, has been joined by the Association of Industrial Electrical Engineers and the Association of Tram and Light Railway Proprietors, in a joint committee to carry on the researches begun by the society first named. There is no attempt made in Germany to ridicule the effects of stray electric currents, but, on the contrary, the companies responsible for these wandering currents acknowledge their obligations and are doing their best to remedy the troubles. Such a course has been followed in a number of American cities, but up to the present time it has not found favor in Great Britain.

THE SMOKELESS COMBUSTION EXPERIMENTS with Illinois coal which Prof. L. P. Breckenridge is conducting at the Engineering Experiment Station of the University of Illinois have attracted so much attention that the following notes concerning them will probably be of interest to many readers. The tests were begun with a Heine water-tube boiler of 210-h.p. having a Green chain grate stoker and induced draft in the furnace. The lower tubes of the boiler have been covered for two-thirds of their length with a special tile, making a roof in the furnace. Over a hundred tests have been made with soft coal, each of 8 to 10 hr. duration. With this setting no smoke has been caused during the operation of the boiler after the fires were once well started. A series of tests is now in progress with two types of heating boilers, using anthracite and bituminous coal, coke and briquettes. In all tests the technologic branch of the United States Geological Survey is co-operating. Prof. Breckenridge is of the impression that the smoke nuisance will be cured mainly by using mechanical stokers suited to the local coals, but the stoker must be combined with the proper furnace details to fit the coal used. Uniformity in the size of coal will be of material help. Where hand firing is adopted, careful firing, which is unusual, will cut down the smoke at least one-half. Details of the experiments and a complete description of several boiler settings which have operated without smoke for more than two years will be printed in a bulletin of the Engineering Experiment Station to appear arly this Fall.

PUBLIC IMPROVEMENTS in the Boston Metropolitan District are to be investigated by a commission consisting of three members appointed by the governor and two by the mayor, these men to be "skilled in finance, commerce, industry, transportation, real estate matters, architecture, engineering, civic administration and law," according to the law authorizing the appointment of the commission. The commission is authorized to investigate the advisability of any works in the district which, in its opinion, will tend to the convenience of the people, the development of local business, the beautifying of the district, or its improvement as a place of residence. It may also consider the establishment of intercommunicating highways between the cities and towns of the district, the control of traffic, the location of docks and terminals and other matters of this nature. The members of the commission, among whom Mr. Desmond Fitzgerald is included, serve without pay, but the commission may spend any sum up to $25,000 for clerical and other services. It will be noticed that the commission is essentially one of investigation, its powers in this direction being limitless, whereas it has no authority to execute anything. The appointment of the commission is particularly interesting in view of the somewhat similar action recently taken by the Local Government Board of Great Britain, and the appointment of a committee by the Royal Institute of British Architects to report on the æsthetic development of suburban tracts. It is becoming evident in all large cities that the time has been reached when a careful planning of the development of all outlying districts is important, not only from an engineering point of view, but also for the best commercial and artistic growth of the suburbs. This is a matter to which Mr. Nelson P. Lewis, chief engineer of the Board of Estimate and Apportionment of New York City, has several times called attention in his official reports.

INJURIES TO WORKMEN engaged in rock excavation by the explosion of charges which have not been fired properly, occur so often that it is rather surprising contractors do not instruct their foremen to use the utmost care to prevent such accidents. The law governing these occurrences in most States was stated lately by the Minnesota Supreme Court in the case of Carlson v. James Forrestal Co., 112 N. W. Rep., 626. In this case the general foreman in charge of the work of excavation for the foundations of a building directed a blasting crew to go to another part of the foundation. He directed a certain workman, the plaintiff in the case, to clear the ice and snow out of a hole which had been drilled in the rock by other men, and this workman was injured by the explosion of a charge of dynamite left there unexploded when a group of holes had been fired electrically. In this case the company itself was not considered negligent in its manner of conducting the blasting, or in allowing the work to get into the condition which existed. Nevertheless, as a matter of law, the general foreman was a vice-principal, charged with an absolute duty to exercise proper care to provide a reasonably safe place for the men to work. The jury found that the foreman did not exercise such care in making a reasonable examination to ascertain if all of the charges had been exploded, and the accident was the proximate result of this negligence. Under such circumstances, the court rules, the defendant was responsible for the injury to the workmen, and it affirmed the verdict of $8,000 which he received in the trial court. This is practically the decision rendered in so many States that it may be accepted as practically universal throughout the country, and indicates that some general rules might very properly be drawn up for the guidance of foremen in charge of blasting operations and cleaning up after explosions.

THE DRAINAGE WORKS of New Orleans from time to time arouse more or less criticism from residents of that city, which seems to be based on the supposition that a drainage system can accomplish the impossible. Few cities are situated like New Orleans. The surface water which has to be handled there accumulates during and after heavy rainfalls in very large amounts, unless means exist for conveying it away rapidly. The drainage system has been constructed for the latter purpose, and where it operates under the conditions which were assumed to govern the work when the plans were prepared, it gives complete satisfaction. It goes without saying, however, that if the inlets to the drainage canals are allowed to become clogged with trash and refuse, the water which accumulates in the gutters cannot enter the inlets at the proper rate, and consequently must flow over the surface of the street until some better escape for it is found. This occurs from time to time in the city and gives rise to complaints that the drainage works are inadequate for their purpose. The contrary is really the case, for the trouble is due to failure to keep the streets and gutters clean. This is no fault of the Street Cleaning Department, for it has less than $200,000 to spend annually for the purpose, which is less than a quarter of the sum really needed for the removal of dirt and rubbish in a fairly satisfactory manner, particularly in view of the fact that in some parts of New Orleans it has long been customary to throw refuse directly into the streets. Complaint has occasionally been made, also, that the drainage works were not of the highest type, and that some of the open canals should be lined and roofed. Lining and covering are certainly desirable improvements, but in view of the financial condition of the city it was unquestionably good public policy to carry out the construction in the manner that has been pursued. There has been trouble in some parts of the city due to flooding of streets, but relief from this situation will come much more quickly if the people will keep trash out of the streets and avoid such public criticisms of the Sewerage and Water Board as tend to increase the difficulty of selling bonds for continuing the improvements.

THE KERN RIVER NO. 1 POWER PLANT OF THE EDISON ELECTRIC CO., LOS ANGELES; PART I.

By C. W. Whitney.

The Pacific Coast, California in particular, has won a goodly amount of renown in engineering circles because of its many note-worthy hydro-electric power plants and its long-distance transmission systems. Going back 14 years to the noted historical work at Redlands and Pomona, practically all the improvements in hydraulic design in connection with high-head plants that have stood the test of time and which mark the best practice of to-day have been evolved in connection with the California water power plants. Substantially the same may be said regarding transmission work; and, although the record for highest voltage has been surpassed quite recently in Michigan, the Golden State still operates successfully the longest lines on the continent.

With this excellent record of pioneer work, and with many modern efficient plants now in continuous operation, it is interesting to note the improvements or innovations incorporated in the design of any new plant. The Edison Electric Co., of Los Angeles, has just completed and placed in operation a station on Kern River, which, while not surpassing any previous records of high head utilized or length of transmission, does employ in its construction many distinguishing features, some of which are distinct departures from previous practice.

In capacity, the Kern River No. 1 power plant equals the rated capacity, 20,000 kw., of the largest impulse wheel plant previously in operation and in overload capacity surpasses it. Its gravity conduit, constructed almost entirely of tunnels excavated through the mountains, is the most permanent and costly hydraulic waterway in the country. The pressure main driven in the form of a tunnel down the mountain slope is probably the most unique feature of the installation and is a decided innovation in power plant construction. The water wheels embody new features in the design of buckets, nozzles and governors. In the electrical details of the station is incorporated the most modern apparatus. The transmission line is at present operated at 60,000 volts and will be raised later to 75,000. The length of transmission, 117 miles, is exceeded in but few instances and the steel towers and insulators are of special design.

Considered in its entirety, or as to its several conspicuous component parts individually, the Kern River No. 1 station typifies the latest modern practice in hydro-electric power plant design and makes timely the following descriptive data. A general description of the plant while it was under construction was given in The Engineering Record of March 18, 1905, and in the issues of February 25 and March 11 of the same year the other plants of this company were discussed.

General Description.—The Kern River is the southernmost large tributary of the San Joaquin River and has its head in the snow-covered slopes of Mt. Whitney, and neighboring peaks of the Sierra Nevada Mts. Water for the plant is diverted at a point ½ mile below Democrat Springs in Kern County and about 14 miles up the river from the mouth of the canyon. An hydraulic conduit consisting almost entirely of a series of tunnels approximately 9 miles in length conveys the water through the mountains on the south side of the river to a forebay at a point about 900 ft. above the river and about 2 miles from the mouth of the canyon where the plant of the Power, Transit and Light Co., of Bakersfield, is located. From the forebay the force main is carried down to the power house in an inclined tunnel.

The power house is located on the bank of the river directly opposite the intake for the Bakersfield plant, and at an elevation of about 20 ft. above the ordinary high water level of the stream at that point. The tail race of the station is designed to deliver the water to the river immediately above the diversion point of the Bakersfield plant. The transmission line is carried down the Kern Canyon and across country to Los Angeles, 117 miles distant.

Diverting Dam.—The dam which is built to divert the water from the Kern River into the hydraulic conduits is placed on bed rock and is carried up to a point 1.25 ft. above the flow line in the tunnel conduit, thus insuring a constant supply as long as the reservoir created by the dam is kept filled. In excavating for the dam, bed rock was found to exist at varying depths, the deepest portions being at the south end at about 35 ft. below the stream bed. A cofferdam was built to divert the river during the construction and while the fill overlying the bed rock was excavated. Trenches were then cut in the bed rock and holes bored in which steel bars were driven in two rows across the canyon. The first layers of concrete were placed on the bed rock and secured to it by means of the trenches and the steel bars. Cyclopean concrete was the material of construction, the rock used being the granite found in the canyon. Many of the rocks were of large size, some weighing several tons each. About 1,500 cu. yds. of material was placed in the foundation, and 3,500 cu. yds. in the dam proper.

The form of the dam is the overflow type as shown in the accompanying illustration. Its length on the crest is 203.56 ft. and its height above ordinary water level in the river about 20 ft. At the base in the widest part it is 52.81 ft. wide. The crest has a small angle with the horizontal and is 7 ft. in width. The crest and lower face were designed so as to give a true hydraulic curve to the water overflowing and to attain this end the top 15 ft. of the face was built with a batter of 1 to 1 so as to allow an air space under the water. The theory of the design is that air will enter this space under the water from the ends of the dam and that enough will be carried down with the water to form an air cushion. With 2 or 3 ft. of water flowing over the dam a very smooth surface is presented. Below the 45 deg. batter the down-stream face has a radius of 100 ft. The up-stream face has a batter of ¾ of an inch to a foot.

Headworks.—The head or diversion works of the gravity conduit consist of an enlarged or widened section of the intake tunnel with controlling gates operated by means of hydraulic cylinders. In order to prevent contraction as the water enters and to afford sufficient screen area to admit the water, the tunnel is widened out at the entrance to 16 ft. 6 in. The screens or grizzlies are made of slanting bars and extend both in front and on the side of the controlling gate. The bars are ½x3 in. and are spaced on edge 3 in. between centers by means of 2¼-in. thimbles, the thimble rods being 4 ft. apart. The screen is 20 ft. long on the slant and 8 ft. high and is supported on 4-in. cast iron pillars. Behind the screen and just above the gate is a 10-ft. platform on to which can be raked any detritus caught by the screen. The grade at the entrance of the tunnel is increased above the normal so as to excellerate the water from its state of rest above the intake to normal velocity in the tunnel below.

Another important feature of the head works is the drainage or sluicing tunnel, 365 ft. in length, that is driven through bed rock below the intake at the south end of the dam, penetrating to the bottom of the reservoir above the diverting dam. A heavy grizzly built of 70-lb. T-rails protects the entrance of this tunnel and behind are two gates operated by hydraulic cylinders, by means of which the tunnel can be closed or opened as desired. The drainage tunnel was first used to divert the water from above the site of the dam during its construction to the river at a point some distance below the headworks. Its permanent purpose will be to sluice out at such intervals as may be necessary, any accumulation of silt collecting in the reservoir above the dam. The gates of this drainage tunnel are constructed for operation under pressure varying from 35 to 45 ft., depending on the quantity of water flowing over the dam, the hydraulic cylinders for the gate being designed to move them under a head of 20 ft. of water over the dam, should a flood of this magnitude ever occur.

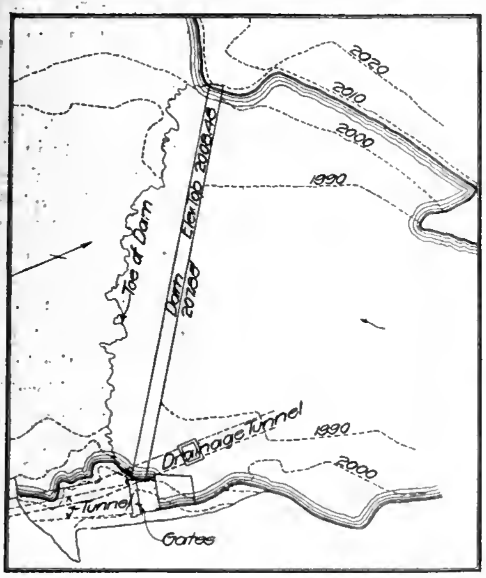
Kern River No. 1 Power Plant.

Each of the gate openings is 8 ft. 10¼ in. high and 3 ft. 8 in. wide, the side frames being of cast-iron and the sill a 10x10¾-in. redwood timber. The gates are built up of 5/16-in. steel plates and 6-in. 15-lb. I-beams, the sides being formed of 12-in. I-beams. There are two cast-iron hydraulic cylinders installed for each gate. The set for the east gate is mounted on top of the concrete operating shaft, the west set being placed directly below as there was not sufficient lateral space to place them both on the same level. The lower cylinders are placed 38 ft. 8 in. above the cylinder gate and operate the latter by lifting rods 26 ft. long. The upper cylinders operate their gate by means of 40-ft. rods. These lifting rods

are 4½ in. in diameter and are made of wrought iron encased in brass tubing to prevent rusting. The gates are guided at each side by 4 bronze rollers 3 in. in diameter. In order to equalize the pull of the two cylinders on each gate there are installed two racks 10 ft. long and 6 in. wide into which mesh two 12-in. pinions mounted on the top of the gate.

The gates for the intake tunnel are similarly constructed. The hydraulic cylinders both for the intake gate and the sluice gates in the drainage tunnel are operated by means of oil pressure supplied by gravity from a tank on the bank. The oil discharged from the cylinders is pumped up to this tank by a triplex pump, electrically driven, a sufficiently powerful hand-pump being installed for emergency use.

Tunnels.—The hydraulic conduit of the plant is noteworthy by reason of its being the most permanent construction of its character in the country. The Edison Electric Co., after its 14 years practical experience with the construction and operation of hydraulic electric power plants, has profited by the knowledge gained of the different forms of conduit used, such as timber flumes, earthen ditches, concrete-lined ditches, cement pipe and tunnels, and for its Kern River work determined that the most efficient and in the long run economical construction would be a system of concrete-lined tunnels. The expense of driving the



Dam and Tunnel Intake.

tunnels was a large item, but it is warranted in this instance because of the large quantity of water handled and by reason of its permanency and the fact that it will be subject to practically no depreciation losses and but little expense from maintenance. Another important feature of the tunnel construction is that there will be practically no evaporation loss from the conduit. As the evaporation from the natural stream is estimated to be from 15 to 20 per cent. in the summer months, this factor will be an important one during periods of minimum flow. Another advantage of the closed conduit is that no leaves, sticks or other debris can enter the water after it leaves the headworks.

Between the intake and the forebay there are 19 tunnels forming approximately eight units of gravity conduit. The tunnels vary in length from 496.3 to 4,373.7 ft., five of them being over 3,000 ft. long, five between 2,000 and 3,000 ft., and four between 1,000 and 2,000 ft. Their combined length is 42,910.5 ft. They are numbered from the intake down, tunnel No. 1 being the intake tunnel, the entrance to which has already been described.

The tunnels were excavated in the rough to be 9 ft. in width and 7½ ft. from the bottom to the springing line of the arch, and 9 ft. in height in the center. Afterwards they were lined with concrete 6 to 10 in. thick on each side and the floor paved with 3 in. of concrete, the net section thus obtained being 8 ft. in width and 7 ft. in height. The entire surface of the side and the floor were covered with a cement mortar plaster ¼ in. thick, composed of 1 part of cement to 2 parts of sand. At the corners of the walls and floor a curve with a 3-in. radius was formed in order to prevent wear at that point and also to smooth up the flow of water.

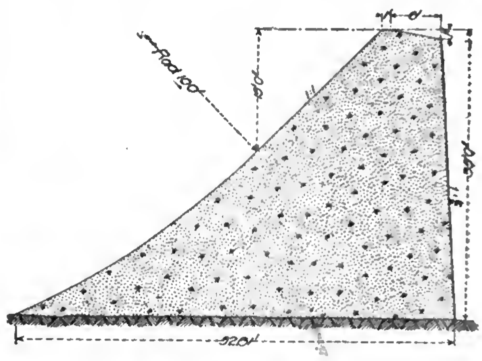
The section of tunnel adopted is not the most favorable to give the highest velocity on a minimum slope, but it is the most advantageous for the purpose, as by making a wider tunnel greater difficulties would have been encountered with the roof of the tunnel where it passed through a loose or shattered formation. The grade of the tunnel is 7.92 ft. per mile, it being intended that the water should be carried at a depth of 6½ ft. The cross sectional area of the stream is therefore 52 sq. ft., the wetted perimeter 21 ft. and the mean hydraulic radius 2.5.

Waste Flume from Forebay.

Assuming the coefficient of roughness to be 0.012 in Kutter's formula, the conduit has a discharge capacity of approximately 470 cu. ft. per second. Judging by experiments made on other tunnels constructed for the Edison Electric Co., and elsewhere, it is likely that the coefficient will not be far from 0.012 for this size of conduit. As is well known, the coefficient of roughness in the Kutter formula should vary somewhat with the mean hydraulic radius and from previous experiments for a hydraulic radius of 2½ and cement plaster as above stated, it will be about 0.012. Observations made during the first day the water was turned into the conduit would indicate that the coefficient would be even less than that value. In places where the tunnels pass through seams and shattered formations or "blocky" ground, they had to be arched overhead in order to support the roof, the concrete at the center of the arch being 12 to 18 in. thick. Less than 15 per cent. of the length of the tunnel required such overhead arching. Where this was necessary it was placed by using a template, with lagging overhead, the concrete being thrown back and tamped into place above the lagging. In excavating through this blocky ground timbering was necessary, the standard bent being formed of 6x8-in. sets spaced 4 ft. centers and holding the rock back by 3-in. plank. In such sections the timber was left in position and completely covered by concrete. The concrete at the sides was tamped into place behind boards supported by vertical forms. Wherever large cavities had been blasted out in driving the tunnels, these were built with rip-rap, the interstices of which were filled with sand and gravel. The same method was pursued above the concrete in the arches. Consequently there are no cavities existing between the bed rock and the concrete lining in the tunnels.

In several places springs were encountered and as the pressure that would be created by stopping them up might be disastrous to the tunnel lining, vents were installed through which the water can flow into the tunnel. These vents consist of sections of pipe from ¾ to 3 in. in diameter and 6 to 8 in. long, set in the floor or wall and left open at both ends. The spring water being under higher pressure than that flowing in the tunnel, continues to flow into the tunnel and thus relieve it of any strain.

The excavation of each of the 19 tunnels was carried on from both ends, thus dividing the work up among 38 headings. The work was principally done by pneumatic drills with 3¼-in. cylinders. Some hand work was done in opening up approaches and adits and where loose formation was encountered. The ardinary progress in driving with pneumatic drills was 5 ft. for a 10-hr. shift, using 2 machines in the face. This varied considerably, however, as the number of holes required for breaking the ground varied from 10 to 24. The depth of the holes usually employed was as follows: cut-ins, 8 to 9 ft.; lifters, 6 to 7 ft.; breast holes 6 to 7 ft.; back holes, 5 to 6 ft. The amount of powder consumed also varied according to the formation, so that no stated quantity per round of holes can be relied upon.



Diversion Dam.

In the toughest rock encountered it was sometimes found necessary to reload the holes the second time in order to break the ground, the first blast blowing out the rock only at the upper end of the hole.

The pneumatic drills were supplied with compressed air by means of 3 and 4-in. steel casings laid from the six construction camps located at suitable points along the canyon between the power house and the intake. Ventilation was provided by means of motor-driven Root reversible blowers located at the tunnel or adit openings and connected with the working faces by means of galvanized iron stove pipe. The company carried on all the tunneled excavation work itself, the only contract work being that for teaming, the supply of provisions, and feeding the men. By this method the company has been able to secure construction data which will be invaluable to it in carrying on similar work in the future and in the consideration of contract work. The only contract work done on the tunnels was the concrete lining. This was done by Glass & Fischer, of Los Angeles and Redlands, this firm also contracting for the boarding houses.

Standard and Colton brands of Portland cement, supplied by the two California mills, were used throughout for the concrete, the mixture

being in the proportion of 1:3:5. For the sand and aggregate the granite excavated from the tunnels was used. The rock was crushed to 1½ and 2 in. size, and for the sand it was crushed and rolled so as to pass through a 60 screen. Gates gyratory and Blake jaw crushers and Buchanan 10-in. rolls were employed. As no adequate water supplies were available along the route of the conduit, the water necessary for mixing the concrete had to be pumped up from the river, Rumsey duplex pumps being employed for that purpose. For mixing one Smith and two Ransome mixers were used. The men were worked on two 9-hr. shifts, illumination being furnished by a construction power plant to be mentioned later. A total of 110,000 ft. of lumber was used in the forms for the concrete work.

After the tracks had been removed from the lower tunnels and when the roads from the upper camps were impassable because of heavy rains and snow, two automobile wagons were purchased and proved indispensable in carrying cement and other supplies through the finished tunnels from camp 1 to the upper tunnel. These machines were of the Lambert friction drive type and were equipped with 20-h. p. gasoline motors. The wheels were fitted with heavy hard rubber tires. About 7,000 bags of cement were thus transferred from camp 1, an average distance of 5½ miles. In all about 1,000,000 lbs. of freight was carried by the two machines. Even the steel rails for the construction track were carried out in the automobiles. With light loads a speed of about 18 miles an hour could be made, precautions being taken at curves which were indicated by white signal flags.

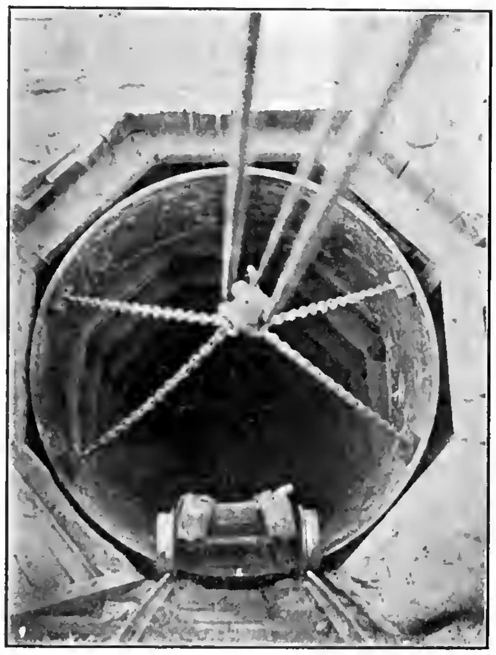
After the tunnels were completed 2-wheeled hand-carts with rubber tired wheels were used for carrying cement and light tools for such finishing and repair work as was necessary. They were also brought into service in stringing the telephone line that is carried throughout the entire tunnel, connecting the power house with the diversion works at the dam. The two galvanized iron wires of this telephone line are carried on inverted T-shaped brackets about 10 in. from the roof of the tunnel. The brackets are formed of ¾-in. pipe with porcelain insulators bolted on each end of the horizontal arm. The vertical pipe is secured in the holes of the rock or cement by wooden plugs.

Timber Flumes.—The tunnel work was planned so as to avoid wherever possible flumes for spanning the side ravines encountered along the line. However, in order to maintain a good alignment and make the line as short as possible, a few exceptions had to be made to this rule. Some of these ravines leading down to the main canyon and crossing the line of the conduit were on such a flat slope that should the tunnel be constructed under the ravine the necessary adits would have been very long. This not only would have increased the cost materially, but also would have added to the length of the line, and the time required to do the work. At such points where there was no danger from falling rocks the ravines were spanned with flumes. There are six of these flumes, the longest being 1,029.6 ft. long and the others vary in length from 49.9 to 167½ ft. All except No. 3, which is built of reinforced concrete with a steel frame, are constructed of timber. They are placed on concrete foundations and are designed with a factor of safety sufficient to make their life from 30 to 40 years. The framework for supporting the flume box is of Oregon pine, being so designed and distributed that no part of the timber comes in contact with the earth or is exposed to the drip should the flume at any point spring a leak. In this way the life of the Oregon pine will be great, as it is invariably kept dry and free from contact with the soil.

The flume box is built up of 3x12-in. redwood planks obtained from butt ends of Sequoia Semper Virens, grown in swamp lands west of the Coast Range in northern California. The grade of this lumber is perfectly clear, and its quality is such that its life should not be less than 40 years. The edges of all planks were bevelled so as to give a ¼-in. opening on the inside of the joints which is caulked with ship chandler's oakum. The bottom seams were covered with hot asphaltum and 1x6-in. redwood battens nailed down over them. On the sides of these flumes a specially designed batten is used. This batten is of 1x6-in. redwood, the upper half being cut away on a curve, permitting asphaltum to be poured between the batten and the side of the flume. At the corners of the flumes a quarter round strip is nailed.

The design of the flume above described has been thoroughly tested and even if it should stand dry for months in the hottest weather, the designers state that it may be again filled with water without having any perceptible leakage.

In some of the flumes where streams are crossed that are apt to carry considerable water in winter, span flumes are constructed. One of



Lowering 90-Inch Pipe Down Shaft.

these span flumes has a length of 32 ft., built with a 10x12-in. timber frame and resting on 12x12-in. beams. In connecting the wooden flume with the portal of a tunnel, a construction of a special nature was used, which offers two points of contact between the wood and the concrete and a well between the two, from which the water may be pumped out and any leaks repaired should these ever occur between the wood and the concrete.

Steel Concrete Flume.—The flume between tunnels 6 and 7 across Laird Canyon, is constructed of structural steel and concrete. The whole structure is carried on 15-in. steel I-beams set 8 ft. 10 in. apart and supported by concrete piers. These longitudinal girders carry 9-in. steel I-beams laid transversely 4 ft. center to center and on them is erected a framework of structural steel for the sides and bottom of the flume. Two layers of expanded metal of 1½ and 3-in. mesh are used in connection with this framework, and being filled with concrete form the plates enclosing the frame. This concrete construction is also reinforced on the floor by twisted ½-in. rods. The outside and inside of the flumes were then plastered, making the thickness of the reinforced concrete sides and bottom 4 in.

This type of flume or conduit had never been tried before, but in this case has proven a decided success and while it costs more than a wooden flume it has the advantage of being as permanent as the tunnels themselves.

Concrete Conduits.—In the lengths of tunnels and flumes forming the gravity conduit enumerated above no account is taken of the concrete conduits which connect some of the tunnels with the flumes. There were places along the line where the tunnel emerged at the foot of a steep incline in such a manner that the flume if constructed on the grade would be threatened by land-slides or boulders rolling down the side of the mountain. These places were spanned by means of concrete conduits, the interior of which have the same cross-section and slope as the tunnels themselves. The walls are made heavy and reinforced with steel and an arch overhead, the arch being covered with a cushion of earthen material to receive the impact of anything rolling or sliding down the hill and passing over the conduit. There are eight of these conduits having an aggregate length of 503½ ft., and with the exception of a very short one vary in length from 31.6 to 121.6 ft.

Forebay.—A terminal equalizing reservoir of some size at the end of the gravity conduit and feeding the pressure main would have been desirable in connection with the project. However, the slope of Mt. Breckenridge, where the lower end of tunnel 19 emerges above the power house, is approximately on a 45-deg. angle, making it impossible to excavate any large area for a tunnel reservoir or forebay. It was necessary, however, to have a small basin for regulating the flow in the force main and for this purpose a chamber 30x42 ft. was excavated to a depth of about 8 ft. below the grade of the supply tunnel. Inside of this and over the mouth of the force main were erected controlling gates and screens through which the water passes into the force main. The walls of the forebay were made of concrete in the form of retaining walls where they were enclosed in the excavation and on the lower side where they were unsupported were made sufficiently heavy to withstand the pressure of the water on the inside. As the formation where the construction is located is somewhat shattered the concrete work was heavily reinforced and the floor paved with 3 ft. of concrete. At the back these walls were extended up to a considerable height to prevent material caving from the mountain above from dropping into the forebay.

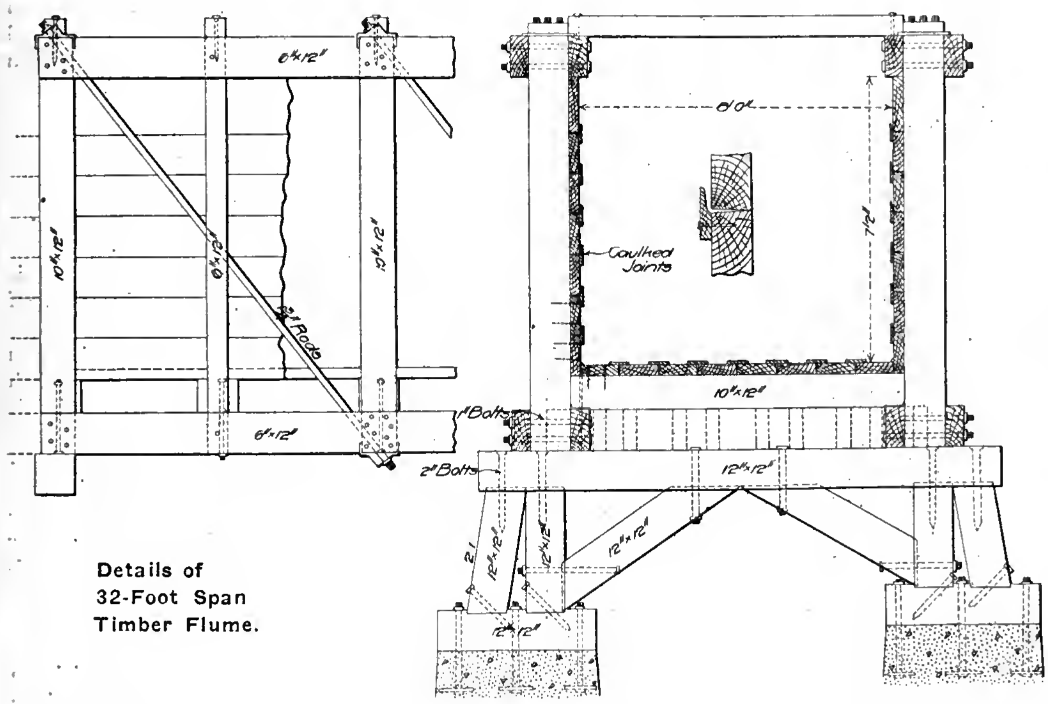
On one side is a spill-way 9 ft. above the floor of the forebay, and consisting of five 6-ft. 10-in. openings over which the water flows into the waste flume when it is desired to divert part or all the tunnel flow from the pressure main. The height of this spill-way can be controlled by means of flash boards which may be inserted and removed as required, according to the quantity of water carried through the tunnels. The extreme height of the spill-way is 3 ft. A 24-in. gate valve is set at each end of the spill-way for sluicing into the waste flume.

The force main starts from the bottom of the forebay, thus making it possible to have the water enter it from opposite directions. This construction tends to prevent the formation of eddies or a whirl-pool at the entrance.

The controlling gates have an opening of 6 ft. 2 in. high and 10 ft. wide and are built up of 4x12-in. timbers on two vertical 6-in. steel I-beams. They are raised by means of hand-operating gearing through four sets of gears working in two racks, 7 in. wide with 3-in. pitch, mounted on the front of each gate. Behind the gate and inclined upward toward each other are two heavy grizzles. These are formed of 3½x½-in. iron straps, spaced 3 in. on centers by thimbles of 2½-in. wrought iron pipe, the rows of thimbles being set 1 ft. apart. Each screen is 11 ft. 6 in. long and is set on an angle with its top supported by a 4-in. steel I-beam. These two beams are 3½ ft. apart, the space between forming a walk.

Waste Flume.—The forebay is constructed so that when the water is diverted from the force main it passes over the spill-way automatically into the waste conduit extending down the moun-

tain side to the river. This conduit is of concrete at the upper end where it is on a comparatively flat grade, the section being 8 ft. wide and 8 ft. 6 in. high. The water is discharged into a redwood flume 20 ft. wide that carries it down the steep slope of the hill. As the slope is about 45 deg., only soft wood, it was believed, would stand the wear due to the high velocity. The spill-way flume is 1,200 ft. long and discharges into the Kern River about 600 ft. above the power station. It rests on 4x6-in. stringers bolted to 3x3x3/8-in. anchor plates embedded in concrete footings. These footings are spaced 8 ft. apart and are securely set, although they are not carried down to bed rock in all cases. The cross-beams of the flume are 4x6-in. timbers 26 ft. 6 in. long. The side posts are 4 in. square and are carried up 3 ft. 3 in., being secured at the bottom by angle plates. They are set 4 ft. center to center and are angle braced by 4x4's, bolted at both ends by 1/2-in. bolts. For lining the flume 2x12-in. redwood planks were used, the joints in the floor being calked and covered by 1x6-in. battens. Quarter rounds were nailed in the corners as in the other flumes. The side lining, which is carried up 3 ft. high, is battened and caulked in the same manner as already described for the smaller flumes.



Details of 32-Foot Span Timber Flume.

Pressure Mains.—The greatest innovation in the entire plant is the pressure main, the construction of which has been along new lines and in decided contradistinction to the customary practice of laying a steel pipe on the surface of the mountain slope or merely burying it sufficiently to cover it for protection against freezing or expansion and contraction such as might be caused by a wide range of temperature changes. The pressure main constructed on Kern River consists of a tunnel approximately 1,700 ft. long driven through the mountains on an incline and lined with steel varying in thickness from 3/16 to 1½ in. This tunnel begins at the bottom of the forebay and is carried down at an angle of approximately 45 deg. and turning into the horizontal section emerges at the lower end on a level with the floor of the power station. There are 3 vertical curves in the tunnel. The upper one forms an angle of 7 deg., 260 ft. from the forebay floor and turns the pipe from a grade of 130.32 per cent. to a grade of 101.35 per cent. The second curve 32.5 ft. lower down has an angle of 5 deg. and turns the pipe into a grade of 84.93 per cent. on which it is carried 994.24 to the last vertical curve. The latter has an angle of 40 deg., and from its lower end the pipe is carried along horizontally to the power house, the total length of the main being 1,697 ft.

The pressure main is finished to give it an inside diameter of 7 ft. 6 in. At the top a taper 20 ft. long and 10 ft. in diameter at the forebay entrance terminates in the regular 7½ ft. diameter of the completed tunnel tube. This diameter of 7½ ft. is maintained throughout the inclined tunnel and on the horizontal beyond vertical curve No. 3 for a distance of 167.39 ft. At this point 1,454.44 ft. from the forebay, the force main emerges from the solid rock and is carried to the portal a distance of 243 ft. through a detrital deposit lying between the mountain and the power house site. Where the tunnel emerges from the solid rock a 20-ft. taper was installed, reducing the diameter of the main from 7½ to 5¼ ft., at which diameter the pipe is carried to the branch piping at the power house.

The inclined part of the pressure main and the portion of the horizontal section that is carried through solid rock were finished by installing a steel lining built up of plates 3/16-in. thick for the incline and 3/8 in. thick for the horizontal, riveted together to form a cylindrical pipe 7½ ft. in internal diameter. The tunnel itself was driven in approximately circular form and 9 ft. in diameter. The steel pipe was centered in the tunnel, being installed in 10-ft. sections and the space between the outside of the steel lining and the bed rock was thoroughly filled with a mixture of 1:3:3 concrete. The work of installing this lining was begun at the lower end in the horizontal section where the pipe is tapered down to a diameter of 5¼ ft. At this point the 20-ft. taper already mentioned was placed. It consisted of 1 3/8-in. steel plates riveted together with butt straps. The taper was placed back in the solid rock and around it was constructed a heavy bulk-head of concrete which was anchored into the bed rock by means of steel rods driven into the sides.

From this point the installation of the light steel lining with concrete back-fill as already stated progressed from the bottom to the top of the tunnel terminating at the reinforced concrete taper that connects with the floor of the forebay. The rock formation through which the force main tunnel was driven is not of the best kind, being very much fractured and broken. It was necessary to timber the greater part of the shaft or incline when it was excavated, and these timbers had to be removed before the steel lining was installed. The timbers were removed ahead of the steel work, the bed cleaned off and the concrete tamped into place without difficulty. At a point about 120 ft. below the top, the men in charge removed some timbers without bracing the bents above. This precipitated a cave-in of the shaft and several men lost their lives, one man being imprisoned for two weeks, after which time he was rescued in good condition. In retimbering the caved portion octagon steel sets of 7-in. 15-lb. I-beams were used, these sets being left in place when the concrete was filled in behind the steel lining.

The lower end of the pressure main, below the taper reducing the diameter to 5¼ ft., was made of 1 3/8-in. steel plates sufficiently heavy to withstand the static pressure without any external support. No concrete was placed around this pipe, and the tunnel was merely left in its original condition with the timber set to support the ground overhead.

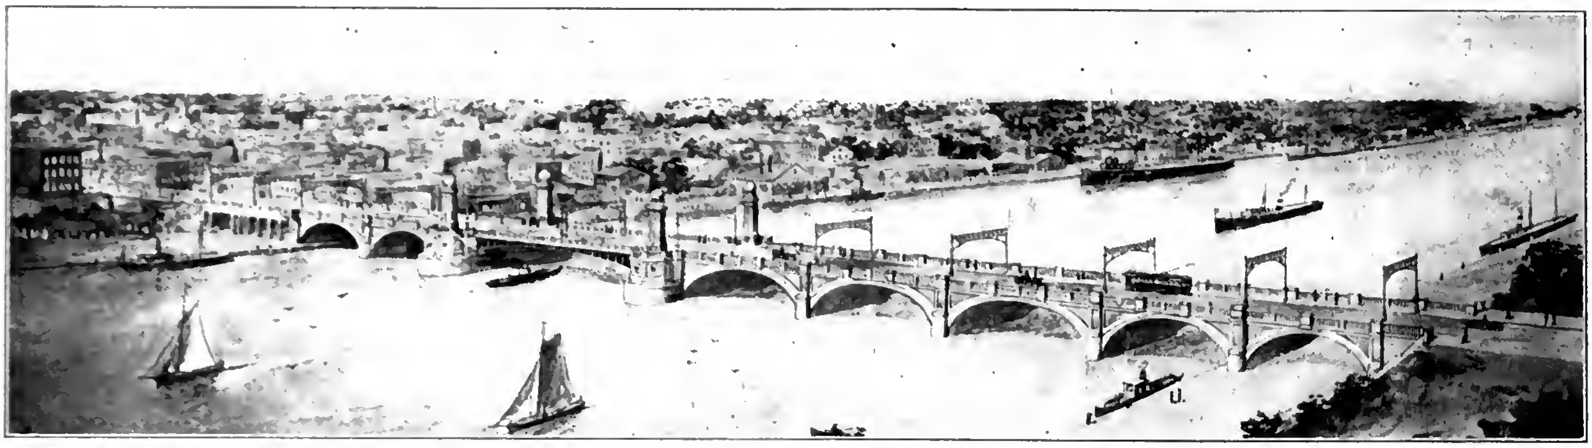
At a point 215 ft. above the power house, a man-hole was placed in the inclined tunnel for convenience in inspecting and for use in case any repair work was necessary. The regular 3/16-in. steel lining was replaced at this point by a section of 1½ in. pipe 30 ft. long.

The steel pipe was shipped to Camp No. 1 at the power house from San Francisco in 5-ft. lengths, 5 sections being nested together for shipment. The outside section was riveted complete on its two longitudinal seams but the 4 inner sections were riveted on one seam only, so as to allow for the nesting. At the camp the pipe was riveted into 10-ft. lengths and hoisted by means of an aerial tram to the forebay site at the upper end of the pressure tunnel. There the sections were secured to a dolly car and lowered by means of a hoist to the point where they were riveted together. This car consisted of a truck at each end of the pipe sections, the latter being hung from two timbers that passed through the pipe and rested on the axles of the truck, as shown in one of the illustrations.

All the piping in the pressure tunnels which is constructed of steel plates of ½-in. thickness and under is made up with standard lap joints, double riveted on the longitudinal seams and single riveted on round seams. All pipe on the work over ½ in. in thickness is made up of butt-strapped joints throughout with triple riveting on each side of the longitudinal seams and double riveting on each side of the round seams.

After the steel lining was completed an inspection of it revealed the fact that there were several places along the bottom of the pipe where voids had been formed in the concrete backing. These voids which were revealed by tapping were caused mainly by the difficulty experienced in tamping the concrete thoroughly around the steel lining. These steel sections were 10 ft. in length and in a few places where large irregular rock excavation occurred at the bottom of a section with but a 9-in. space at the top for handling the tamping bars, some voids were naturally formed because of the insufficient tamping.

Whenever these voids occurred, the pipe was tapped and liquid cement forced until the hole was filled. The apparatus designed on the spot to accomplish this work was an ingenius one. A section of 3-in. steel tube 20 in. long was fitted at the bottom with a cap that would fit the hole drilled in the steel lining. Liquid cement was poured into the void by means of this pipe, which had a capacity of about an ordinary pail. When no more cement would run in there was fitted in the pipe a screw with a plunger at the lower end and a crank at the outer end. By means of this device the cement was forced into the void under pressure until it would hold no more. The pump was then removed and the hole in the lining was stopped up by an ordinary flush pipe plug. There were 116 of these voids tapped and filled through the lining, although but three of them were of any size.



The Proposed Cherry Street Bridge across the Maumee River at Toledo.

A number of the voids required but a pint of the liquid cement, the quantity used varying up to the largest for which ten buckets of the slush was necessary. The slush used was a liquid mixture of Portland cement and sand. The work was carried on from a dolly car fitted with bevelled wheels and lowered down from the top by a steel cable. About 15 days were necessary to complete this special work. After all the voids were filled the entire pipe was painted with asphaltum, the same dolly car being used for the purpose.

Although the design of the pressure main has been criticised by some it is believed that the structure will stand criticism and will prove to be permanent and for that reason economical. The steel lining has a low factor of safety, being only heavy enough to keep its form and resist the internal pressure, while all external pressure is taken up by the concrete back filling, which backed by the rock itself also resists the internal pressures. Being entirely underground and some distance from the surface no trouble will be experienced by reason of expansion and contraction due to temperature changes. The anchorage is a mountain itself so no disastrous effects could result to the pressure main from any water ram that might be caused by improper handling of the water wheels or gate valves.

Branch Piping.—At the lower end of the pressure main was constructed the header pipe made of steel plates, varying in thickness from 1⅜ to ¾ in. at the outer end, and consisting of the following lengths and diameters:

PIPES FOR HEADER.

Length.	Size of Pipe.
33.5 ft.	4¾ ft.
23.0 "	4¼ "
21.0 "	3¾ "
11.5 "	3 "
16.7 "	2⅓ "

These diameters were graduated to maintain as nearly uniform velocity as possible after withdrawing the water for the various branches to supply the water wheel units in the power house. In reducing the force main at the various branch pipes to meet the diameters given, the following taper pipes were employed:

TAPERS FOR HEADER.

Length.					
20 ft.—	Tapering	from	7½	to 5¼	ft.
10 ft.—	"	"	5¼	to 4¾	ft.
10 ft.—	"	"	4¾	to 4¼	ft.
10 ft.—	"	"	4¼	to 3¾	ft.
10 ft.—	"	"	3¾	to 3	ft.
10 ft.—	"	"	3	to 2⅓	ft.

The branches from the force main were taken off by means of a Y on the header pipe and laid out in curved form entering the power house at right angles to the rear well. There is one branch 28 in. inside diameter 50 ft. long, made of ¾ in. plate, for each of the eight water wheels and a 10-in. inside diameter branch pipe for each of the two exciters.

At the end of the last section of the force main is a 28-in. gate valve which discharges into the river. It is proposed to attach to this pipe an experimental nozzle for the purpose of testing nozzle tips, needle valves and similar apparatus and it is expected from such tests data will be obtained regarding the flow of water under varying conditions. In each of the branch pipes leading from the force main to the water wheels are installed two 28-in. gate valves, one outside of the power house and the other inside. The former is intended solely for the purpose of closing off the branch pipe in case of any repairs to the gate or piping. The outside gates are arranged only for hand drive, while those inside of the power house are equipped for operation either by hand or by electric motors as will be mentioned later. The Risdon Iron & Locomotive Works, San Francisco, furnished the steel lining for the pressure main, the branch piping and header, and the gate valves.

(To be Continued.)

The Cherry Street Bridge, Toledo.

The acompanying illustration shows the general appearance of a bridge designed early this year by the Osborn Engineering Company, of Cleveland, for the Cherry Street crossing over the Maumee River at Toledo. The total length of this bridge over all is 1,184 ft., and the width of the river between the established dock line is 900.1 ft. The roadway for which provision has been made is 52 ft. wide and there are two sidewalks of 9 ft. each, making the total width 70 ft. The draw span is of the simple trunnion bascule type, resting on piers 40 ft. wide, and has a clear opening of 200 ft. The masonry arches have various spans, three of them 108 ft., and the others from 66½ to 100 ft.

THE BRUSH CREEK VIADUCT on the Alabama extension of the Illinois Central R. R., is a structure 1,231 ft. long and having a maximum height of 171 ft. 2 in. from the masonry footings to the base of the rail. The total weight of the structure is 1,943 tons. The structure consists of ten 75 ft. deck plate girder spans, nine towers with 40 ft. deck plate girder spans, and two 60 ft. deck plate girder approaches.

The Syracuse Break in the Erie Canal.

An unusual accident happened to the Erie Canal at Syracuse, N. Y., on July 30. The Onondaga Creek flows under the canal at this place through three stone culverts about 175 ft. long. The west and middle culverts have 25 1/3 ft. span, 6 3/4 ft. rise and abutment walls about 6 ft. high. The arch stones are 2 ft. in depth at the crown, increasing to 2½ ft. at the springing lines. The east culvert is about half the size of the others. The arch of the west culvert probably failed first, under the brick wall of a flour mill, which pitched into the canal. The break extended some 50 ft into the canal, and the stone retaining wall along the south side of the canal caved in for a distance of about 100 ft. The bottom of the canal was washed out 10 to 20 ft. deep for a distance of 150 ft. The general appearance of the canal after the accident is shown in the accompanying illustrations.

At the present writing it is impossible to state just what was the cause of the accident, for the wall of the Amos mill, the wreckage of two canal boats and a great mass of debris cover the ruins of the masonry. It is conjectured by some local engineers that water from the tailrace of the Amos mill, which entered the creek in close proximity to the culvert, probably undermined the foundations and was the direct cause of the accident. It is expected that repairs will be completed in the course of a fortnight.

A Rapid Ore Car Unloader has recently been installed on the Duluth ore docks of the Duluth, Missabe & Northern R. R., to replace manual labor in breaking up or dislodging the ore in bottom-dumping ore cars when discharging into storage pockets. A traveling crane spans the unloading tracks above the pockets, the cross traveling trolley of which carries vertically adjustable racks of blades which may be forced down into the load of ore in a car with a pressure of 8 tons. Then by the longitudinal movement of the bridge, the blades may act as a sweep to clear the car of contents from either end to the hopper. All three movements of the crane are electrically operated so that the blades may be rapidly spotted over any car on any of the unloading tracks. These machines operate continuously in all conditions of weather and unload the cars at the rate of one car per minute, each machine replacing a large number of men and enabling the work to be carried on continuously throughout the 24 hr.

Tests of Concrete Columns.

A paper read before the American Society for Testing Materials by Arthur N. Talbot, professor of municipal and sanitary engineering and in charge of theoretical and applied mechanics, University of Illinois.

Before taking up a discussion of the recent experiments, I desire to modify a statement made in a discussion of this subject at a meeting of the Society a year ago, since the form of the printed discussion may be misleading. The remark was made that in the tests of reinforced concrete columns made at the University of Illinois there was indication that the steel buckled before the ultimate strength of the columns was reached. Further study of the tests shows that the steel did not buckle or reach its elastic limit until after the load taken by the concrete had reached its maximum, although in a few instances the load sustained by the column when the rods buckled, was equal to or a little greater than the load when the concrete was seen to be taking its maximum stress. Fig. 1 gives the stress-deformation diagram for one of the columns. The line marked "Line for steel" represents the stress in the steel as though distributed over the full area of the column, based on the observed deformation in the column and a modulus of elasticity of 30,000,000 lb. per square inch for the steel, under the assumption that the concrete and steel act together. The line marked "Line for concrete alone" was found by setting down the line for concrete and steel (*i. e.*, for the column as a whole) an amount equal to that given by the "Line for steel." The line for concrete obtained in this way corresponds closely with the line obtained in tests of plain concrete columns. This diagram gives a convenient method of comparing the stress taken by the steel with that taken by the concrete, if we assume that the stress in the steel is proportional to the shortening of the column. The ratio between the unit stress taken by the steel and that taken by the concrete at any stage of the loading of the column, based on the above assumption, for the column tested, is shown in Fig. 2. The average value for this ratio at the beginning of loading is 13; at three-quarters of the maximum load (corresponding to one-half the ultimate shortening) it becomes 18, and at the maximum load 26. The extreme range of this ratio for the individual columns is considerable. It may be also added that in these tests the strength of unreinforced columns was considerably less than the strength of 12-in. cubes made at the same time. A more complete discussion of these tests may be found in a bulletin of the Engineering Experiment Station of the University of Illinois.

Passing now to the tests which have recently been made at the University of Illinois, it should be stated that only a summary of the results will be given here and that a more thorough study of the tests will be made later. The tests include three classes of columns: (1) plain or unreinforced concrete columns, (2) columns reinforced with circular hoops or bands, and (3) columns reinforced with wire in the form of spirals or helices.

The concrete used, unless otherwise stated, was composed of one part of Portland cement, two parts of sand, and four parts of broken stone, by loose volume. A detailed description of the materials and of the method of mixing will not be given here. The columns were fabricated in galvanized iron forms. The concrete was a wet mixture, wet enough to allow stirring or churning in the forms. The forms remained in place for ten days. The columns were built on cast-iron base plates, and an upper base plate was embedded in plaster of paris on the top of the column a few days before the test. The average age at test was about 60 days. The columns were circular, 12 in. in diameter and 10 ft. long. A few were made 9 in. in diameter. In order not to complicate the analysis of strength, the hoops and spirals were barely covered at the surface of the column, the thickness outside the hooping being generally less than ¼ in. The area of the column was taken to be equal to the area corresponding to the diameter of the hooping. The circular bands used for hoops were 1 in. wide and of three thicknesses, No. 8, No. 12, and No. 16 gauge. The yield-point of this material was about 48,000 lb. per square inch. The hoops were electric welded. Tests of the hoops usually showed failure outside of the weld. In the few cases where failure occurred at the weld the breaking load was beyond the elastic limit of the steel. Generally the hoops were spaced 2 in. apart, center to center, although in some columns the spacing was 3 and 4 in. The spirals were No. 7 wire and ¼-in. wire. Ordinary black wire and high-carbon steel wire of both sizes were used. Considerable difference was found in the elastic limit of the high-carbon material; the smaller size gave about 60,000 lb. per square inch, and the larger size 110,000 lb. for the yield-point. For the black wire the yield-point for the No. 7 was 38,000 lb. and for the ¼-in., 54,000 lb. No longitudinal reinforcement was used. The thin longitudinal spacing bars used to hold the hooping in place were not considered in the calculations. In the statement of amount of reinforcement the percentage is based upon the volume of the hooping and the volume of the concrete core; or what is

the same thing. upon the area of the hooping considered to be uniformly distributed over the length of the column and the area of the concrete core.

The plain concrete columns gave results similar to those tested a year ago, both in the ultimate strength and in the character of the stress-deformation diagram. The strength of the 1:2:4 columns averaged about 1620 lb. per square inch, with a range of variation of 30 per cent. on either side of this. The stress-deformation diagrams approximate a parabola, but the total shortening at failure was somewhat less than that given in the 1906 tests. Fig. 3 gives a diagram for one of the columns. An interesting feature of these tests was the determination of the lateral deformation or enlargement of the column. The measurement of this expansion is extremely difficult, and this work is of an experimental nature and the results are not to be considered final. Further study of the data will be required to interpret them fully. It seems, however, that the value of Poisson's ratio found from these tests is generally less than that given in text-books. This is particularly true for the smaller loads. The ratio increases rather suddenly somewhat before the maximum strength of the column is reached. The line at the left of Fig. 3 gives the amount of the lateral unit-deformation. From a hasty study of the results it would appear that Poisson's ratio averages 0.1 or somewhat more, for the lower loads, and that near the maximum load this ratio rapidly increases to 0.25 or 0.3.

Fig. 4 gives the strength of columns made with different mixtures of concrete. The abscissas give the proportion of cement in terms of the weight of the sand and stone used. The results given are the average of two to five test columns. The diagram brings out the effect of adding cement in giving strength to concrete columns.

The general phenomena of the tests of hooped columns are as follows. The early part of the test is much the same as for plain concrete columns. At a load equal to that which would cause failure in a plain concrete column or a little above, the concrete over the spacing bars begins to scale, and this is soon followed with a scaling and shelling off of the surface of the column over the hoops everywhere. With added increments of load the amount of shortening increases rapidly and the column correspondingly expands or bulges laterally. The lateral deflection of the column from a straight line begins to be apparent just before the maximum load carried by the column is reached, and it rapidly increases after the maximum load is passed, forming a curve having the characteristics of the figure shown in text-books for columns with fixed ends. The columns finally bent out of line, in some cases as much as 4 or 5 in., the load finally carried being only a small proportion of the maximum.

Fig. 5 shows the stress-deformation diagram for a column reinforced with circular hoops and may be considered to be characteristic. In this and in the other columns, the load carried when the column had shortened an amount equal to that which plain columns exhibit at failure corresponded to the maximum load of plain concrete columns. If the line beyond the elbow (approximately straight) is produced to the vertical axis or axes of ordinates, the load there indicated agrees closely with the maximum strength of plain concrete. The diagram indicates that up to the load where a plain concrete column would fail, the shortening and the lateral deformation correspond closely with those obtained for plain concrete columns, and but a small stress is developed in the hoops. The line at the left of the figure gives the lateral unit-deformation. Beyond the critical point referred to, the longitudinal deformation or shortening increases rapidly with an increase of load, and the lateral deformation increases correspondingly. The total amount of shortening is considerable, in this column being nine times as much at the maximum load as may be expected in a plain concrete column at its maximum load. The maximum strength of the columns occurs when the bands have been stretched to their yield-point. Beyond this point the deformations increased rapidly, but the load falls off Fig. 6 gives a view of one of these columns after the outside scale has fallen off and some time after the maximum load has been applied.

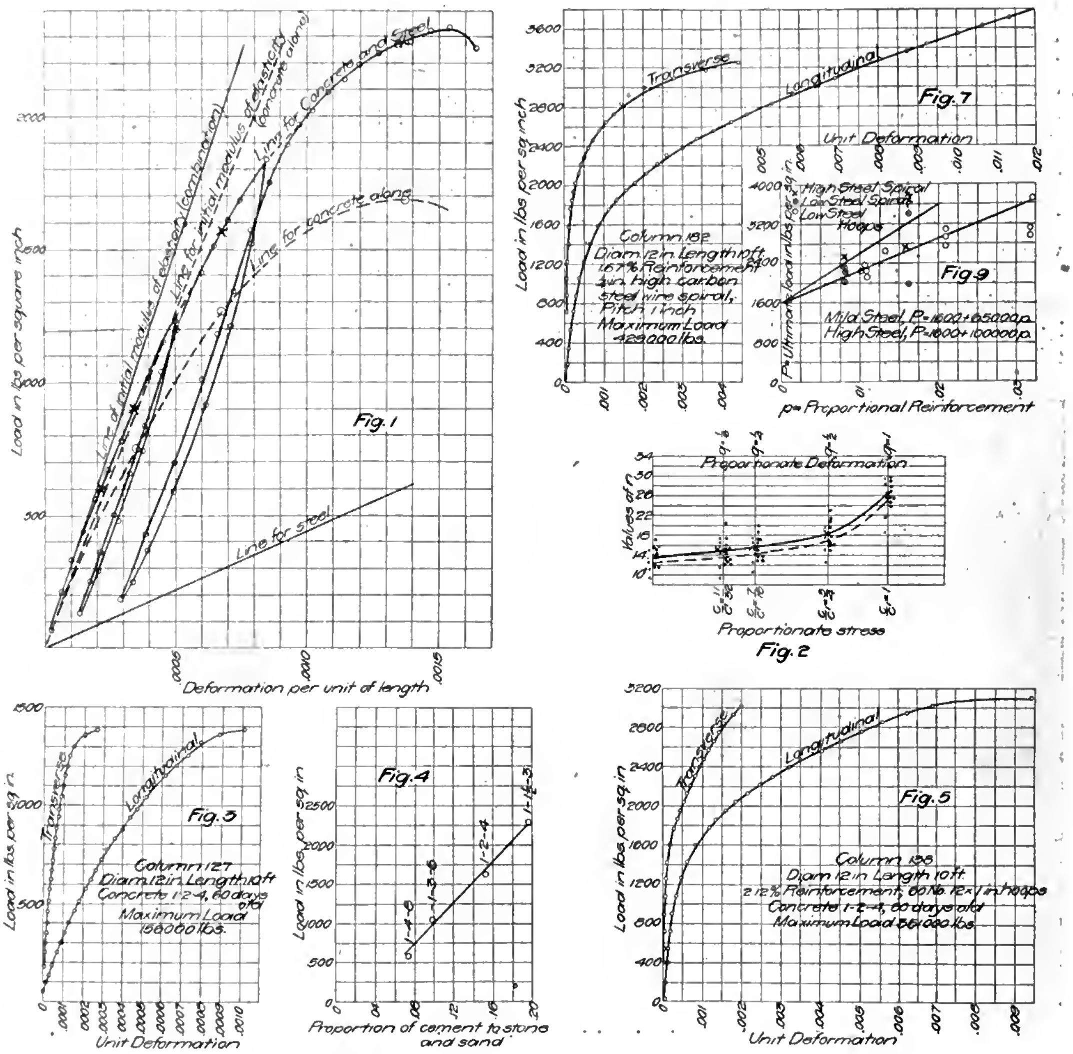

Fig. 1, Stress-Deformation Diagram for Column with Longitudinal Reinforcement. Fig. 2, Ratio of Stress in Steel to Stress in Concrete. Fig. 3, Stress-Deformation Diagram for Concrete Column. Fig. 4, Effect of Mixture on Strength of Concrete Column. Fig. 5, Stress-Deformation Diagram for Hooped Column. Fig. 7, Stress-Deformation Diagram for Column with Spiral Reinforcement. Fig. 9, Strength of Hooped Columns.

Fig. 7 gives the stress-deformation diagram for a column reinforced with high-carbon wire. The early part of the diagram is similar to that already described. The total amount of shortening is greater, as may be expected from the higher elastic limit of the reinforcing. The total shortening at the maximum was 13 times what may be expected in a plain concrete column at the time of failure. The lateral deformation curve shown at the left of the figure cannot be compared with the former one since the instruments were placed on the concrete between the wires and, as would be expected, the lateral swelling at these points is greater than for the reinforcement itself. Fig. 8 gives a view of one of these spirals after the maximum load had been applied.

The results indicate that the strength of the columns is dependent upon the strength of the concrete mixture, the amount of the hooping reinforcement, and the yield point of the reinforcing. In other words, the additional strength over that of plain concrete columns is a function of the amount and strength of the reinforcing. In Fig. 9 are plotted the strength of the hooped columns, and the amount of hooping. The lower line may be considered to represent the strength of the columns with mild steel hooping. Its equation is $P=1{,}600+65{,}000p$, where p is the ratio of the hooping to the concrete core. The upper line is for hooping, having a higher elastic limit. Its equation is $P=1{,}600+100{,}000p$. The columns reinforced with wire having a yielding-point of 110,000 lb. per square inch, gave a still higher strength and, of course, a greater amount of shortening. Equations of the same general nature may be derived from the results of other experiments on hooped columns. The first term represents the strength of plain concrete columns. These equations are given tentatively as expressing the results of these experiments.

It may be of interest to note the relation which exists between the load or longitudinal pressure on the column and the lateral pressure which may be considered to act on the hypothesis of hydrostatic pressure to give the deformation of the mild steel bands. Such of these tests as have been studied indicate that this hypothetical lateral pressure amounts to about 0.35 of the longitudinal pressure acting in excess of the strength of the plain concrete. Comparing the effect of hooping with the additional strength given by longitudinal reinforcement with concrete of the same character (counting in the

latter case that the stress in the steel at the ultimate load is twenty-five times as great in intensity as the stress in the concrete), it appears that the additional strength produced by a given amount of reinforcing material is from two to four times as great for the hooped columns as for columns with longitudinal reinforcement. Attention should be called to the fact that since the shortening in a hooped column at the maximum load is several times as great as in a column with longitudinal reinforcement at the yield-point of the steel, the effect of combining longitudinal reinforcement and spiral hooping is uncertain.

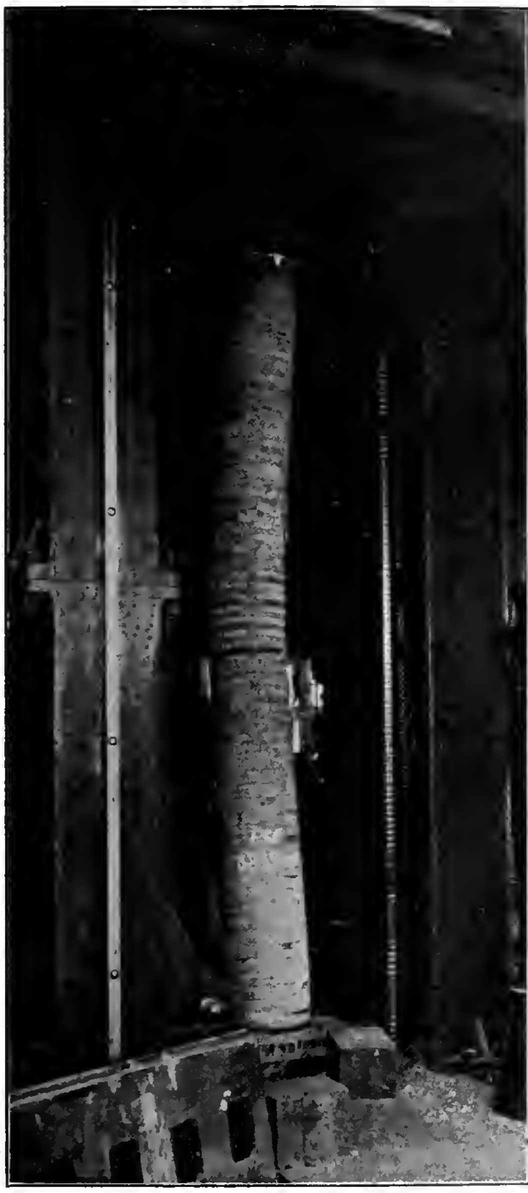

Fig. 6. Hooped Column.

Fig. 8. Helical-Wound Column.

An experiment of some interest was made by first loading a hooped column and then stripping the wire from it and testing the naked column. This column was loaded to 2000 lb. per square inch, and showed a unit shortening of 0.0036. The load was released and a set of 0.0025 was found. A load of 2000 lb. per square inch was again applied (the unit-shortening becoming 0.0041) and then released. The spiral was then stripped from the column without taking it from the machine and the naked column failed at 1080 lb. per square inch. As the indications of the stress-deformation diagram are that the plain concrete would have held 1200 lb. per square inch on the first application of the load it may be considered that the concrete sustained 90 per cent. of its original strength. The hooped column itself might have held 2200 or 2400 lb. per square inch. A test was made with a column eccentrically loaded. It was found that the hooped column acted as would be expected of a homogeneous column under the same conditions. This may have a bearing upon the explanation of the action of such columns. An analysis based on hydrostatic pressure would require that the internal pressure be distributed uniformly over the column, and hence only concentric loading would be allowable.

The writer feels that there is much yet to be learned about hooped concrete, and he has already had to give up several preconceived notions of the action of restrained concrete. As experimental work which helps to clear up uncertainties may be of advantage to the engineering public, the writer presents this matter without waiting for a complete study of the data, and gives the following tentatively as observations on these tests.

1. Poisson's ratio for concrete in compression is a variable quantity, increasing considerably just before the ultimate failure of the concrete. A value of 0.1, or somewhat more, may be tentatively given for the lower loads, and 0.25 to 0.3 near the crushing load. This concrete set in air.

2. In hooped columns the hoops do not come into action to any great extent before a load equivalent to the ultimate strength of plain concrete, or a little below, is reached. The longitudinal deformation and lateral deformation of the concrete are not modified by the hooping to any great extent before this load is reached.

3. Beyond this point both the longitudinal deformation and the lateral deformation are approximately proportional to the added load. The ratio of lateral to longitudinal deformation is more nearly constant, and in these experiments the ultimate strength of the column is controlled by the elastic limit of the hooping.

4. The total amount of shortening before failure occurred was very great, averaging something like 8 or 10 times that for plain concrete columns, and 60 times that at the ordinary working stress in plain concrete. The longitudinal shortening is, say, 8 times that of mild steel at its elastic limit. Cracking and peeling of the concrete appear at loads corresponding to the ordinary ultimate strength of concrete.

5. The excessive amount of shortening before failure affects the problem of combining hooping and longitudinal reinforcement very unfavorably, if the stresses are to be kept within the elastic limit of the latter.

6. The lateral deflection of hooped columns is large and may affect the ultimate strength which is available for the column. For continued application of stress beyond the maximum load, the column deflects enormously. Scaling of surface of concrete and lateral deflections are warning signs given well before danger of failure exists.

7. The concrete itself retains a considerable element of its strength even after it has shortened in a hooped state four or five times as much as would produce failure in unhooped concrete columns.

8. Columns of richer and leaner concrete exhibited phenomena of similar characteristics, the hoop stress becoming effective at the ultimate strength of unhooped concrete.

9. Hoops of high elastic limit steel give greater strength than of mild steel, but the increased amount of shortening necessary to develop the full strength of the column is an undesirable feature.

10. One experiment indicates that hooped columns will resist eccentric stresses in somewhat the same way as will other material.

11. Light hooping offers security against sudden failures and unevenness of concretes, and will enable higher working stresses to be used. In combination with rich concretes and longitudinal reinforcement, using low stresses in the hoops, i. e., basing the strength upon an assumed ultimate strength but little beyond the average ultimate strength of plain concrete) a satisfactory column may be made. It is suggested that a column of this character may be designed in such a way that the longitudinal reinforcement may carry the load during construction and still not be overstressed later for the additional stress which goes with the concrete, provided the basal point for the column strength is somewhat below the ultimate strength for plain concrete.

12. Heavy hooping gives added strength, but in utilizing the full strength of such columns the column shortens unduly, deflects laterally, and will strain longitudinal reinforcement many times beyond the deformation which exists at the elastic limit of the metal. It may be applicable where a large limit of safety is desired, or where large variations in shortening are unobjectionable, as where the structure is articulated. So far as ultimate strength is concerned, hooping adds two to four times as much strength to the column as does an equal amount of longitudinal reinforcement.

A Heavy Rainfall, 1.85 in. in 25 min. and 2.78 in. in an hour occurred in Baltimore on July 18. On July 12, 1903, 2.78 in. fell in 35 min., the record precipitation for the city. The heaviest storms recorded in the United States are 11.5 in. at Campo, Cal., in one hour; 8.8 in. in one hour at Palmetto, Nev., and 6.9 in. in 55 min. at Tridelphia, W. Va.

The Fall of an Arch of the Berlin City Railway.

The accident to an arch of the Berlin City Railway described in the following notes is considered by "Beton und Eisen," from which the information is taken, as a complete proof of the unreliability of the tensile strength of masonry, for the high character of the construction of this viaduct is well known. The fallen arch differs from the others only in the fact that the latter have the rough brickwork exposed. Owing to its location it was considerably ornamented, as were a few other spans adjoining it. The fallen portion shows an interesting view of the structural character of the arch. The brickwork of the latter is about 2 ft. thick and below it a large hollow space exists, the lower side of which was formed by the ornamental work, which did not have the same shape as the main arch. In order to give it the necessary support a wire cloth with coarse mesh was employed. The space between the brickwork and the ornamental surface amounted in some places to as much as a couple of yards. The piece that fell from the arch came from the neighborhood of the abutment and in falling badly injured the decorative arch below. It was a triangular mass of masonry weighing about 3 tons, the sides measuring from 6 to 10 ft. The smooth bed of concrete over the masonry shows a yawning diagonal crack, opening as much as 6 in. at the widest point, which apparently existed for considerable time. Below it the masonry was smeared with oil and tar, which apparently had gradually worked down for a long time from the ballast above. It is considered possible that eventually water and oil forced their way down into the pores of the masonry and that the adhesion of the joints was thus gradually destroyed.

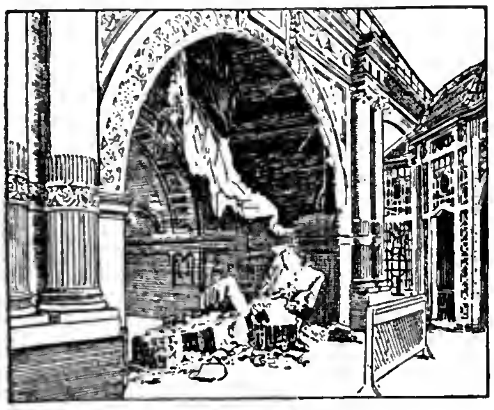
Opinions concerning the cause of the accident are very divided. It is reported that an investigating committee found that one of the foundations had sunk about 1¼ in. In other quarters it is believed that in consequence of the continued vibration due to the passing trains cracks were caused in the masonry which were not observed on account of the decorations hiding them from the eye. Part of the damage has also been attributed to the very severe winter. The moisture entering into small cracks of the main arch might have been frozen on account of the severe cold and thereby caused heavy stresses.

It is not to be overlooked, according to the journal from which these notes are taken, that the falling of so large a block of masonry would not have been possible had the disturbing forces not been great enough to overcome the shearing strength of the masonry and the friction due to the horizontal pressures. Nevertheless it is possible that the assumptions made in the course of the computations of the arch may not have been entirely fulfilled by the actual construction, and that during the setting of the masonry a part of the arch became pressed together very little or not at all, since in this work there was no provision made for a general uniform division of the loading over the individual arches. Under such conditions, if a few cracks destroying the shearing resistance arose, they would be sufficient to allow the mass thus separated to fall.

An Improved Arrangement of Service pipes has recently been adopted by Mr. Frank E. Merrill, water commissioner of Somerville, Mass. Instead of laying numerous small pipes across the street, one for each house, the method is now employed of laying one pipe 1½ in. in diameter from the street main to the sidewalk, and then extending smaller branches from this service pipe up and down the sidewalk to the various houses. Where the conditions are favorable a brick chamber is constructed in the sidewalk so that the main service gate and all the branch gates and connections can be reached.

Dust Prevention in the Boston District.

Dust prevention and road destruction in and about Boston have been receiving the attention of the Massachusetts Highway Commission, the Metropolitan Park Commission and the Boston Park Commission, and so many experiments are being made on a large scale that before long it is reasonable to expect some valuable information will be obtained. The work is particularly interesting on account of the extensive use of automobiles in the Boston district, and the consequent destructive travel on most of the good roads in that vicinity. One of the most thorough tests is being made by the Metropolitan Park Commission on the Revere Beach Parkway. A portion of this well-known roadway was treated with tarvia last year and another portion has been similarly treated this year. The procession of motor cars along this parkway is a close one at certain times of every pleasant day, and the effect of the treatment in preventing dust and the destruction of the road is consequently being determined with unusual thoroughness. In places the roadway which was treated last year has gone to pieces, raveling out somewhat like an ordinary



Damaged Arch at Berlin.

broken-stone road in very dry and windy weather; the surface shows a considerable quantity of loosened stones, but even there the road is practically dustless. The latter condition has been obtained without any watering, which shows the value of such applications in preventing dust, and indicates that while the first cost of an application may be large, the saving due to the omission of watering may largely counterbalance the expense of applying the tarvia.

It is believed that these badly worn places are due to the effect of the heavy motor car travel, but there are other places where holes occur which are believed to be due to the presence of too much clay or loam in the binding material used in making the road or to the application of the tarvia when the roadbed contained considerable moisture. In this connection it might be stated that there is a marked difference between the methods of applying tar preparations in the vicinity of Boston and the methods which are considered most satisfactory in France. In France never more than a thin coat of grit, amounting to little more than a mere sprinkling, is applied to the treated roadway, while about Boston a heavy coat of screenings seems to be considered necessary. This and some other differences in methods result in an average cost of about 12 cents per square yard for tarring some of the Massachusetts roads as compared with about 3 cents in France.

While tarvia has been used extensively, other preparations are being employed and some of them have already had considerable use. An experience with one of these, a preparation of Kentucky oil, in which some asphalt is dissolved at Revere Beach indicates that where the surroundings of the road have to be kept as clean as practicable, it is necessary to take special precautions to prevent their staining from the spreading of the preparation beyond the surfaces to which it is applied. In this particular case concrete gutters had been constructed and great care was taken to prevent the liquid from reaching them. This liquid leaves the roadway almost black, and an attempt was consequently made to keep any of it from the light gray gutters. This was successfully done while the material was being applied, but during the night following its application a rain occurred which washed some of it into the gutters, which were badly stained in consequence, thereby injuring one of the particularly attractive features of the roadway. An attempt will be made to restore the appearance of these gutters by cleaning. Another interesting experiment with this preparation of Kentucky oil and asphalt is being made by the Metropolitan Park Commission in Watertown, where a long stretch of gravel road is being treated with it. If a gravel road can be made more durable and its dust reduced by such an application, the result will be decidedly important, particularly in those districts where good road gravel is abundant and broken stone is costly.

The State Highway Commission is proceeding in a conservative way to test the various methods of reducing the wear on roads, and expects to spend about $20,000 this year in the work. For the present its experiments are confined to the use of tarvia, as it seems to give a more durable surface than other preparations which the Commission has observed in service; while the latter may be successful in laying dust, the Commission desires to obtain some material which will actually improve the surface of the road or at least reduce the rate of its deterioration. An interesting fact which has been brought out by the experience to date is that the application of preventatives of dust and wear to a new road is of little value. The surface of the new road is open and until it has been subjected to enough traffic to become consolidated and to permit the cementing action of the materials to form a compact mass, the application of tarvia and other preparations seems to be of little use.

Right-of-Way Areas.

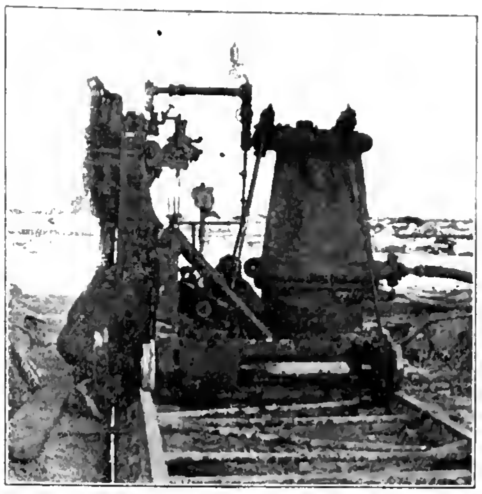
Rights-of-way of various widths are readily reduced to acreages by means of the following table, compiled for use by the engineers of the Western Pacific Railway Co. The acreages are for rights-of-way 100 ft. long and of the widths respectively stated; thus: a right of way 100 ft. wide and 1 mile long contains 1.21 acres ($0.229568 \times 52.8 = 1.21+$.) Logarithms of the respective areas as well as the acreage of 1 square foot and its logarithm are also given. Areas may be readily figured by the use of the slide rule in conjunction with the table:

Right of Way Width.	Area in Acres.	Logarithm.
10 feet	.022957	8.3609113
50	.114784	9.0598813
60	.137741	9.1390633
100	.229568	9.3609113
120	.275482	9.4400932
148.5	.340908	9.5326371
150	.344352	9.5370026
180	.413222	9.6161834
200	.459136	9.6619413
1 sq. ft. =	0.0000229568	—5.3609113

A Vitrified Clay Water Main 12 in. in diameter and 3 miles long has been constructed at Hobart, Okla., under the direction of the U. S. Geological Survey. It is made of double-strength pipe and is subjected to a maximum head of 14 lb. The joints were calked with oakum and run with a mixture of both pure and crude asphalt and petroleum.

The West Neebish Channel of the St. Mary's River.—II.

Rock Excavating and Handling.—The depth of the rock cutting varies from nothing at each end of the 8,600-ft. cut to as much as 27 ft. at the middle of the latter, with an average depth of 15 to 16 ft. The rock has mostly all been taken out in two lifts, the faces being worked the full width of the cut. Four steam shovels and four cableways have been used, one shovel to each cableway. Generally, the shovels have been worked in pairs, one shovel removing the top lift, and being followed by the other working on the second lift. The work has been handled in two lifts in this manner, in order that the sides of the cut could be made vertical with channeling machines. Four of these machines have been used, two Sullivan and two Ingersoll-Sergeant, all of which are capable of cutting to a depth of 14 ft. The specification provided payment for the removal of the sides of the excavation to a slope of 1 on 1, but stipulated that the contractor would be paid for all excavation out to these slopes, if the sides of the cut were channeled, which has been done accordingly.

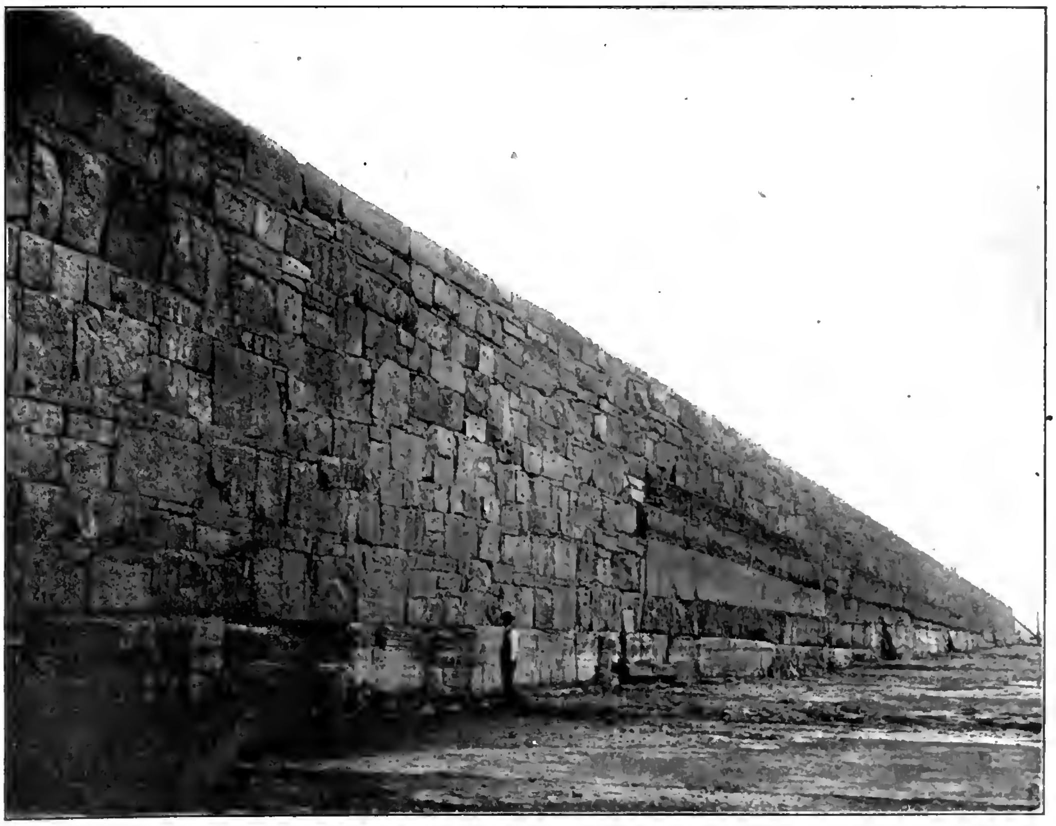


One of the Channelers.

General View of River Improvement at Rock Section.

The holes for the blasts necessary to break up the hard rock are made with 3¼-in. Rand drills, 30 of which are installed. The holes are made in two or three rows, depending on the character of the rock and other circumstances. Owing to the nature of the rock, the blast holes have to be placed at the four corners of 4 x 6-ft. or 5 x 5-ft. squares, making the cost of blasting very high. Half of the face of the cut is shot at a time, in order that the drills may be working on one half while the shovel is removing the muck from the other half. Dynamite is used for blasting, which is done almost entirely in the daytime.

The four steam shovels used in loading the loosened rock into the cableway skips are specially adapted to working in the cut. They are Model 60 Marion shovels, each with a 26-ft. boom carrying a 2½-yd. bucket. Each shovel is equipped with a traction gear which is capable of propelling it on wheels with 30-in. tires, without track, the same as the Model 20 shovel made by the same company is propelled. The driving gear is attached to the front wheels, the 10-in. steel axle of which is fixed, the steering being done with the hind wheels, which are on a pivoted axle. The shovels move on the rock bottom of the cut back and forth along the face without difficulty and can make a complete turn to start work in the opposite direction in 15 to 18 minutes. At rare intervals the shovels become stalled on rough bottom, or toward the ends of the cut where the rock runs out. The fall blocks of the cableway serving the shovel are then fastened to the front or the rear end of the latter, which can thus be helped along over the bad spot without any trouble.



Part of the Heavy Walls along a Portion of the Channel.

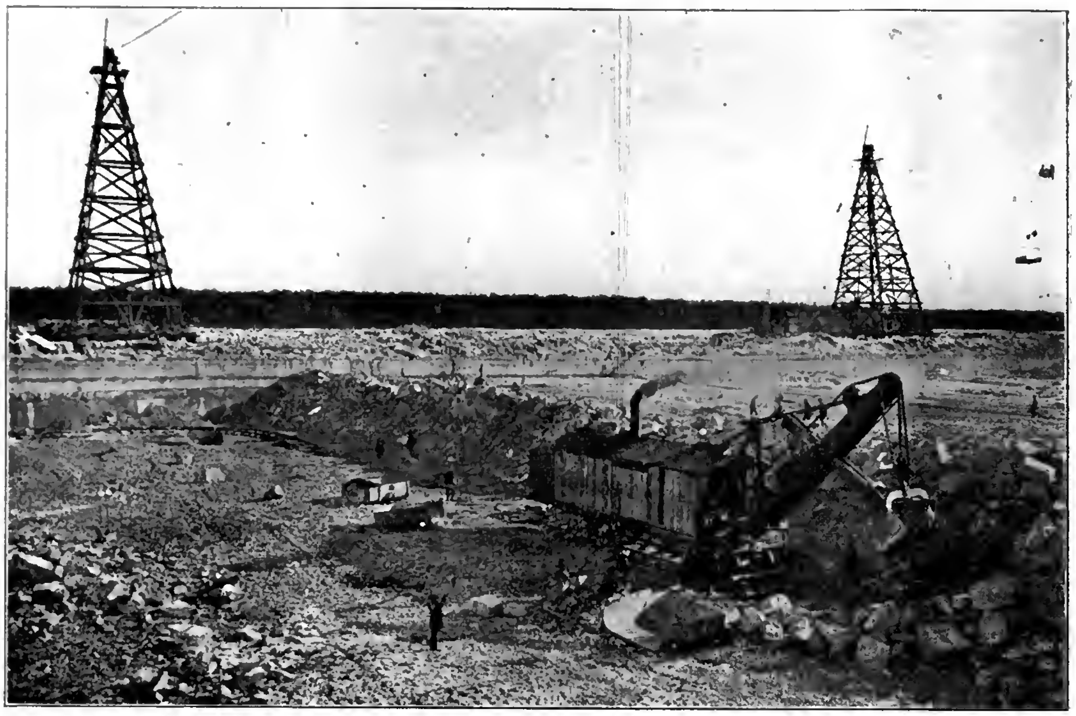
The boilers of the shovels are all supplied with water from a pump in the plant midway on the cut which houses the boilers supplying steam to the 8-in. and 12-in. reciprocating pumps in that plant. A 2-in. exposed pipe line, extending to both ends of the work from this plant has been able to supply water to the shovels and to hoisting engines for the derricks that are installed during the coldest weather by a method of operation which has been developed since the work was started. A 5,000-gal. circular wooden tank is placed in the boiler room of the plant and is heated during cold weather by the exhaust steam from the 8-in. and 12-in. pumps. Either of the two pumps on the supply line to the shovels and derricks draws from this tank, the steam exhaust of the pump in service being turned into the suction pipe of its water end. The temperature of the water is thus raised to about 100° Fahr., by the exhaust from the three pumps, so it does not fall below the freezing point before reaching the shovels and derricks even during the most extreme weather, due to a method of operation that has been adopted. When a shovel engineer needs water he can ring an electric signal bell in the pump house. The pump is then started and run until the engineer signals again, when it is shut down. The water left in the pipe leading to the shovel is then immediately blown out under a pressure of 90 lb., with air from the compressor supply line, and the pipe closed until water is required again. Arrangements were made to use steam to thaw the pipes after the water has been drawn from them, but the steam has never been necessary, as the distributing pipes are free from ice at all times.

An interesting condition developed in connection with the operation of the air line used to blow out these 2-in. water supply pipes. Shortly after the 2-in. air line for blowing the water pipes was installed it became difficult to maintain the usual pressure in the main air lines. Investigations determined that, on the average, the 2-in. water supply pipes required air about 7

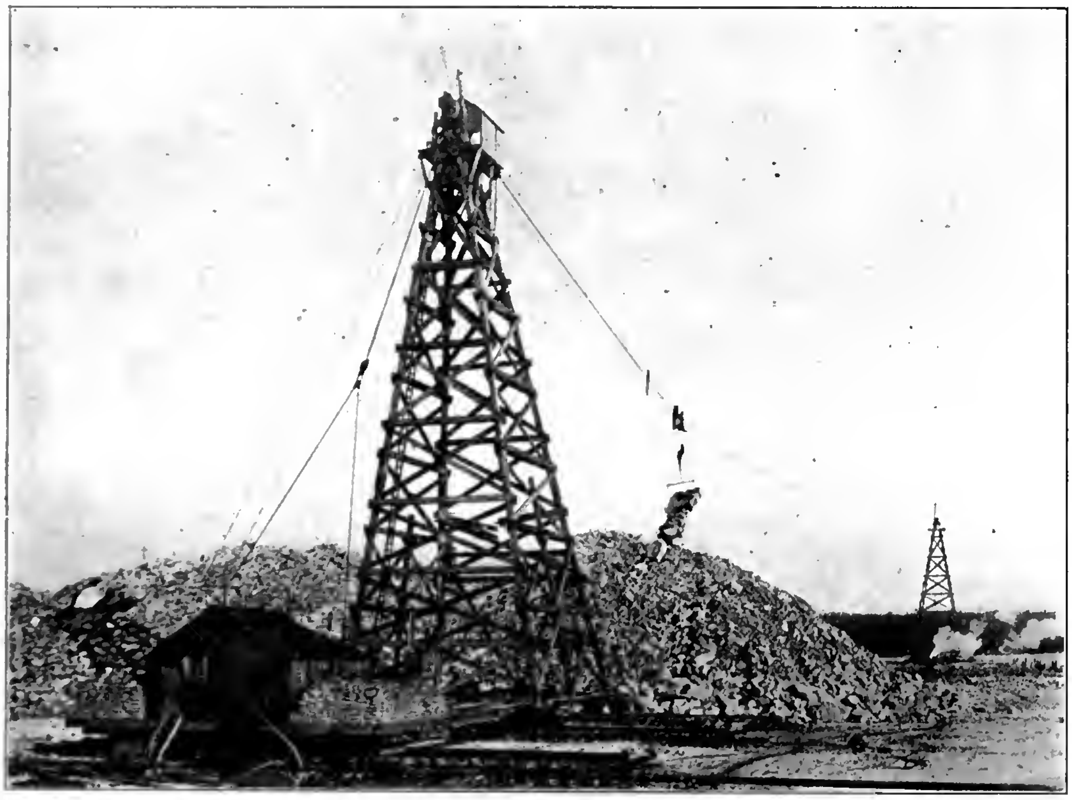
hr. out of the 24 hr., so a large amount of air was thus consumed. A plate with a ¼-in. circular hole was then placed in the 2-in. air supply line to the pump, in order that no air might be wasted. The result was that the pressure in the main air lines was at once restored, although the water could be blown out of the supply line as efficiently as before.

The four cableways are worked in two pairs, one pair operating from a point near the middle of the cut to the downstream end of the latter, and the other pair from the middle to the upstream end. The specifications were written with the idea that the channel may eventually be widened on the east, or island side. Accordingly, the material from the excavation can be dumped in the river adjacent to the improved channel, so long as the spoil banks within 300 ft. of the east side of the latter are not higher than the top of the retaining wall along that side of the cut. On the west side of the channel, the spoil banks are permitted to come within 50 ft. of the cut and the space between them and the latter can be filled to the level of the top of the wall. Owing to the nature of the river bed and bank on the west side of the cut for about 3,600 ft. from the upstream cofferdam, head towers for traveling cableways could not be operated with any degree of safety or satisfaction. The ground on the island side of the upper end of channel was satisfactory for the operation of the head tower, however, so cableways long enough to span the 300-ft. channel cut, the 300-ft. berm along the latter and sufficient space for spoil banks between the edge of this berm and the head towers had to be installed. At the downstream end of the channel conditions were much more favorable for the operation of head towers on the mainland side of the river, permitting shorter-span cableways to be installed.

The four cableways were made by the Lidgerwood Mfg. Co.; the two upstream ones have spans of 1,100 ft. each and the two downstream ones, spans of 800 ft. each. The capacity of the cableways is probably best illustrated by the loads which they have carried regularly in service. The stone which is being removed from the cut is very dense, weighing about 4,600 lb. to the yard; pieces of this stone containing 6 to 8 cu. yd. have been lifted out of the excavation, however, and conveyed to the spoil banks without any apparent difficulty. The head and tail towers are all mounted on trucks traveling on rails parallel with the cut. These towers have a clear height of 103 ft. above the base of rail, each pair of towers containing 85,000 ft., board measure, of timber. The front end of each tower of the 1,100-ft. span cableways is carried by seven pairs of wheels, three pair in a group under each corner and one pair on the center line. Seven more pair of wheels are placed under the rear legs of the tower and are spaced the same as those at the front end of the latter. Three lines of rails laid under the counterweight end of the tower platform carry eight pairs of wheels, staggered alternately so each outer rail of the three carries four wheels and the middle one eight. As compared with the usual arrangement of wheels for a cableway tower, in this case an extra pair is added under each leg of the tower and a pair under the middle of each side of the tower platform. The great load on the wheels and rails is thus distributed in such a way that bending of the rails is prevented. The tracks can therefore be kept up and the towers can be moved much more easily than if fewer wheels had been used. The towers for the 800-ft. span cableways are the same as those just described except they have five pairs of wheels in a row where the others have seven. A 50-h.-p. moving engine is provided on each tower.



Steam Shovel Loading Cableway Skip.



One of the Cableways and Its Spoil Bank.

Each cableway is operated by a double 12¼ x 15-in. engine driving a 59-in. hoisting drum, all in a house on the head tower. This engine gives the carriage a hoisting speed of 250 ft. and a traveling speed of 1,200 ft. a minute. The section of the hoisting drums carrying the endless cable line is covered in each case with a rim of boiler plate steel which wears much better than the regular material in the drum and can be replaced readily when worn. The carriage of each cable is equipped with an extra block, and an increased diameter section is added to the hoisting drum of the engine, so the skips can be dumped in the air by the hoisting engineer. This aerial dumping device was invented by Mr. Locher during the progress of the work on the Chicago Drainage Canal, and is the one which has been in general use since then.

A 2¼-in. lock-bar cable, made by the Trenton Iron Works, is used on the main cable in each machine. The repairs to the lock-bar cables have been very much simplified since the inception of the work, until now all minor repairs and some rather extensive ones are made without lowering the cable. When a strand breaks the ends at the break are lapped about ½ in. and are filed down on a bevel to form a flat joint, as nearly as possible. This is wrapped with fine brass wire, then covered with a little borax and heated to the welding point with a blow torch. The brazed joint is then filed down to the same cross section as the remainder of the strand, in order that the latter may be driven back into place. In case the ends at a break are not long enough to lap, a piece is cut out of the strand and another piece long enough to lap is welded in its place. Small steel clamps with tightening screws are placed around the cable to hold the loosened strands in position

while the repairs are being made and to assist in replacing the mended strands.

The repairs to the cables and cableway carriages are greatly facilitated by small cabins erected over the ends of the cables at the head towers. During the extremely low temperatures which occur in the winter it would be practically impossible to make repairs on these towers, 100 ft. or more above the ground without some such protection, and even with the latter men are often frost-bitten.

The skips used in connection with the cableways have a capacity of 6 cu. yd. each. They are built of heavy steel plates, but the extremely hard rock which is handled into them with the steam shovels breaks and bends them very quickly, 35 of these skips having been used in this work.

Retaining walls varying from 5 to 20 ft. in height and having a minimum top width of 5 ft., are built along both sides of the channel for a length of 5,000 ft. The tops of the walls are 6 ft. above extreme low water, the walls being built as a guide to traffic. They have been built of large stones taken from the cut, many of these stones containing 2 to 6 cu. yd. The limestone through which the channel cut is being made is quite evenly stratified and breaks out in regularly shaped pieces. At points where the stone occurred in particularly uniform strata, areas were reserved from the general excavation in order that the rock might be quarried carefully out of these areas for use in the walls. Four stiff-leg derricks operated by steam-driven hoisting engines, are used in handling the stone in these small quarries and in building the wall. With the exception of these four hoisting engines, the steam shovels and three pumping plants, all of the equipment on the work is operated on air from the central compressor plant.

The work within the cofferdams is now rapidly approaching completion. The rock cut is finished up to within a short distance from each end, the excavation having been carried to and below the required grade, and the bottom finished as the work progressed. The excavation had to be carried below the grade in places in this manner in order that the steam shovels could follow the plane of the inclined strata which occur in the rock. The retaining walls along this cut are practically done. A small amount of earth excavation between each end of the rock cut and the main cofferdam will be taken out with the steam shovels and conveyed to the spoil banks by the cableways. When this is finished and the work has been cleaned up it is planned to admit the water into the area enclosed by the cofferdams very slowly to prevent any of the loose material being washed into the channel. The portion of the cofferdams across the channel and the small portion of the channel in earth between the ends of the rock cut and the cofferdams will then be removed with a dredge.

The progress that has been made in executing this work is well worthy of notice. As has been mentioned the first work was started early in the summer of 1904, but it was early in the summer of 1905 before the whole area enclosed by the cofferdams was unwatered. Therefore, practically all of the work will be done in two and one-half years; at the same time, it should be borne in mind that the time limit on the work does not expire until Aug. 18, 1908, or in other words, the contract will be completed nearly a year ahead of time.

The quantities of materials handled by the plant installed also merit attention. During the month of June, last, the four cableways and four steam shovels handled approximately 86,000 cu. yd. of rock, or an average of 21,500 cu. yd. to each shovel and cableway. The output for July will be approximately the same amount. The monthly output since the four shovels and four cableways have been installed has ranged in the neighborhood of 65,000 cu. yd. In this connection it is interesting to observe that the ouput of the cableways used most sucessfully in rock cuts on the Chicago Drainage Canal ranged in the vicinity of 8,000 cu. yd. a month when operated an eleven-hour day shift. At the same time, the rock in that work was much more easily blasted and was not so hard on plant as is the rock which has been encountered in this contract.

Sixty-five Ton Shovel and Six-Yard Skips.

Another significant feature of the operations on this work is that the number of skips of stone handled at night by the cableways is about the same as the number handled in the day time. This condition may probably be attributed to two principal causes, the lighting and the efficient method of inspection and repairs which is followed. The method of inspection and repairs is also largely responsible for the maintenance of operations so successfully during the winter.

The lighting in the field is done with portable Kitson gasoline lamps, enough of which are used so all operations can be carried on without interference. The blasting is practically all done during the day, but when any blasting has to be done at night the lamps can very readily be moved out of range.

The method of inspection and repairs that is followed is very thorough. In the first place, the whole work is so far isolated from a base of supplies that a very large amount of extra parts and materials for repairs are kept on hand constantly. For instance, an extra steam shovel dipper, a dipper arm, one of the heavy traction gears and shaft, and so forth, are always ready for use. The small parts of the various machines are also kept in quantities in a supply house, the total quantity of extras and repairs on hand representing about $20,000. The parts of each machine which are most liable to need replacing, such as the cableway sheave wheels and the like, are kept at the machine in order to save the delay necessary to bring extras from the supply house. A blacksmith and machine shop in which most repairs can be made is also provided. The second feature of this maintenance system is the inspection method followed. A mechanic and helper are placed in charge of each two cableways, the carriages of which are carefully inspected at meal hours, or at other times when they are brought to the head towers. Any necessary repairs are made then, if possible, but if it is impracticable, they are delayed until a more favorable time. The steam shovels are also under the constant supervision of a mechanic, whose sole duty is to go over the shovels daily in an endeavor to find any defective parts. That this unusually close system of inspection has proved profitable, is evident from the rapid progress which has been made.

The supplies for the three camps which the contractor built and maintained on the mainland at the work are brought from Sault Ste. Marie by boat during the open navigation season, and over land in sleighs the balance of the year. Coal to operate the various plants and for the camps is delivered entirely by boat, enough being brought in each summer to last through the winter. Thus far, in the neighborhood of 40,000 tons of coal has been used. The majority of this has been required in the compressor plant. A road was built through the dense timber along the river by the contractor and such coal as is used at points where delivery is not made by boat is hauled along this road in wagons.

The improvement of the West Neebish Channel is being carried on under the direction of Col. Chas. E. L. B. Davis, Corps of Engineers, U. S. A. Mr. L. C. Sabin is assistant engineer, Corps of Engineers, U. S. A., with headquarters at Sault Ste. Marie, Mich., and has charge of all construction and administration of the nagivation in the St. Mary's River. Mr. Sutton Van Pelt is in immediate charge of the work under Mr. Sabin. Mr. A. S. Robinson is local manager of the Sault Ste. Marie office of the MacArthur Bros. Co.

The New Warehouse of the Newark Warehouse Company.

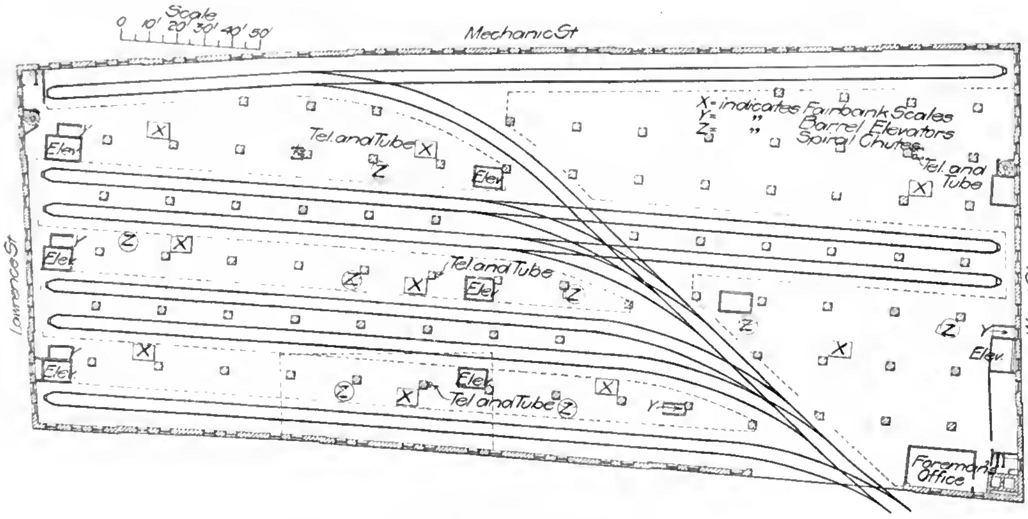
The Newark Warehouse Co. has just completed a large 6-story fireproof building in Newark, N. J., which presents some interesting features of warehouse design, many of them due to the peculiar local conditions in Newark. The building will be used by the Central R. R. of N. J. to accommodate its local freight business and this fact combined with the scarcity of available property and the elevation of the tracks of the railroad through the city caused the adoption of a design differing widely from those customary for terminal facilities. At the same time the building offers a safe and convenient storage for freight which is not taken promptly by the consignee and thus allows the release of cars and their prompt return to service. The building, therefore, combines the facilities of a freight delivery and receiving terminal and of a general storage warehouse.

These facts made the method of managing the building an important consideration which was finally worked out so that the entire structure with its contents is under the control of the warehouse company. The tariff covering the storage charges varies according to the class of merchandise and is double the rate for the first month, and single rate thereafter, the double charge covering the cost of handling the freight to and from storage. The question of insuring a building of this character together with its valuable contents is also a matter which received careful consideration. The building was constructed and equipped with fire protection apparatus to meet the requirements of the Associated Mutual Fire Insurance Companies with the result that they have written the insurance not only on the building but have taken a blanket policy on its contents.

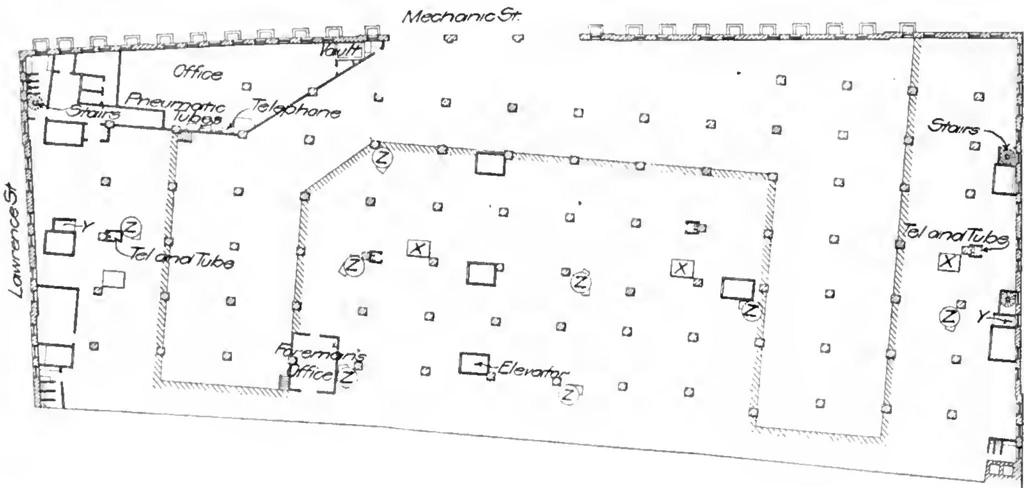
The building is situated on Mechanic St., between Ward and Lawrence Sts., extending back to the property of the Central R. R. of N. J. It is 360 ft. long with a width varying from 130 ft. on Lawrence St., to 165 ft. on Ward St., and has a storage capacity of about 1,200 carloads of freight. It is a steel frame structure with reinforced concrete walls and floors, containing 7 floors in all, the first devoted to teaming, the second to the freight tracks and the basement and the four top floors to storage. The fact that the tracks of the railroad are elevated through the city made it advisable from the first to unload the cars on the second floor and this immediately required provisions for lowering large quantities of freight to the teaming floor as well as a skillful arrangement of tracks inside the warehouse to allow of the unloading of as many cars as possible at the same time. The transfer of large quantities of freight between the first and second and the storage floors further emphasized the need of rapid and adequate elevator facilities.

The use of the ordinary platform elevator was considered not only expensive but very slow and it was therefore decided to put in spiral conveyors suitable for lowering packages in the form of barrels, boxes or bags of a limited size. These spiral chutes though used to a limited extent in some department stores have not, so far as is known, been applied to the handling of large quantities of miscellaneous freight. They are 8 in number, 5 with single and 3 with double spirals, all made by the Otis Elevator Co. They are constructed of sheet steel enclosed in cylinders 7 ft. in diameter. Three of them extend from the top to the first floor, one from the 6th to the 2nd, two from the 2nd to the basement, five from the 2nd to the 1st floor. The reason for the principal connection between the 1st and 2nd floors is that the majority of freight passing through the warehouse will be direct from the cars to the teams. The conveyor extending from the 6th to the 2nd floor is for freight which may come from the storage floors to be reloaded into cars. The discharge openings of these conveyors are permanently fixed at certain floors but packages can be placed in them at any of the floors which they reach. They are adapted for any packages no matter how small up to a maximum of 36 in. square and 4 ft. long. Their carrying capacity is only limited by the rapidity with which the packages can be put in at the top or taken away at the bottom.

There are 5 electrially-driven barrel elevators installed by the Link Belt Engineering Co., two running from the basement to the top floor and three from the 2nd to the top floor, having carriers about 8 ft. apart attached to an endless chain. They are adapted for either sacks, barrels or boxes and have an almost unlimited capacity, it being possible to raise a carload of flour to any of the floors in half an hour or less. They can be run in either direction, so that the packages can be lowered as well as elevated by them, but the probability is that practically all the freight which they raise will be lowered by the spiral conveyors. Automatic trips are installed at each floor and when once set discharge the elevator without further attention. When the elevators are used for raising packages, special arms are attached to the frames of the elevator shafts and on these arms are placed the packages to be carried up by the elevator. The carriers come up between these arms and pick up the packages. In case the elevators are used for lowering freight the packages are placed on the carriers by hand and caught by the arms just referred to on the floors where they are to be discharged. Special skids or platforms are used to aid the safe delivery from the elevators. The nine platform freight elevators are of the direct-connected electric type made by the A. B. See Electric Elevator Co., and have a carrying capacity of 6,000 lb., with platforms either 7 x 10 ft., or 8 x 12 ft. in size. One elevator runs from the 1st to the top floor, two from the 1st to the 2nd floor and the other 6 from the basement to the top floor. They will be used for large packages which cannot be handled by the barrel elevators or the spiral conveyors.



Plan of Second or Track Floor.



Plan of First or Teaming Floor.

The design of the 2nd floor of the building influenced to a large extent the arrangement of the other floors. As seen by the accompanying sketch the cars are brought inside the building and unloaded from 6 parallel tracks to platforms which are raised to the level of the car floor. The ends of the tracks toward Lawrence St., are intended particularly for inbound freight and at the Ward St. end for outbound freight, which may be reloaded in the cars from the different storage floors. The cars on the tracks at the Lawrence St. end of the building can be handled by a switch engine, but those placed on the tracks toward Ward St. will be handled by ropes running to an electrically-driven capstan. The capacity of all the tracks is about 45 cars.

The location of the elevators and spiral chutes was arranged so as to afford the greatest facility for handling the freight as it came from the cars, whether intended for immediate delivery to the teams on the first floor or for storage in the rooms above. The platforms on both the first and second floors are provided with Fairbanks automatic scales, nine on the second, and four on the first floor to afford a convenient means for weighing the freight.

The first floor is devoted to the delivery of freight to teams, and to the main office which is located at the corner of Mechanic and Lawrence Sts. The large platform in the center is intended for freight coming direct from the cars and the two end platforms for the freight com-

ing from storage, but in case of emergency either or both of the two end platforms can be used for freight going direct from the cars to the teams.

The entire operation of the warehouse is controlled from the office by a private telephone system with stations on all the platforms of the first and second floors and at the center of the storage floors. The system also connects with the lines of the Central R. R. of N. J., reaching all outlying points in the railroad yards, and with the public telephone system of the city of Newark. On the platforms the telephones are placed in the small offices which have been provided for the clerks looking after the freight. In addition to controlling the operation of the warehouse by means of the private telephone system, there has been installed a pneumatic tube system which affords means of sending orders or receipts from the office to any point in the warehouse. The telephone and the tube systems together will afford a quick and positive means of communication between the office and the various sections of the building and will thus greatly expedite the handling of the business. The pneumatic tube system was installed by the Lamson Consolidated Store Service Co.

The basement is divided into 13 sections, 10 of which are devoted to storage and are intended for such stocks as it is desired to keep cool and in a uniform temperature. One of the remaining sections contains a reservoir for supplying the fire pumps and the other the engine and boiler room. The latter contains a heating boiler for warming certain sections of the building and a reserve space wherein can be placed a turbine generator if it is ever desired to make the building independent of outside sources for electric current. A twin stack has been put in the building so that a ventilating equipment can be installed in the basement should that ever become necessary, one of the flues being reserved for this purpose. The fire pumps and air compressors are also located in this section of the building.

The third, fourth, fifth and sixth stories are divided transversely into 5 large storage compartments reached by 7 platform and 5 barrel elevators and 3 spiral chutes. In addition, at each end of the storage floors, there is a large open space around the elevators which can be used temporarily for freight that has not been allotted regular storage space. The floors are divided into about 100 sections each, by having numbers painted on the beams overhead to indicate the sections, these divisions permitting a record to be kept of the definite location of any merchandise which may be stored in the building. The carrying capacity of each floor is also plainly marked at each section. The elevators and chutes are lettered and numbered and at each opening of the spiral conveyors the floor at which the packages will be discharged is shown by a number.

The partitions between the compartments are of hollow tile double-celled blocks 8 in. thick, and the stairways and elevator shafts are enclosed with tile blocks 4 in. thick, laid in Portland cement mortar. The doors between the compartments are standard tin-covered fire doors, made of 3 thicknesses of 1-in. white pine boards, hung on an inclined rail, with a standard automatic fusible fastening allowing the door to close in case of fire. Similar doors are used for the barrel elevators and stairways. The doors for the platform elevators were made by the Automatic Door and Gate Co., and are self-closing whenever the elevator leaves the floor and can be opened only from the elevator side except on the first story. The windows have metal frames and sash, glazed with wire glass, with an automatic fusible attachment making them self-closing in case of fire.

New Warehouse of the Newark Warehouse Company.

The building is equipped throughout with the dry system of sprinklers installed by the General Fire Extinguisher Co. In this system numerous air valves throughout the lower stories of the building cut off the water from the sprinkler heads, thus leaving the pipes and headers charged with air, which is released by fire, acting on the sprinkler heads, permitting the discharge of water from the heads. The system can be supplied from three independent sources, thus guaranteeing against failure of any one or two of the supplies. Water can be obtained from the high pressure service of the city of Newark, maintaining a pressure of 140 lb. to the square inch, from two hemispherical-bottom tanks, furnished by the Chicago Bridge and Iron Works, of 30,000 gal. capacity each, carried 25 ft. above the roof of the building, or from two 750-gal.-per-minute electrically-driven centrifugal pumps drawing on a 150,000-gal. reservoir in the basement of the building. The pumps were furnished by the Fales & Jenks Co., Pawtucket, R. I., and were designed to meet the requirements of the Mutual Insurance Companies. The three independent water supplies are connected to a header located near the pumps on the Ward St. side of the building and by a system of valves any of the sources can be used at will. There are also stand pipes on each floor, with connections for 2½ in. hose, which can be used in case of necessity, but the main reliance is upon the automatic action of the sprinkler system. The power for operating the fire pumps as well as for the elevators and lighting is supplied by the Public Service Corporation and is distributed from a switchboard located in the engine room.

Except for the office on the first floor, the toilet and air valve rooms, and a 60 x 75-ft. section on each of the four upper floors, the building will not be heated.

The building is equipped with the Eco-Magneto clock system with stations at different points to insure the proper patrol by the watchman, and fire-alarm stations connected with the headquarters of the Newark fire department will also be installed throughout the building. These excellent fire protective measures have resulted in insuring the building and its contents at a very low premium with the Mutual Companies.

Construction.—On the south side of the warehouse is the freight yard of the Central R. R. of N. J., elevated above the street about 25 ft. at Ward St., and about 12 ft. at Lawrence St., the embankment being held up by a retaining wall running the entire length of the building. This wall had to be underpinned for a depth varying from 12 ft. at the low end to 25 ft. at the high end before the excavation of the building could be started. The material used for underpinning was concrete put in in short sections, thus avoiding any shoring or bracing. It had to be done with great care as the tracks next to the wall were constantly in use.

The retaining wall was utilized as a foundation for the enclosing walls of the building above the second story, but not for the support of the steel structure, the foundations for the columns being entirely independent of the retaining wall. The latter had a considerable batter which necessitated cutting chases into the wall so as to set the outside columns out far enough to permit the enclosing walls to rest on top of the retaining walls. The cutting of these chases was slow and expensive and after various methods had been tried it was found that the most efficient was by the use of air drills. The chases varied from about 3 ft. deep at the bottom to nothing at the top.

Borings made at the site showed that the natural ground was sand with slight indications of quick-sand. The spread of the grillage beams as at first planned allowed for a load of 4 tons per square foot on the soil and to avoid any risk of settlement the foundations were made a continuous plate of reinforced concrete extending the entire area of the building, and projecting from 6 to 8 ft. beyond the center lines of the outside columns. This plate was 15 in. thick, made with Vulcanite Portland cement, reinforced with extra heavy expanded metal and on it was placed the grillage beams carrying the cast-steel pedestals of the columns. Both the grillage beams and the pedestals were enclosed in concrete.

The steel work of the building carries the entire live load and is unusually heavy. The floor of the second story, which carries the tracks, was designed under the specifications for railroad bridges of the Central R. R. of N. J.,

taking as the load the heaviest type of switch engine, the remainder of the track being filled with cars having a capacity of 80,000 lb. each. In addition the usual live and dead loads are allowed for on the platforms adjacent to the tracks. The lay-out of this floor compelled the omission of certain columns above the first story and the span of the track entrance doors necessitated unusually heavy girders. The steel in the structure weighs over 7,000 tons, was furnished by the American Bridge Co., and erected by the Pittsburg Construction Co.

The building was first designed to have the enclosing walls above the street of brick with stone trimmings, but labor conditions arose in Newark which necessitated changing to reinforced concrete. The walls are independent of the steel work and are carried down to the concrete plate for a foundation. They are embellished to an unusual extent for concrete work with rustications, mouldings, dentils, and cornices, which have resulted in giving the building a very finished appearance.

The reinforcement of the walls consists of expanded metal supplied by the Expanded Metal Engineering Co., and of ¾-in. rods laid horizontally about 4 ft. apart, overlapping at the ends, with special reinforcement in front of the columns. The concrete in the walls is very dense and there have been no indications of moisture working through. The concrete was a 1:2:4 mixture, using Cow Bay washed sand and ¾-in. trap rock, mixed with Atlas Portland cement. Particular care was taken in the selection of the sand and stone so as to insure getting perfectly clean and uniform material.

The walls are 20 in. thick to the second story, 16 in. thick to the third story, and 12 in. from there up to the top, the parapet walls above the roof being 3 ft. high. The mouldings forming the horizontal lines, such as belt courses, cornices, were carefully levelled, great pains being taken to secure true lines for the concrete work. The cornice has a projection of about 3 ft. from the face of the walls and required very heavy construction for the support of the forms. After the forms were removed from the walls the latter were refinished by applying a very thin 1:2 mortar so as to thoroughly fill all voids, and then rubbed, leaving no thickness to the finish. This has proved very satisfactory and there is no indication of chipping or flaking and no cracks have developed.

The floors above the basement are of reinforced concrete, 6 in. thick for a live load of 300 lb. to the square foot, and 8 in. thick for a live load of 500 lb. to the square foot, the reinforcement being extra heavy expanded metal. They are made of the same proportions of concrete as the walls and finished with 1 in. of cement mortar applied at the same time that the concrete was laid. The surface has been treated with a special material imported from Germany which has made it hard and durable and done away with the dust which usually arises from cement floors. The roof is a 4-in. concrete slab of the same proportion as the floors, covered with a 5-ply felt and gravel roof. The water caught in the gutters is carried to cast-iron pipes carried inside the building with a steam pipe alongside of them so as to prevent freezing in winter.

On the second floor the rails for the tracks rest directly on the 7/16-in. steel floor plates, which are supported by I-beams about 16 in. apart. The rails are fastened with bolts and clip washers, the hole in the plate being made water-tight by a heavy felt washer. After the rails were laid, the joints in the plates, which in all cases came over the I-beams, were carefully cleaned out and run full of a specially prepared coal tar pitch, and the entire surface of the plates was coated with a prepared asphalt paint, making the floor water-tight. The ends of the tracks are protected by Ellis bumpers. The roadway on the first floor is made of rock asphalt blocks with a special asphalt coating or cushion about ⅜ in. thick, this coating being of such a consistency as to afford a firm footing for the horses. The pavement was laid by the Neuchatel Asphalt Co. An oak wheel guard is laid in front of the platforms, with an oak buffer fastened to the upper edge to protect the latter from the wheels of the wagons backing in. The basement floor rests upon the fill, which was put in over the concrete plate, forming the foundation, after the grillage beams and column bases were set.

The columns throughout the building are encased in stone concrete having a minimum thickness of 3 in. outside the steel work. For a height of 4 ft. above the floor they are protected by a steel plate guard, filled with concrete, with an additional cast-iron wheel guard around columns in the driveway of the first floor.

The concrete for the building was all mixed in two 1-yd. electrically-driven Smith mixers located in the basement of the building. A temporary track was laid on the steel work of the second floor and the crushed stone was brought in on cars and dumped into large bins built on the steel work of the first floor. The sand was delivered by carts on the first floor and dumped into a hopper from which it was elevated by a bucket conveyor to bins adjoining those for the stone. The cement was received in cars brought in on the temporary tracks and lowered by a chute to a storehouse on the first floor. The sand and cement were discharged by gravity into measuring bins and the cement and water were added as the material passed into the mixers. This reduced the labor of handling the material to a minimum.

Concrete was raised to the different floors by a contractors' platform elevator driven by a steam hoisting engine. The concrete was discharged by the mixers into specially designed carts having a capacity of 6 cu. ft., consisting of a bucket swung between two high spider wheels. They were easily handled by one man and when raised to the floor on which the concrete was needed were run onto plank runways laid on the steel work and wheeled to the point where the concrete was being placed. The use of these carts required the erection of some extra scaffolding, but that was fully paid for by the increased capacity of the carts over wheelbarrows.

The concrete was put in in sections, generally from the top of the windows to the sill of the windows above, and then the piers between the windows were put up. Where the height was too great for these sections to be put in in one operation, work was stopped and levelled off at the height of one of the V-shaped horizontal joints. In the top surface of each section steel dowels were embedded in the concrete, sticking up about 5 in. with an inverted V projection to prevent any water which might be driven into the horizontal joints, from passing to the inside face of the walls. Vertical expansion joints were provided about once in 50 ft., finished with a V-shaped joint on the outside or concealed in the angles formed by the offsets of the outside walls. The concrete was placed in the forms for the walls by being dumped into a sheet iron hopper, attached to the bottom of which was a telescope canvas chute, the lower part of which was kept just above the concrete already deposited

Track or Second Floor of the Warehouse.

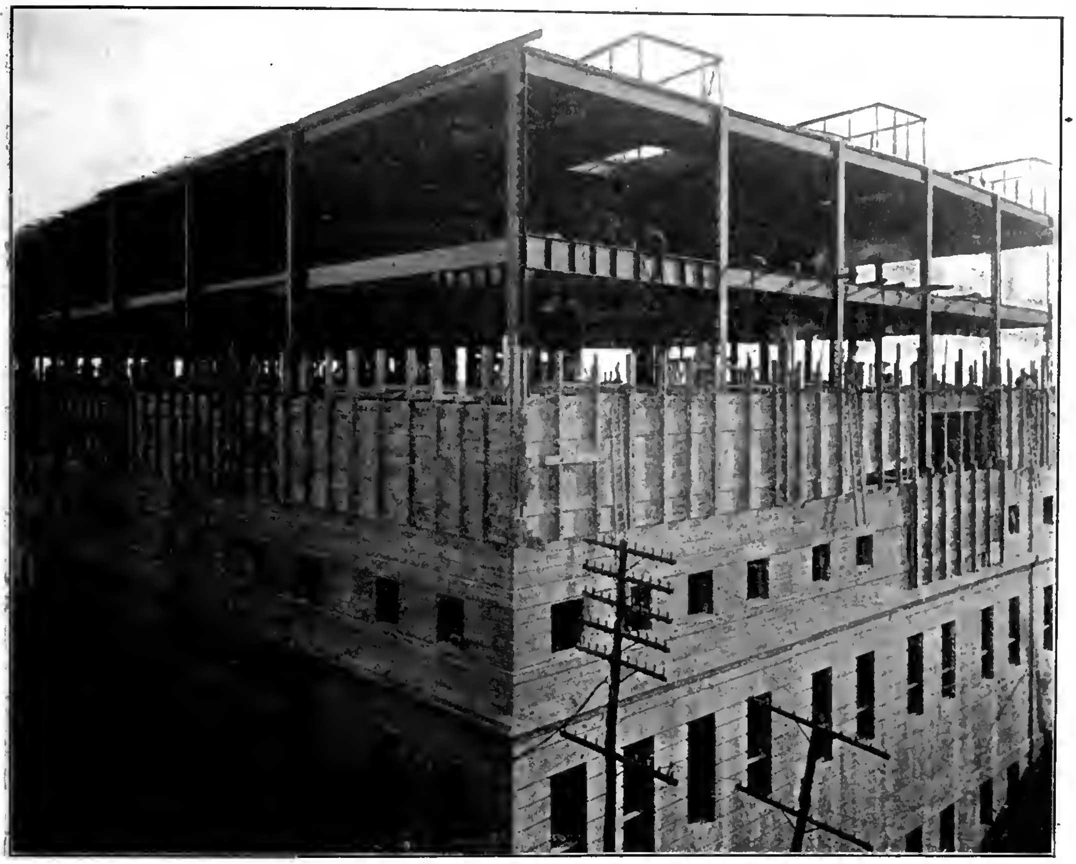
This prevented any splashing as the concrete was placed in the forms and aided materially in getting a good surface. The forms were not coated with any special materials to prevent the concrete from sticking to the boards any more than to keep the wood thoroughly wet before the concrete was put in. The concrete was in a very plastic state and was thoroughly spaded to remove all air bubbles and to push back the stone from the fact of the wall.

The building being of skeleton steel construction, permitted of attaching the forms to the steel frame in such a manner as to absolutely insure stability and accuracy. On each tier of beams outriggers were placed which were securely fastened to the beams by special steel clips which were easily removed. To these outriggers the uprights or studding were bolted and the plank forms were attached to the studding in sections, the outside of the form in many cases being used several times without being taken apart. The inside section, however, had to be practically rebuilt each time the form was raised.

The ⅝-in. bolts which held the forms together were passed through moulded concrete blocks about 4 in. square which had been prepared beforehand and allowed to season. The blocks were of the same length as the thickness of the walls, and the hole being ¾ in. in diameter allowed the bolts to be readily withdrawn

when the forms were struck. They were moulded into the walls and when the forms were removed the holes were filled with cement mortar.

The delay in erecting the steel work, due to the strike of the iron workers last year, prevented the enclosing walls being built before the cold weather set in last fall and when the steel work was finally completed the novel experiment was tried of putting on the roof before any of the floors were constructed. After the roof was made watertight the centering which was built for the reinforced concrete of the roof was lowered to the floor below and there formed the centering for the sixth floor. This was repeated from floor to floor and reduced the cost of removing the centering to a minimum. This procedure had the added advantage of preventing the drip from the floors as the concrete was laid from injuring the floors below as would have been the case if they had been laid from the bottom going up. The enclosing walls were carried up and connected with the roof before the severe cold weather of January. The windows were then closed and the work on the floors continued by the use of salamanders throughout the winter, no damage being done by the frost.



Method of Constructing Walls with Shutter Forms.

The building was designed and constructed under the general direction of Mr. Jos. O. Osgood, engineer of the Newark Warehouse Co., by the John W. Ferguson Co., Paterson, N. J., and New York City. Mr. Wm. Verbaarschot was the superintendent for the contractor and Mr. A. W. Smith represented the Newark Warehouse Co.

Heavy Galvanized Sheets are in use on the Northern Pacific Ry. for the decks of wooden bridges to guard against fire, as the burning of timber bridges is mainly due to hot cinders from the ash pans of locomotives. Galvanized sheets are put on in 8-ft. lengths with copper rivets, the rails being laid on top of the sheets and spiked through. Bolts for the bridge timbers are also passed through the sheets and at the ends of the bridge decks the sheets are flashed under the first tie of the road bed on either end and no part of the framework is exposed.

The Massachusetts Position Regarding Pollution of Streams by Mill Wastes.

The brief note in this journal on Aug. 3, concerning the decision of the Massachusetts Supreme Judicial Court in Parker v. American Woolen Co. has interested so many readers that the text of the court's statements regarding stream pollution are reproduced below without change.

It is difficult, if not impossible, to reconcile all the decisions which have been made upon the question of the right of riparian proprietors to use the waters of streams flowing through or along their lands. This is a common right, and each must exercise it with all due regard to the rights of others, and each must submit to that degree of inconvenience and hardship in the exercise of his rights which results from the existence of like rights in others. In such cases, each proprietor is entitled to use the stream in such reasonable manner, according to the usages and wants of the community, as will not be inconsistent with a like use by other proprietors above and below him. Cary v. Daniels, 8 Metc. 466, 41 Am. Dec. 532; Thurber v. Martin, 2 Gray, 394, 61 Am. Dec. 468; Gould v. Boston Duck Co. 13 Gray, 442. Many of the decisions relied upon by the defendant are instances of the application of this rule. Pitts v. Lancaster Mills, 13 Metc. 156; Springfield v. Harris, 4 Allen, 494, 81 Am. Dec. 715; Jones v. Portsmouth Aqueduct, 62 N. H. 488; Snow v. Parsons, 28 Vt. 459, 67 Am. Dec. 723; O'Riley v. McChesney, 49 N. Y. 672.

Cases in which the proprietors of sawmills have been allowed to throw sawdust and similar refuse into the streams frequently for the reason that the mills practically could not be run unless this was allowed to a reasonable extent, generally have been put upon the same ground. Haskins v. Haskins, 9 Gray, 390; Hayes v. Waldron, 44 N. H. 580, 84 Am. Dec. 105; Jacobs v. Allard, 42 Vt. 303, 1 Am. Rep. 331; Canfield v. Andrew, 54 Vt. 1, 41 Am. Rep. 828; Prentice v. Geiger, 74 N. Y. 341. But permission to do this has been refused where it was found to make the water impure and unfit for drinking and domestic purposes. Lewis v. Stein, 16 Ala. 214, 50 Am. Dec. 177. And the tendency of the later decisions is to restrict somewhat the liberality of the original rule. Lockwood Co. v. Lawrence, 77 Me. 297, 52 Am. Rep. 763; Canfield v. Andrew, 54 Vt. 1, 41 Am. Rep. 828; Red River Roller Mills v. Wright, 30 Minn. 249, 15 N. W. 167, 44 Am. Rep. 194. And in Canfield v. Andrew, supra, the court is careful to say in its opinion that no one is allowed to deposit any substance in a running stream that will pollute its waters to the injury of a lower riparian proprietor.

It is of course true that many of the uses which properly may be made of the water of a natural stream by the upper riparian proprietors will be likely to tend somewhat to defile the water. Sprague v. Dorr, 185 Mass. 10, 69 N. E. 344. Its use for watering cattle and for the irrigation of fertilized land, or for bathing or other domestic purposes, will have directly that tendency. Water cannot be made to pass through the propelling machinery of a mill without becoming more or less impure; nor can the water be made available for any manufacturing use without some incidental deterioration of its quality. Surface drainage into the stream will become more and more injurious to the condition of the water as population along its banks grows denser. No one has the right to complain of injury to the quality of the water coming from any of these causes. Wells, J., in Merrifield v. Worcester, 10 Mass. 216, 219, 14 Am. Rep. 592. The natural flow of surface drainage from occupied land or from streets, though much increased by the adoption of newer systems, so as materially to injure the water of a brook into which it runs, will afford no cause of action to a lower riparian proprietor. Bainard v. Newton, 154 Mass. 255, 27 N. E. 995. Perhaps the decision in Pennsylvania Coal Co. v. Sanderson, 113 Pa. 126, 6 Atl. 453, 57 Am. Rep. 445, can be justified upon the ground that the injury there complained of resulted in reality from the water pumped from the plaintiff's mine having drained over the surface of the ground into the brook; upon which reason indeed it is partly rested in the opinion of the court. See Crossley v. Lightowler, L. R. 2 Ch. 478.

We regard it however as settled that no riparian proprietor has the right to use the waters of a natural stream for such purposes or in such a manner as will materially corrupt it to the substantial injury of a lower proprietor, or to cast or discharge into it noxious and deleterious substances which will tend to defile the water and make it unfit for use. This was the doctrine laid down in Wood v. Ward, 3 Exch. 748. It has been maintained in the English courts. Mason v. Hill, 5 B. & A. 1; Pennington v. Brinsop Hall Coal Co., L. R. 20 Eq. 769, 772. It is affirmed in our own decisions. In Merrifield v. Lombard, 13 Allen, 16, 90 Am. Dec. 172, it appeared that by the mode in which the defendant had conducted his business a large quantity of poisonous and corrosive substances was permitted to run into a stream, which defiled and corrupted the water to such an extent that the machinery in the plaintiff's mill, lower down on the same stream, was corroded and his use of the water for proper purposes was impaired and prevented; and the defendant was enjoined from continuing so to act, and the court said: "We know of no rule or principle of law by which such a mode of appropriation of a running stream, in the absence of any proof of a paramount right or title, can be justified or excused as against a riparian owner of land on the same stream below." In Dwight Printing Co. v. Boston, 122 Mass. 583, it was held that a riparian owner has no right, in the absence of express

grant or prescription, to use the waters of a stream for dyeing or printing woolen or cotton cloths in such a way as to pollute the water and render it unfit for drinking purposes.

The same doctrine has been incidentally affirmed in other decisions of this court. Washburn & Moen Manuf. Co v. Worcester, 153 Mass. 494, 497, 27 N. E. 664; Walker Ice Co. v. American Steel & Wire Co., 185 Mass. 463, 471, 70 N. E. 937; New England Cotton Co. v. Laurel Lake Mills, 190 Mass. 48, 52, 76 N. E. 231. There is nothing inconsistent with it in Harris v. Mackintosh, 133 Mass. 228. It has been repeatedly and strongly declared in other states. "Riparian proprietors, mill owners or others have no right to render the water of a stream unwholesome or offensive." Richmond Manuf. Co. v. Atlantic De Laine Co., 10 R. I. 106, 14 Am. Rep. 658; Silver Spring Bleaching Co. v. Wanskuck Co. 13 R. I 611 (in which the court said: "The right of every owner of land bordering on a stream to the use of the water is well settled; and the fact that he also owns a mill does not lessen his rights. * * * And he has a right to have the water pass his land in its natural, pure state"); Bradley v. Warner, 21 R. I. 36, 41 Atl. 564; Holsman v. Boiling Spring Bleaching Co. 14 N. J. Eq. 335; Chapman v. Rochester, 110 N. Y. 273, 18 N. E. 88, 1 R. A. 296, 6 Am. St. Rep. 366; Middlestadt v. Waupaca Starch & Potato Co., 93 Wis. 1, 66 N. W. 713. In all these cases, it was held that the right of the lower riparian proprietor to the free use and enjoyment of the water of a natural stream extended as well to its quality as to its quantity. And see the cases cited in Gould on Waters, § 219; Wood on Nuisances, 427 et seq; Angell on Water Courses, § 136 et seq. The right to use the stream to carry away mere waste matter in a reasonable manner and to a reasonable extent is not so to be extended as to include a right to discharge into the stream noxious and deleterious matter to such an extent as sensibly and materially to foul the water and destroy its purity and fitness to be used by others.

It is true of course that there is in any large body of water a purifying principle which will, either by ordinary sedimentary deposit or by chemical change, obviate the evil effects which otherwise would arise from the deposit therein of some limited amount of noxious matter. Accordingly it is not for every small deposit of such matter that the law will give a remedy. This was the case in Brookline v. Mackintosh, 133 Mass. 215. There doubtless must be a material and sensible deterioration of the quality of the water; and this was recognized in the rulings made by the single justice. So in Townsend v. Bell, 167 N. Y. 462, 60 N. E. 757, it was found as a fact that the defendant's use of the stream did not render its waters unfit for manufacturing, mechanical or domestic purposes. Merrifield v. Worcester, 110 Mass. 216, 14 Am. Rep. 592, was decided on the doctrine that a city is not to be held in damages for having adopted an improper sewerage system.

Nor can we doubt that the plaintiff is entitled to an injunction to restrain the defendant from continuing to pollute the stream, in order to prevent it from gaining a prescriptive right, even though such pollution does not interfere with any use of the water which the plaintiff is now making. Crossley v. Lightowler. L. R. 3 Eq. 279; Pennington v Brinsop Hall Coal Co., L. R. 20 Eq. 769, 772; Brookline v. Mackintosh, 133 Mass. 215, 224. And it follows from what we have already said that the plaintiff is entitled to an injunction which will restrain the defendant from discharging into the stream any noxious or offensive substances to such an amount or in such a quantity as to affect noticeably or appreciably the purity of the water when it reaches the plaintiff's premises so as to render it materially less fit for drinking or for other uses than it was when it entered the defendant's premises. Simpson v. Hoddinott, 1 C. B. (N. S.) 590; Merrifield v. Lombard, 13 Allen, 16, 90 Am. Dec. 172; Richmond Manuf. Co. v. Atlantic De Laine Co., 10 R. I. 106, 14 Am. Rep. 658; Holsman v. Boiling Spring Bleaching Co., 14 N. J. Eq. 335. The court can fix no standard of reasonable use which will be more favorable to the defendant, or restrict any farther the terms of the injunction to be issued. The defendant must at its peril see that it does not overpass this limit.

Nor can an injunction properly be refused on the ground of the magnitude of the defendant's interests and the importance of its business. Some stress was laid upon this consideration in Pennsylvania Coal Co. v. Sanderson, 113 Pa. 126, 6 Atl. 453, 57 Am. Rep. 445; but the case was decided on other grounds. The same argument was urgently pressed to no purpose in the somewhat similar cases of Lockwood Co. v. Lawrence, 77 Me. 297, 52 Am. Rep. 763, Silver Spring Bleaching Co. v. Wanskuck Co., 13 R. I. 611, and Holsman v. Boiling Spring Bleaching Co., 14 N. J. Eq. 335. And here, as in the case last cited, the effect of the injunction will not be to stop the defendant's works or to interfere with its manufacturing industry, but simply to restrain it from discharging offensive matter into the stream and thereby polluting the waters which flow through the plaintiff's land. Here, as in that case, it does not appear that the offensive matter cannot readily and at small expense be otherwise disposed of; if a system of filtration or other purification is necessary, the expense of this should not be thrown upon the plaintiff. Richmond Manuf. Co. v. Atlantic De Laine Co., 10 R. I. 106, 14 Am. Rep. 658. Nor is it material that other causes have contributed to the pollution of the stream. This does not excuse the defendant for its wrongdoing. Crossley v. Lightowler, L. R. 3 Eq. 279. This is the principle of Corey v. Havener, 182 Mass. 250, 65 N. E. 69, and Ouliglan v. Butler, 189 Mass. 288, 293, 75 N. E. 726. Nor is this a case in which the defendant is simply discharging noxious matter into an already polluted stream. It is expressly found by the master that the water when it reaches the defendant's premises "is good, clean, clear brook water, fit for any kind of manufacture or for domestic use."

TRACING CLOTH makes a good window shade in drafting rooms where the sunlight from an unshaded window is too strong. It is also useful in shading electric lights.

Experiments With a Jewell Filter at the Posen Water Works.

By E. A. Gieseler, C. E.

Posen is a city of about 140,000 inhabitants, and the capital of the German province of the same name. It is an important fortress and for this reason it is imperative that the sources of its water supply should be located within the fortified lines.

The present supply is drawn from wells bored into the top layer of sand down to the underlying clay, which is reached at a depth of from 7 to 15 meters. This water, the so-called "Eichwald" water, is practically sterile, but contains a great deal of iron. It is conducted through a length of about 4,000 meters of 450-mm. syphons to the works in the city. There the water is aerated and filtered through slow sand filters. After having passed through these it is quite clear, and in every way satisfactory for household use.

This present daily supply of about 18,000 cub. met. is not sufficient for the growing needs of the city. Two ways are open to obtain an increase. The first one consists in a more exhaustive utilization of the present sources of supply by boring additional wells and by pumping instead of syphoning. The second way open for an increase of supply consists in the utilization of water which is also found within the fortified lines in abundant quantities at a depth of from 100 to 150 meters over a stratum of brown coal and which rises in the bored wells above the surface of the soil. From its contact with the coal this so-called "Herzog" water is of a deep brown color (about 1,000 degrees, according to the platinum-cobalt standard), but it is practially sterile, clear, without odor and taste and does not contain any objectionable substances. If it were not for its deep brown color, it would probably be fit for household use in its natural state.

TABLE 1.—ANALYSES OF EICHWALD AND HERZOG WATERS AND A MIXTURE OF EQUAL PARTS OF EACH.

	Eichwald.	Herzog.	Mixture.

Laboratory experiments have shown that when a mixture is made of Herzog and Eichwald water in certain proportions, then the color of the former and the iron of the latter are precipitated without any previous aeration being required. After removing the flocculent precipitate of this mixed water by filtration, a perfectly clear and sterile potable water is obtained. The coagulating action of the two waters on each other takes place very rapidly when both are fresh from the soil, while when they are not fresh from the soil a certain period of subsidence is required, the length of which seems in a measure to depend on the time elapsed be-

tween pumping and mixing the two waters. A paper has been published on the subject by Prof. Dr. Wernicke and Dr. Weldert in "Mitteilungen aus der Koeniglichen Pruefungsanstalt fuer Wasserversorgung und Abwaesserbeseitigung, Heft 8, 1907." From this paper the analysis of the two waters given in Table 1 has been taken.

The remarkable result obtained by mixing the two waters is ascribed by Professor Wernicke and Dr. Weldert to the action of the iron in the Eichwald water on the humic substances contained in a very finely divided state in the Herzog water. I quote again from the above mentioned paper as follows:

"Tests made for the purpose of determining the nature of the substance causing the brown color of the Herzog water have shown that this substance is not held in solution, but in colloidal solution, because in the first place the colloid becomes pectenised when heated to the boiing point, and, secondly, because, as is apparent from the following table, it does not diffuse through parchment:

Duration in Hours of Dialysis Test.	Chlorine mg. per Liter.	Permanganate of Potassium Consumed.
0	174	228
48	119	226
120	64	222

"Further tests have shown that the amount of colloid is about 60 mg. per liter when dried at a temperature of 110° C. The analysis of this residue has rendered the following result: Organic carbon, 7 per cent.; nitrogen, 3 per cent.; residue on ignition, 22; loss on ignition, 78 per cent.

"The residue on ignition, besides a small quantity of iron, consists principally of lime respectively magnesia and silicic acid . . . . The mixture of one part Herzog and one part Eichwald water, when filtered immediately after mixing, renders a clear effluent of a slightly yellowish color (7 to 12 degrees) and free of iron . . .

. . . The mixing of the two waters was tested in various proportions and it was found that the best proportion was between the limits of three parts Eichwald water to from two to seven parts Herzog water, in other words that 1 liter of the Eichwald subsoil water containing iron would remove the color of from 0.6 to 2.1 liters of the brown Herzog subsoil water and at the same time be freed of the iron contained in it. On the basis of these figures we can compute that 1 mgr. of iron precipitates from 2.2 mgr. to 7.0 mgr. of the brown coloring substance.

"Professor Wernicke's tests had shown that besides the proportion in which the two waters are mixed, the age of the water containing iron (the Eichwald water) was likewise of importance, in other words that the time elapsing between the taking of the Eichwald water from the well and the mixing of the two waters exerted an influence on the reaction. The brown deep subsoil water was indifferent in this respect. It found that the longer the Eichwald water was kept without special care being exercised, the slower the reaction would be. After all iron of the Eichwald water had been precipitated as hydroxide no reaction at all would occur.

"This is of importance as regards the theoretical explanation of the reaction. It corroborates Professor Wernicke's opinion that the precipitation of the brown color is caused by the iron contained in the Eichwald water, but only by such iron which is held in solution."

In view of these remarkable laboratory results it was decided to conduct experiments with a filter furnished by the Jewell Export Filter Co. with a view to demonstrating whether and under what conditions of subsidence and coagulation the Herzog water alone or a mixture of it and the Eichwald water could be made potable on a large scale, or, failing that, whether rapid filtration would deal as successfully with the aerated Eichwald water as the present slow sand filter does.

The experiments were made with a plant consisting of a 4-ft. Jewell filter, two subsidence tanks and a chemical apparatus, all of which were arranged in the usual way. The two subsidence tanks had an aggregate capacity of 18 cu. m., but this capacity was later on increased by the addition of further tanks.

a, Test not concluded.
b, With preliminary filter.
c, Milk of lime was poured on filter.
d, With preliminary filter; effluent good until end.
e, Effluent contained 0.1 mg. of iron; color of effluent, 7 to 12.
f, Effluent free from iron.

Experiments were commenced on Aug. 1, 1906. and were concluded on March 31, 1907. They included the treatment of mixed Herzog and Eichwald water alone without the use of sulphate of alumina and the treatment of Eichwald water alone without the use of sulphate of alumina.

It may be stated generally that the results obtained with the water containing iron were entirely satisfactory in regard to the quality of the effluent as well as in regard to the length of runs and the percentage of wash water required. The experiments with Herzog water were likewise successful so far as the removal of color was concerned, but they were not as sucessful as the one previously mentioned, either in regard to length of run and quantity of effluent furnished during one run, nor in regard to the percentage of wash water required. It was found, especially when using high rates of filtration, that the color would penetrate the filter bed after a comparatively short time. The results obtained are given in the appended tables, from which the conditions may be seen under which each individual test was made and how much water was satisfactorily clarified per square meter of filter bed during one run under such conditions. The limit of satisfactory clarification (removal of color) has been assumed at 15 degrees of the platinum-cobalt standard.

We will first consider the tests during which sulphate of alumina was applied, a summary of which is given in Table 2. No great difference was apparent in the action of sulphate of alumina on the pure Herzog water and on the mixed water. From a consideration of the figures of both tables we arrive by means of interpolation at the results given in Table 3, regarding the amount of water that can be satisfactorily clarified during one filter run:

Table 3.—Amount of Satisfactory Effluent Obtained per Square Meter of Filter Area During One Run. Mixed Water with Application of $Al_2(SO_4)_3$.

Rate of Filtration, Meters in 24 Hours.	When Applying per Cubic Meter— 30 gr. $Al_2(SO_4)_3$.	50 gr. $Al_2(SO_4)_3$.
120	20 cub. met.	30 cub. met.
110	28 " "	38 " "
100	36 " "	47 " "
90	45 " "	55 " "
80	53 " "	63 " "
70	61 " "	72 " "
60	70 " "	80 " "

It is clear at once from Table 3 that the high rates of filtration as well as the very low ones are practically out of question, because in the former case the filter runs are too short and in the latter case the required area of filter beds is too great. A rate of filtration of 80 meters when 30 grammes of sulphate of alumina are applied and a rate of filtration of 90 meters when 50 grammes of sulphate of alumina are applied, seem, however, to meet the practical requirements. In view of the considerable hardness of the raw water, there is not the slightest objection against the application of such quantities of sulphate of alumina.

When a rate of filtration of 80 meters is assumed with 30 grammes of sulphate of alumina being applied and a duration of subsidence of about 4 hours, then two daily washings would be sufficient and the amount of wash water used would not exceed 5 per cent. of the effluent. The existing slow sand filter bed in which the proposed rapid filter plant is to be accommodated affords space for fourteen 21-ft. Jewell filters, which with the rate mentioned above would furnish 36,000 cub. met.

During all these tests, the end of the run was brought about by the penetrating through the filter bed of the color, long before the loss of head had reached its highest limit. There is, therefore, no doubt that, if finer sand was to be used than that employed during the experiments, it would be possible to increase the velocity of filtration without at the same time increasing the dose of sulphate of alumina and the number of washings required.

We now have to consider the clarifying of the mixed water without the application of sulphate of alumina. A summary of the results obtained is given in Table 2. Six of these tests have been made with the aid of a preliminary filter and have yielded good results. For instance, with a rate of filtration of 93 meters, a sedimentation of 20 hours and the use of a preliminary filter, 43 cu. met. were obtained per square meter of filtering area in one filter run. A rate of filtration of 80 meters would therefore appear to be practicable and only require two washings in 24 hours. But the quantity of the wash water would certainly be great, as not only the filter proper but also the preliminary filter would have to be washed. Again, the space required for the entire plant would be very large. The tests made without the use of a preliminary filter are numbered 16, 17 19, 20, 22, 23, 25, 26, 28, 32 and 33. Their results have been produced graphically by laying off on the axis of abscissae the rates of filtration and on the ordinates the quantities of clarified water obtained per square meter during one filter run. The points thus obtained could be joined without any considerable deviation by a continuous curve and from this curve the figures of Table 4 have been obtained. This table contains a source of errors, inasmuch as the duration of sedimentation has not been considered.

It varied between $4\frac{1}{2}$ and 34 hours, but for the rates which practically come into question, namely those of about 60 meters, the average duration of sedimentation has been about 14 hours (tests Nos. 20 and 22).

Table 4.—Amount of Satisfactory Effluent Obtained per Square Meter of Filter Area During One Run. Mixed Water Without Application of $Al_2(SO_4)_3$.

With a filtration-rate of 100 met............	17 cub. met.
With a filtration-rate of 90 met............	22 " "
With a filtration-rate of 80 met............	28 " "
With a filtration-rate of 70 met............	35 " "
With a filtration-rate of 60 met............	43 " "
With a filtration-rate of 50 met............	53 " "
With a filtration-rate of 40 met............	65 " "
With a filtration-rate of 30 met............	79 " "

It is seen that when a rate of filtration of 60 meters and a sedimentation of 14 hours are employed the mixed water can be clarified under conditions that are admissible in practice. Two washings in 24 hours would be sufficient and the above mentioned plant of fourteen 21-ft. filters would supply a daily quantity of 27,000 cub. met. But it would be necessary to construct subsidence basins of very considerable size, and it should also be mentioned that the removal of color in none of these tests was as satisfactory as when sulphate of alumina was applied.

We now have to consider the tests which were made with the Eichwald water alone, without the use of sulphate of alumina. These tests were made with a rate of filtration of 93.4 meter and a subsidence of 3 hours 45 minutes, and again with a rate of filtration of 120 meter and a subsidence of $1\frac{1}{2}$ hour, the raw water being aerated before filtration. In both cases the result was excellent. According to the Royal Hygienic Institute at Posen the effluent was free from iron. At the same time the color was removed almost totally and even towards the close of each run it amount to only 12 degrees. In all cases the filter could be operated until the loss of head had arrived at its highest limit. With the rate of 93.4 meter a quantity of 643 cub. met. were filtered in one run and with the rate of 120 meters an average quantity of 461 cub met. was filtered in one run, as shown in Table 2. The amount of wash water used was considerably less than 2 per cent. of the effluent in both cases.

We may deduce from these results that the rate of filtration for this water may be considerably still more, when coarser sand is used in the filter bed. It is certain that a rate of 140 meters in 24 hours, with two hours of sedimentation, can be successfully employed and that then one daily washing will be perfectly sufficient, the amount of wash water used remaining below 3 per cent. With this rate of filtration the above mentioned plant of fourteen 21-ft. filters would have a daily capacity of 63,000 cub. met.

Table 5.—Sizes of Filter Plants Required at Posen for Different Methods of Supply and a Daily Capacity of 45,000 Cub. Meter.

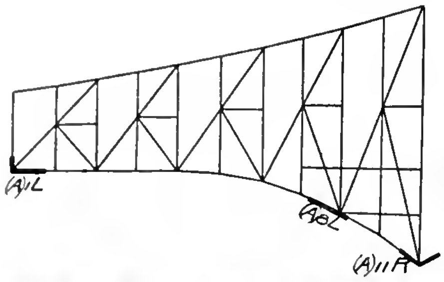
	Rate of Filtration in 24 Hrs.	No. of 21' Filters.	Capacity of Subsidence Required.	Dimensions of Filter House.	Total Area, Including Subsidence.
A	60 m.	24	26,300 cu. m.	93x19 m.	10,500 sq. m.
B	80	18	7,500	77x19	4,000
C	140	10	3,750	38x19	2,000

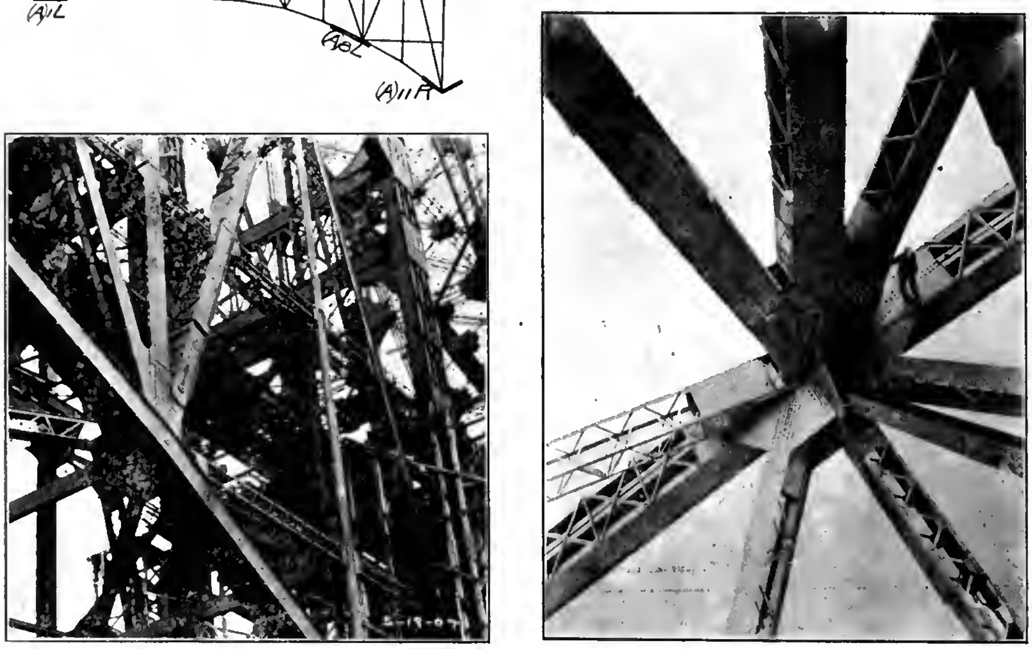
As stated in the above, the following three methods have been tested to obtain the necessary increase of potable water for Posen: (A), the clarifying of mixed water with application of sulphate of alumina; (B), the clarifying of mixed water without application of sulphate of alumina; (C), the clarifying of the water containing iron without the application of sulphate of alumina. The tests have shown that under certain conditions of subsidence and of rate of filtration all these three methods can be employed in practice, and we find that for a daily capacity of 45,000 cub. met. the size of plant required in each of the three cases is that given in Table 5.

Notes on Tar Macadam.

A paper read at the annual meeting of the Association of Municipal and County Engineers by C. F. Wike, City Surveyor, Sheffield.

These notes are not intended as an argument in favor of better roads. Discussion of road-making problems has recently been so thorough, and the demand for an improvement is so general, that road engineers need now only consider how the desired improvement is to be effected, and how paid for. The necessity has chiefly come about through the rapid development of motor traffic. Those interested in motors disclaim responsibility for the present dust nuisance and blame the roads, upon which, they say, motor vehicles have no more destructive effect than horse traffic. This, however, will





Second Bottom Chord Panel Point from Main Pier, Quebec Bridge.

scarcely be admitted by those engineers who have charge of the roads. In the opinion of the writer, the additional wear caused by self-propelled vehicles, and particularly by those fitted with non-slip devices, is considerable. Whether such vehicles ought to pay a larger contribution towards the upkeep of the highways is a question which undoubtedly will have to be fought out and settled.

One effect of the new traffic will be an extension of the paved roads leading out of the towns, and possibly a development in the direction of cheap paving. Another result will be that, where the amount of traffic and rateable value does not warrant the expense of paving, some other construction of road involving the least amount of dust will have to be adopted.

Where paving is too expensive, perhaps the best material for minimizing dust is tar macadam, which is by no means a recent introduction, it having been adopted in some of the Northern and Midland towns for at least thirty or forty years. In Sheffield it has certainly been laid nearly forty years, and it is with regard to what has been done in this direction that the following detailed observations are offered.

At present there are 392 miles of roads, of which 241 miles are macadam roads; about 151 miles of the latter are repairable by the Highway Authorities, and of these, nearly 10 per cent. are laid with tar macadam. The proportion may seem small, but the reason for this at once brings us face to face with one of the difficulties in the general adoption of tar macadam roads.

Many of the roads in the writer's charge have steep gradients, and no one who has had experience of tar macadam will suggest that it is a desirable material for hills. Up to the present a gradient of 1 in 20 has been considered sufficiently steep, and perhaps other engineers will be good enough to give their experience as to laying tar macadam on steeper gradients.

At one time most of this work was let by contract, and this is still the case to a liimted extent but about five years ago a plant was constructed by the corporation at an approximate cost of £1,000, consisting of sheds, iron-plated floors, with flues beneath for drying the broken stone, and heating apparatus for the tar compound. During the last three years the quantity of tar macadam prepared has averaged 2,300 tons per annum, in addition to 900 tons of tarred chippings for footpaths.

The specifications to which the tar macadam is made is as follows:

First Coat.—About 2 in. in thickness of limestone "dark" in color, and of approved quality, sound, hard and free from spar, and equal to sample. The stone to be broken uniformly to a $2\frac{1}{4}$-in. gauge.

Second Coat.—About $1\frac{1}{4}$ in. in thickness, of best slag, of sound, uniform material, free from honeycomb and dirt, from approved works, all equal to sample. The slag to be broken uniformly to a $1\frac{3}{4}$-in. gauge.

Third Coat.—About $\frac{3}{4}$ in. in thickness of slag shingle to a $\frac{3}{4}$ in. and $\frac{1}{2}$ in. gauge in equal proportions, free of dust, of the quality specified for the second coat, and eqaul to sample. The total thickness of the tarred material, after being rolled with the steam roller, to be 4 in., and the top of its surface to be $\frac{3}{4}$ in. above the level of the channels.

After rolling the roadway is to be covered with a dressing coat of granite chips ($\frac{1}{2}$ in. dust out) of approved quality and thickness, as may be ordered, and again rolled.

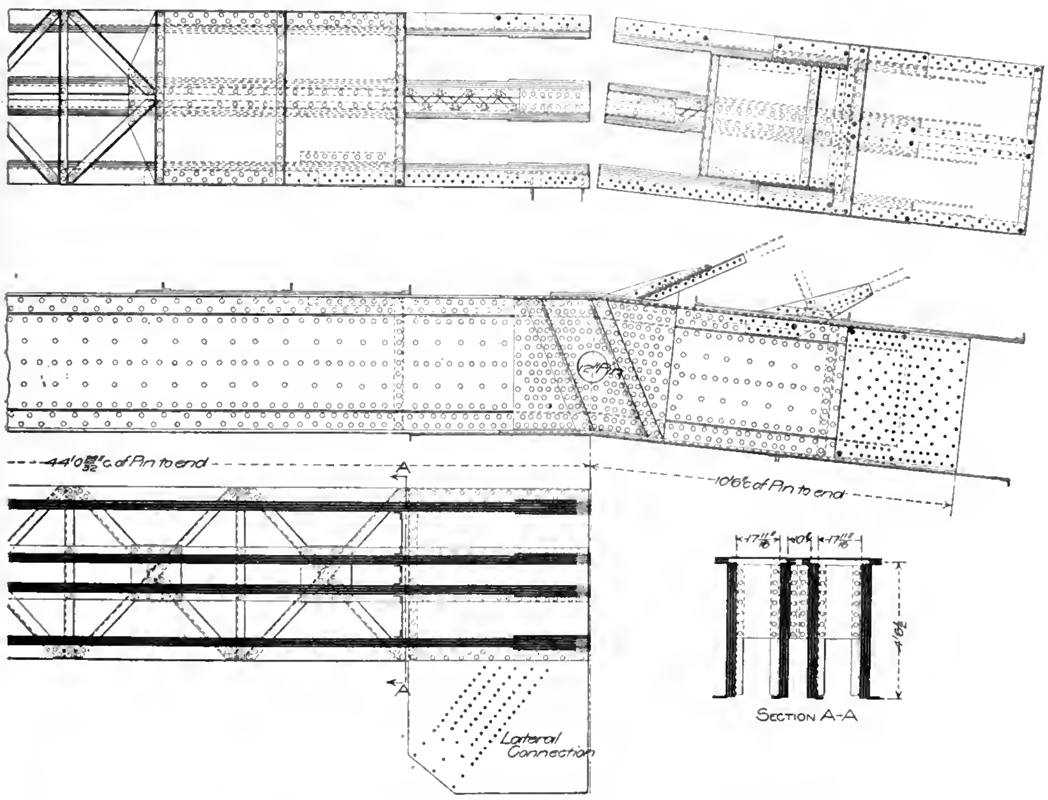
The whole of the limestone and slag must be thoroughly well dried on hot plates; a mixture of pitch and tar must then be boiled in the following proportion: For the first and second coats 90 imp. gal. tar and 125 lb. of pitch; and after boiling for two hours, 17 imp. gal. of the mixture must be mixed with 30 cwt. of the broken limestone and $1\frac{3}{4}$ in. slag.

For the third coat 14 imp. gal. of the above

mixture, after boiling, to be added to each cubic yard of shingle.

The limestone and slag to be perfectly dry and warm at the time of mixing, and the whole thoroughly turned over, so that every part of the surface of the stones will receive a coating of the mixture. The above-mentioned proportions may vary according to the quality of the pitch and the strength of the tar. The prepared limestone and slag is then to be put in separate heaps, and left a sufficient time to toughen before being laid. After it has been properly toughened and freshened with a further quantity of pitch and tar (if considered requisite), it is then to be spread on the foundation in layers as specified.

The cost of slag and limestone tar macadam is about the same. If of the best quality, probably slag is the better material, and in certain instances, it has been used for all three coats. The difficulty, however, is to get it sufficiently uniform and free from lime and other constituents which render it liable to early disintegration.



Intermediate Section of Lower Chord A_8L, Anchor Arm.

This is one of its disadvantages as compared with limestone, which can be obtained of uniform hardness, and, as the use of tar macadam increases, so will the difficulty of getting sufficient slag of suitable quality increase.

Granite has not hitherto been looked upon as a suitable material for tar macadam, on account of its want of absorption. It was laid by the writer nearly twenty years ago in several streets, but for the reason given, was not a success. It has recently been laid in some districts with tarred chips for binding, and similar work is in preparation in Sheffield. If the necessary adherence could be obtained, granite would, on account of its better wearing qualities, be more economical than either limestone or slag, and perhaps, with modern methods of retarring roads at frequent intervals, the old difficulty may be got over.

With regard to the cost of tar macadam roads compared with dry granite macadam, the initial cost is about the same, about *2s. 3d. to 2s. 6d.* per super. yard, exclusive of foundation, the extra expense of tarring being balanced by the fact that a cheaper material is used than the granite macadam usually employed for important main roads, when these are not paved. Statistics have been prepared with regard to a typical suburban road, taking a considerable amount of traffic, and the annual charge (including initial cost) for a period of fourteen years has averaged about *4d.* per square yard; this is for a fairly flat road. In another case—a road with light traffic—the average has been a little less than *2½d.* per square yard.

If the best results are to be obtained, it is very advisable that, after the first laying, tar macadam should be kept in thorough repair, and for many years it has been the practice to tar paint the surface at intervals of three or four years, or as soon as roughness begins to show. This has been done not so much with the idea of laying the dust as to prolong the life of the tar macadam.

At present a considerable mileage of dry macadam road is being tar sprayed, and, so far as can be seen at present, it will be practicable to apply this system to gradients steeper than those upon which tar macadam has been laid. Nevertheless, there must be a limit to the gradients upon which tar can, in any form, safely be employed, as it is a material very susceptible to heat, and slippery in hot weather.

To sum up the writer's experience, tar macadam is a very suitable and economical material for many situations, and its use is bound to increase, but it has its restrictions, the principal one being that it cannot safely be used for roads with a considerable gradient. So far, the materials used have been inferior in durability to granite or whinstone, and therefore it has not been suitable for macadam roads with the heaviest traffic. The great advantages are the comparative absence of dust, and the quietness. Tar macadam roads are also economical in the matter of cleansing. The introduction of tar-spraying apparatus has materially helped to minimize the dust nuisance, and it is through the application of tar, in one form or another, that the nearest approach to a dustless road must be looked for, where paving (which, after all, creates the least dust) cannot be used.

THE TREES ALONG STREETS in East Orange, N. J., are under a Shade Tree Commission, of which Mr. Alfred P. Boller is president. It plants and prunes trees, carries out measures to destroy insect pests, and repairs injured trees.

The Quebec Bridge Superstructure Details.—Part VII.

Anchor Arm Bottom Chords.—The bottom chords of the anchor arm trusses form chords of parabolic curves with 500-ft. span and 112 ft. rise, divided into ten panels of a uniform horizontal projection of 50 ft., which, at the river end where the inclination is nearly 45 deg., gives a maximum length of about 68 ft. on centers. All vertical and sub-vertical posts are connected to the lower chords with 12-in. pins and the connections of the diagonal members of the trusses are made through the lower ends of the vertical posts so that they are not directly attached to the chord members.

The bottom chords have a uniform rectangular cross section 4 ft. 6 in. deep and 5 ft. 7½ in. wide, made with four built channels with the thicknesses of their webs and the sizes of their flange angles varied to correspond with the total cross-sectional areas of 301 to 776 sq. in. The top flange angles on the two inner channels are turned inward. All other flange angles are turned outward. The flanges are connected by ½-in. batten plates at the splices and between them are divided into panels about 5 ft. long by transverse 3x3-in. angles. Each panel is X-braced with 3x3-in. lattice bar angles having two rivets in each end. On the top flange both of these angles are continuous, one of them having its vertical flange cut to clear the other. They are riveted together at the intersection and have one rivet in each flange of the chord channels. Batten plates are riveted across the lower flanges of the inner channels of the chords where the lattice angles intersect them and serve as splices for one of the latter, which is cut to clear the other, running continuously across it and secured with four rivets. At panel points the lower bottom plates project beyond the inner face of the chord to form, with parallel plates field riveted through the upper flanges opposite them, jaw plates for the field riveted connection of the lateral struts and diagonals.

As the chords change direction at panel points they are cut through there, and have at these places radial butt-joints spliced with shop-riveted web cover plates one on each side of the outside webs and one on the outside only of each of the inside webs. In order to facilitate erection the field riveted splices between the bottom chord sections are made at points 10½ ft. beyond the panel points on the river side. This arrangement enables all members to be connected at any given panel point without assembling the lower chord section for the next panel.

The eighth panel from the anchorage of the bottom chord is typical of the intermediate panels in the anchor arm truss, is 54½ ft. long over all and weighs 164,000 lbs. It has a maximum stress of 15,079,000 lb., and a gross cross sectional area of 767 sq. in. Each channel is made with three 54x13-16-in. and one 37¾x13-16-in. web plates riveted together with five lines of rivets exclusive of two lines in the vertical flange of each of the two 8x6x15-16-in. flange angles. The ends of the chords are stiffened in the field splices by vertical diaphragms and the field splices are made with 1-in. rivets through the webs of the outer channels and 1-in. turned-bolts through the webs of the inner channels which are inaccessible for field riveting. The open holes enclosed by hexagons, in the drawings, indicate shipping bolts.

The bottom chord in the river end panels of the anchor arm truss is 39 ft., 2⅞-in. long over all and weighs 120,000 lbs. It has a maximum stress of 16,129,000 lb. and a cross sectional area of 842 sq. in. The outer ribs are each made with two 54x15/16 in. web plates, two 46x15/16-in. side plates and two 8x3½x15/16-in. flange angles. The inner ribs are each made with three 54x15/16-in.

web plates, one 37¾x15/16-in. side plates, and two 8x6x15/16-in. flange angles. This section of the chord is special in that it has no pin connection, the connection to the main vertical post over the center pier being made with a riveted splice to the short section engaging the pedestal at this point.

The bottom chord section in the shore end panel of the anchor arm truss is special on account of the connections for the inclined end bars and the vertical portal post and the provisions made for the group of vertical anchorage bars connecting it to the reaction platform in the bottom of the pier. This section is 43 ft., 1⅛-in. long over all and weighs 119,000 lb. Its maximum stress of 4,950,000 lb. is less than that of any other section of the bottom chord and is provided for by a cross sectional area of 301 sq. in. The ribs are each made with a single 54x15/16-in. web plate and two 8x6x15/16-in. angles and are divided into 4½-ft. panels by inside vertical 3x3-in. stiffener angles. The river end of this cross section is like those of the other pieces except that the splice is made on the shore side of the pin. At the shore end the flange angles terminate about 2 ft. from the panel point and the webs project 2 ft. beyond it and are bored for a 10½-in. pin engaging the vertical anchorage eyebars. A slot 1 in. wide and 4½ ft. long is cut through all of the webs on the center line about 6 ft. clear of the panel point to receive a 53x¾-in. horizontal diaphragm plate about 5 ft., 2 in. long, which is connected by a pair of horizontal angles to each of the webs and affords connection for two intermediate vertical webs. The main webs are spliced about 10½ ft. from the end of the chord to short end sections 120 in. wide and 15 in. thick, which, with the two intermediate diaphragms of similar shape, provide 6 wings or jaws, engaging the foot of the inclined end bars with the 12-in. pin on heavily reinforced bearings. The plates extend beyond the pin hole to the end of the chord and above it are connected and stiffned by two sets of transverse diaphragm plates, thus making a massive rectangular pillar field riveted to the double end floor beam and receiving from it the heavy lateral stresses which are transmitted to the masonry pier.

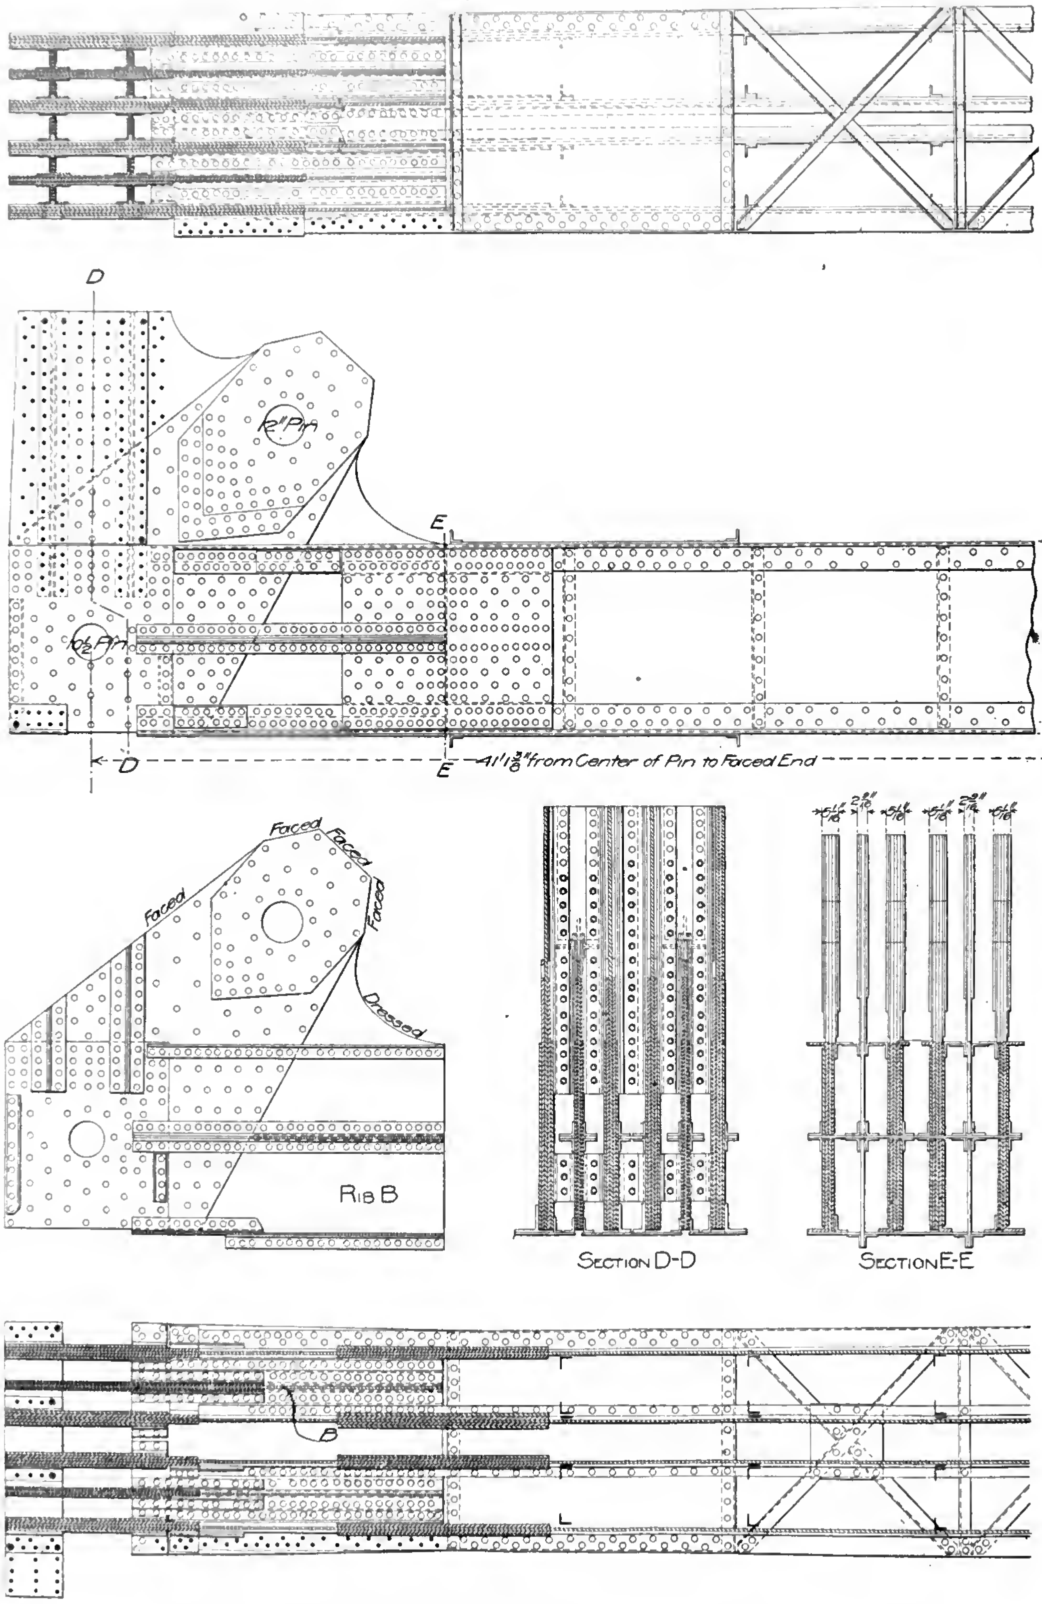
The bottom chords in the anchor and cantilever arm are connected together over the river pier by a special V-shaped section about 23 ft. long and 9 ft. high over all exclusive of end splice plates, which weighs about 40 tons and was riveted up complete in the shop and shipped as a single piece. It has 4 massive webs corresponding with those of the chord sections and is bored at the intersection of the center lines of the two wings, to engage the 24-in. pin through the foot of the main post. The webs interlock with those of the shoe and pedestal and provide full hole bearings of an aggregate length of 15 in. The ribs are made in halves with vertical butt joints on the center lines, each half rib has 4 full-length 15/16-in. web plates and two 6x8x15/16-in. flange angles. The halves of each web are spliced together by two cover plates on each side which are continuous across the center line and are bored with full pin holes.

The webs are connected on each side of the pin by three sets of oblique solid plate diaphragm, one of them parallel and one perpendicular to the axis of the chord and the third one making an angle of about 30 deg with it. Except near the vertex, the flanges are connected by top and bottom cover plates with open holes to match those in the inclined plates shop riveted to the shoe and pedestal with which they are field riveted or bolted. Four lateral connection plates with maximum dimensions of 117¾x½x120 in. are shipped loose and are field riveted to the top and bottom flanges as indicated in the general plan and elevation to receive the main bottom lateral members. The outer edges of these wide plates are stiffened by single 6x4-in. angles.

(To be Continued.)

Open Tank Timber Treatment.

The open tank treatment of timber is rapidly gaining favor, according to the Forest Service of the Department of Agriculture. The reason for this is that the appliances necessary for the treatment can be readily transported from place to place and are comparatively inexpensive, whereas the retorts and other apparatus required for the treatment of timber by the older methods are expensive and permanent. Hence, preserving plants have been located at lumber centers as a rule, where a large business might be expected, and the transportation charges to and from the treating plant have been quite heavy. The equipment for open-tank treatment, consisting of an open tank warmed either by steam coils or by a fire below, is so simple and low in cost that it is within reach of small companies and contractors. Moreover, it is so portable that it can be taken into the heart of the forest if necessary. An advantage claimed for the process is that it can be applied effectively to parts of timbers which are particularly subject to rapid decay, such as butts of fence posts and telephone poles, without wasting preservatives on other parts. It is also applicable to the treatment of mine props, cross-ties, piles, shingles, and small timbers of loblolly pine, black and tupelo gum. Western yellow pine, lodgepole pine and similar kinds of wood. According to the Forest Service, fairly good results have also been obtained in treating arborvitae, chestnut and red oak, but the experiments thus far made do not warrant the application of the method to the treatment of piles and ties of such woods. While the open-tank treatment does not ordinarily secure so deep a penetration of the chemicals as is secured by the pressure retort method, it is considered sufficient to protect timber for many purposes.



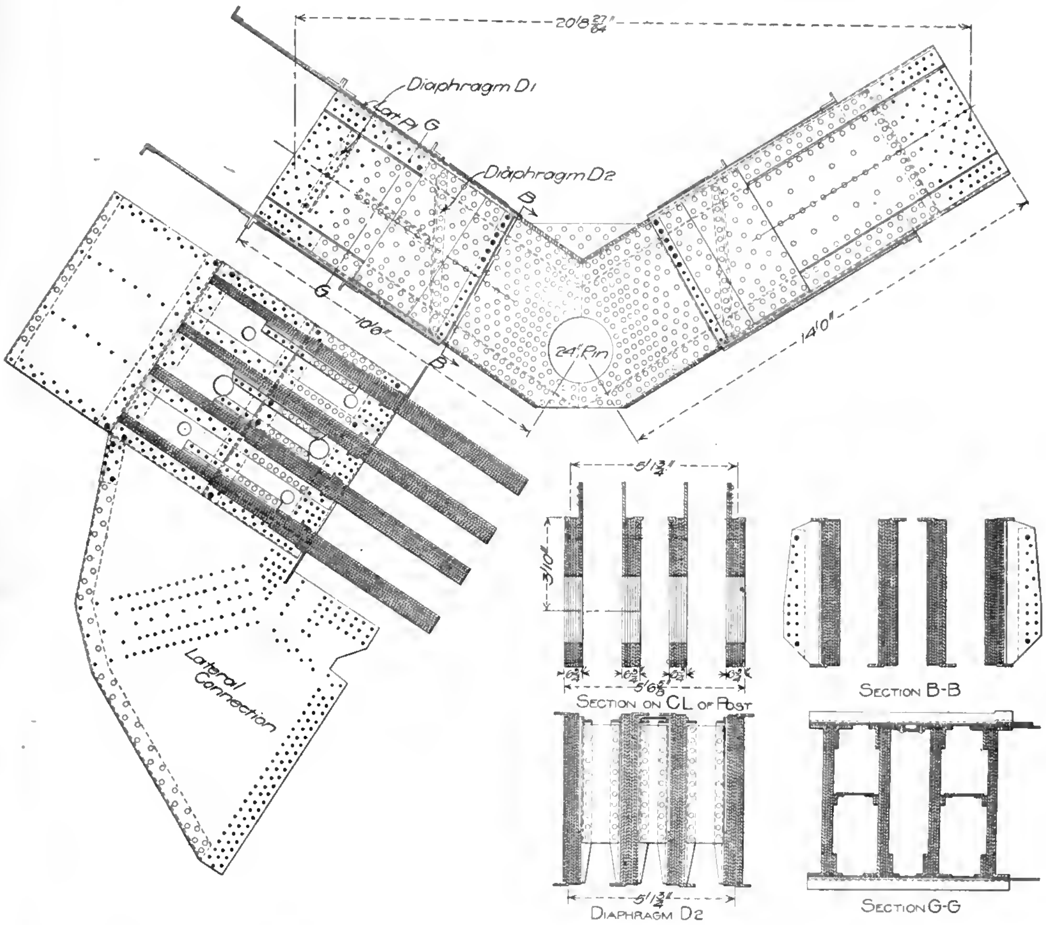
Lower Chord A₁ L at Shore End, Anchor Span, Quebec Bridge.

The Concrete Pier at Newlyn Harbor, England

The Newlyn south pier or breakwater, 25 ft. wide on top and 707 ft. long, is built of concrete on solid rock in water of a maximum depth of 14 ft. The concrete was cast in 15-ft. sections in molds made of shutters, placed by divers, on vertical transverse falsework bents. Each bent had a center vertical post and two side posts battered respectively 1:8 and 1:12 to correspond with the inclined faces of the pier. The posts were single 10x10-in. timbers about 40 ft. long, with their lower ends seated in shallow pits excavated in the surface of the bed rock and loaded with sufficient kentledge to overcome their buoyancy. In each transverse bent the posts were connected by horizontal struts bolted across them at just about low water level and at the top. The two upper panels thus formed were X-braced with single 6x6-in. angles and the entire bent considered as a single panel was X-braced with chains reaching from top to bottom of the posts and adjusted by turnbuckles. Similar adjustable transverse guys in the planes of the bents were attached to the tops of the outside posts and were anchored by a weight on the bottom of the bay. The bents were anchored by a weight on the bottom of the bay. The bents were X-braced longitudinally by adjustable chains.

Before each batter post was sunk one end of a long longitudinal angle was bolted to it, and after it was in position the other end was bolted to the adjacent bent by a bolt with an eye head, which was easily turned by a diver inserting a cross-bar into its eye. Greased eye-bolts also projected through the inclined posts into the interior of the mold, and were easily removed by divers after the concrete was in positon. The shutters or sides of the molds were made in sectional panels, the lower ones having cast-iron cutting edges which not only served to sink them but penetrated into the shallow layer of sand overlying the surface of the rock. These panels were provided with outside vertical cleats projecting above the upper edge and serving as guides to receive the lower edges of the successive upper panels, which were sunk to position by saddle castings afterwards hoisted to the surface by means of lines. The shutter panels were placed and the surface of the rock cleaned by divers, who also leveled off the concrete deposited under water. Up to low-water level the concrete was made 1:8 with large granite stones embedded in it, but was faced with 3 ft. of 1:4 concrete. The upper part of the pier was made with 1:10 concrete with a facing 12 in. thick. The work was executed with hand derricks and cost about $150 per lineal foot.

Subsequently another pier 40 ft. wide and 1,025 ft. long was built with two parallel concrete face walls chained together at distances of 100 ft., and filled between with rubble. As this pier was nearly all built above low-water level, ordinary molds were used for the concrete and no difficulty was encountered in its construction. A third pier, 890 ft. long, in water 14 ft. deep, was built with 10-ton molded blocks of 1:6 concrete lowered by an overhead gantry on a concrete bed made by divers. Mr. J. C. Inglis was the engineer, and Messrs. Hill & Lester, of London and Plymouth, were the contractors. The details of the work were described in a recent issue of "Engineering," London.



Section of Lower Chord over Pier A11 R Connecting Arms, Quebec Bridge.

THE DECOMPOSITION OF CEMENT in sea water is the subject of a valuable monograph by Henry Le Chatelier, in the "Annales des Ponts et Chaussées." His investigations led him to the conclusion that all hydraulic cements are decomposed by sea water, but at very unequal rates. This decomposition is slower as the content of alumina is lower and as the hydraulic index is higher. Quick-setting cements with high sulphate of lime and a high hydraulic index give very satisfactory results. The addition of pozzolana produces a considerable increase in the resistance. A dense mortar seems to be most essential to ensure the preservation of concrete in sea water. On this account, independently of all chemical action, the addition of pozzolana is important as increasing the density of the mortar.

Book Notes.

About five years ago an investigation of allowable pressures on foundations was made by Dr. E. L. Corthell in connection with harbor works in South America. He sent a circular letter to about 300 engineers in different countries, asking them to send him notes of actual pressures and attending settlements, if any, that had come under their observation. About one-tenth of those to whom these letters were sent replied, and from them voluminous tables giving facts regarding 178 works were compiled. This material was worked up as a paper for the Institution of Civil Engineers, which printed a very brief abstract of it about a year ago. The information in the paper would thus be practically lost for useful purposes, since but very few engineers have access to the unpublished manuscripts in the records of the Institution, had not Dr. Corthell arranged for the publication of the paper in full for general sale. In this way a quantity of valuable information relating to the pressures actually imposed on deep foundations is now available, and will unquestionably prove of much value to those engaged in foundation work of any sort. The paper is entitled "Allowable Pressures on Deep Foundations," and is sold in this country at $1.25, with the imprint of John Wiley & Sons, New York.

A few weeks ago attention was called in this journal to some studies made by Dr. A. S. Cushman, assistant director, Office of Public Roads, throwing much light on the nature of the corrosion of iron. A great deal of comment has been made on this announcement, and naturally enough some of these criticisms have been unwarranted on account of their proceeding from incomplete knowledge of just what Dr. Cushman has personally claimed regarding his studies. It is accordingly gratifying to state that the Office of Public Roads has issued for free distribution a monograph on the subject, written by Dr. Cushman, and containing all the information it is considered advisable to give out concerning his work at present, together with a resume of work done by others along the same line. It will be seen that the author draws attention to the investigations of Dr. Whitney, Dr. Walker and others, and it is probable that had the similar theory advanced by Mr. Freeland Howe, Jr., in a trade publication some time ago been available in scientific journals it would have similarly been noticed, although it does not appear to have been founded on experimental evidence. Dr. Cushman does not claim that no other man has ever understood the fundamental reactions upon which the rusting of iron depends, but merely states that he had to work the subject out for himself, for the available literature was unsatisfactory. The investigation was started in connection with investigations of the corrosion of fence wire requested by farmers in letters to the Agricultural Department and opens up an important possibility of using sheet iron for culverts on some classes of roads. The pamphlet explains the carbonic acid and the peroxide theories of the corrosion of iron and the reasons for considering them unsatisfactory and then outlines the electrolytic theory. Methods of stimulating and inhibiting the corrosion of iron are then explained, and the action of hydrogen peroxide on iron is discussed at some length. There is an interesting account of experimental work demonstrating electrolytic action, and the pamphlet closes with an account of some practial work done in applying the theory to prevent rusting. On account of the great interest shown in the subject, the pamphlet must be regarded as one of the most important issued by the department of Agriculture for some time.

Letters to the Editor.

A System of Structurally Reinforced Concrete.

Sir: In view of the regrettable accidents to reinforced concrete buildings at Rochester, Philadelphia and other places, it is a pertinent question whether it is not possible to make the designs of such a character that they may be "foolproof;" so that if foreign substances are accidentally introduced, or a batch of bad concrete escapes the inspector's notice, or an ignorant workman knocks out some props while the foreman's back is turned, the structure will not suddenly collapse. Such a design the writer here shows and he has been assured by several eminent engineers that it possesses features of merit.

As will be seen by the accompanying drawing, a structural steel column is utilized and for the bottom reinforcing metal of the girders and beams a pair of angles are used. These are connected to the column by means of diagonal shear bars and at intervals along the angles other shear bars, with their ends curved over to give adhesion to the concrete, are spaced as needed for the requirements of shear. These shear bars are securely connected to the angle by means of bolts and, being inclined, the shear or diagonal tension is transmitted by them directly to the bottom reinforcing angles. The beam acts like a Warren truss, the steel shear bars resisting the diagonal tension and the concrete the diagonal compression. To transmit the horizontal component of this latter to the reinforcing angles, rounds are introduced through the angles of the girders, and these together with the bolt heads and nuts and the adhesion of the concrete to the steel will amply provide for the development of all the tensile stresses in the bottom reinforcing angles.

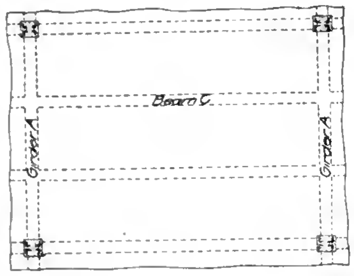
Where the beam intersects the girder a pair of light angles are placed near the top of the concrete to provide for the negative moment and prevent cracking over the girder. Several of the shear bars adjoining the girder are connected to these top angles for the purpose of developing their strength. While in the present design the girders are figured as if they were non-continuous, it might be permissible to figure them as being continuous.

A comparison of costs of this system of construction and for the standard steel cage system reveals a saving of about 10 cents per square foot of floor or about 37 per cent. for this typical floor panel. Some of the advantages of this system of reinforced concrete construction are as follows:

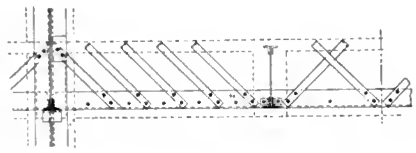
By providing a structural steel column and making a connection thereto by seating the bottom reinforcing angle on a shelf and running a diagonal bar from the angle up to the column and securely fastening the other bars to the angle, it is possible to thoroughly reinforce the beam for diagonal tension or shear, and it gives enough strength to the beam even when the concrete is green or of a poor mixture or weakened by the presence of foreign matter to guard against sudden collapse. If the forms are removed after only a few hours, the result would probably be either the concrete would crumble and drop to the next floor in small fragments not large enough to make their impact injurious or else the concrete would hold together and although perhaps it would sag perceptibly, it could not give way in a sudden manner. The angles securely tied to the column would by virtue of their tensile strength keep the structure from a sudden collapse and if the concrete had any compressive strength at all the shear bars would be brought into action, fulfilling the function of providing for the diagonal tensile stresses and by virtue of their being securely fastened to the bottom reinforcing bars, the structure would act as a whole as above stated in a manner similar to a Warren truss.

By bolting on the shear bars they may be spaced as required, the spacing being ascertained in a manner similar to that of finding the pitch of rivets in the flange of a plate girder; that is, the shear at any point is divided by the value of one bar and the quotient represents the number of bars that should be in a length equal to the effective depth of the beam. This is a distinct advantage over the method of having the shear bars a uniform length, size and spacing, or of having rods bent up at the ends of the beam only and making no provision for the intermediate shear.

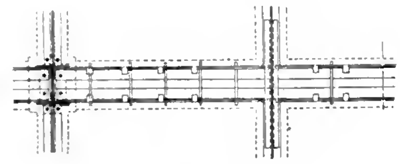
In buildings of four stories or more in height it is usually necessary in order to keep the size of interior columns down to moderate dimensions



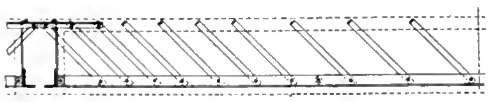
Typical Floor Panel-Plan



One Half of Girder A



Plan of One Half of Girder A



One Half of Beam C

Structurally Reinforced Concrete.

to use a core of structural steel up to within one or two stories of the roof, and in Philadelphia when this is done the building laws require this core to be designed to carry the whole load. Hence, for a building of this height or more the cost of columns would be little more for the system here described than for a rod system. As for the cost of the beam and girder reinforcing, the angles would be shipped punched in one leg only and the shear bars bent at one end and punched in the other, so that the cost of the fabricated material should be quite low, say about 2.7 cents per pound in the east f. o. b. cars and for large jobs a portable punch might be used and the cost materially reduced below the above mentioned figure, perhaps to 2¼ cents per pound. It would seem therefore that the cost of the reinforcing material might be considerably lower than the most of the patented assembled rod systems now in the market.

By using angles and shear bars as shown there is no danger of the reinforcement being displaced by depositing of the concrete, and an inspector could tell at a glance if all the material required was in place.

By using this system, concrete construction could be safely applied to buildings of twenty stories or more in height, for the connection between the concrete beams and girders and the structural columns, being rigid, could be designed to provide for wind pressure or earthquake. It also would be well adapted for use in subway work where it is necessary to use steel columns to keep their dimensions down to a minimum.

The writer feeling that there is a wide field for the above described invention and believing that reinforced concrete construction must eventually come to some such system has protected the salient features of the above by letters patent.

Winfield W. Conard.

Norristown, Pa.

A Proposed Municipal Engineering Board.

Sir: Will you assist one of your readers by advice or comment to form an opinion in the following matter:

A certain city has a number of engineers at the heads of its different departments. For instance, there is a city engineer, who has charge of paving, etc.; a hydraulic engineer, who has charge of the water department; an electrical engineer, who has charge of electric subways, conduits, etc.; a harbor engineer, who has charge of the work around the water front; and a park engineer, who has charge of the engineering work in the park department; also a superintendent of street cleaning. These men are selected, in theory, at least, for the special ability each is supposed to have for his particular work.

It is proposed to form a board of engineers of the above departmental heads, and that this board of municipal engineers, as a whole, form a board of consulting engineers for the members of the city government. In the case of criticism of the plans of any one of these engineers, this board will pass an opinion on such plans, and thus determine for the lay members of the city government the justice of the criticism mentioned. If approved by the mayor, this board may correct or change the plans of the departmental heads to meet the ideas of the mayor and this board as a whole. It is stated that, under this idea, the city may be saved the fees of experts that might otherwise be called in.

Let us assume that within the sphere of his duties, each departmental head is an expert. Waiving the question as to whether the advice of an electrical engineer would be valuable on a question of piling, or whether the opinion of the street cleaning commissioner be worth anything on questions concerning the details of water supply, the question arises in the mind of your inquirer as to whether or not these engineers, joining in such a board and responding to requests for advice on subjects in which they may be inexpert, are doing themselves and their profession justice.

We hear a great deal of complaint, from time to time, regarding the small salaries paid members of the engineering profession. Your paper has several times suggested that the blame for this might frequently be laid at the doors of the individual members of the profession, and that a proper appreciation of his duties, responsibilities and ethics would do much toward placing the engineer and the profession in such a light before the general public as would result in the latter willingly paying a competent engineer a proper compensation for his work.

Should an engineer, no matter how thoroughly familiar with one specialty, allow himself to be placed in a position of advising or criticising the specialty of another and in which he is not thoroughly posted? Will your other readers interested, out of the breadth of their experience, help to clear up the mind of your inquirer by a frank statement of opinion?

Very truly yours, Specialist.

[This plan is about the worst example of executive confusion The Engineering Record has heard suggested. It is discussed in the editorial pages of this issue.]

THE ENGINEERING RECORD

PUBLISHED WEEKLY BY THE

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:
114 LIBERTY STREET, NEW YORK.

BRANCH OFFICES:

CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.

LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico..........$3.00 a year
Canada.................................$4.50 a year
Foreign subscription...................$6.00 a year
25 shillings. 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGES OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,250 copies are printed. Total circulation for 1907 to date 479,250 copies, an average of 14,522 copies per week.

TABLE OF LEADING ARTICLES.

Electric Locomotives on Mountain Grades.

Engineers are so accustomed to the high cost of operation, the dangers, the delays and limitations inherent in the operation of mountain divisions of railroads with steam locomotives, that these things have come to be looked upon as essentially inseparable from mountain railroading. Until the trial of the Mallet compound locomotive, with its tremendous weight on drivers and correspondingly increased drawbar pull, it had been necessary to break up long trains at heavy grades and operate each of the sections with two or more steam locomotives of the largest capacity. The Mallet compound has done much to improve conditions where a large drawbar pull and great horse-power capacity are required, but the results thus far obtained in its operation still leave much to be desired, especially in view of the improvements in operating methods which seem to be possible with the adoption of the electric locomotive.

Electric operation on mountain grades appears to offer many advantages of greater importance than a generally admitted small saving in the expense of fuel, though this in itself may prove a most attractive feature under certain conditions and in certain localities. Admitting that electric power produced in hydroelectric stations costs less per ton-mile hauled than coal inefficiently burned under the abnormal overload conditions obtaining in steam locomotive operation on mountain grades, this item in itself will seldom show a sufficient return on the capital required for electrification to make it attractive to the steam railroad management.

It is a well known fact that the figures given in annual reports for locomotive maintenance running from six to ten cents per locomotive-mile do not apply to those locomotives operating under heavy grade conditions, and a maintenance charge ranging from ten to eighteen cents per locomotive-mile is not uncommon in this class of work. It is contended that the electric locomotive can perform the same service with a much less maintenance charge than is required in steam locomotive operation; while the 50,000-mile endurance run of the New York Central locomotive extended but a year, it showed a maintenance charge of less than one and one-half cents per locomotive-mile, and it is probable, according to electrical specialists, that an electric locomotive properly proportioned for service can be maintained for much less than a steam locomotive performing the same service. Just what the gain will be in this direction is not apparent from operating figures, and it will be interesting to see results from the New York Central electric zone after electric locomotives have been in service operation for a year or more. The saving in the maintenance charge of locomotives is reflected more generally than merely in labor and material for necessary repairs, as a low maintenance account means great reliability, and freedom from breakdowns and delays, so that if all expenses due to failure of locomotives in service were charged directly to maintenance of locomotives this item would assume formidable proportions. Hence, a saving in this item is of far-reaching importance and should prove a valuable asset to the electric locomotive on heavy-grade work, where the conditions of operation are very exacting as regards performance of the motive power.

The great advantages offered by the introduction of the electric locomotive seem to lie more in the direction of increasing the tonnage capacity of the single track, commonly met with on heavy grade divisions, and the general reduction in cost per ton-mile resulting from the handling of heavier trains at higher speeds with a certainty of operation not shared to an equal extent by the steam locomotive. Where the capacity of the electric motor is properly proportioned to the work which it has to do, there is no doubt of its being a highly efficient and extremely reliable piece of apparatus, requiring little or no attention, only periodic inspection, and with complete independence of the round houses, coaling towers, water tanks, and ash pits, required for the frequent repairs and grooming of the steam locomotive. This freedom of action and reliability must be reflected in a greatly increased daily mileage, a lower crew expense, and a considerable curtailment of the false mileage common to steam locomotive operation.

The electric locomotive is merely a transforming or converting piece of apparatus and can draw an unlimited supply from its distant stationary power house; hence its output is limited only by mechanical considerations, and the result is a type of locomotive capable of delivering an enormous power if designed to do so. Its motive power can be sub-divided into several motor units without loss in efficiency or increase in dead weight, thus permitting a construction which can utilize the entire weight of the locomotive upon the drivers and still keep within the recognized limits of weight upon each driving axle. Not only can the motive power in one locomotive structure be divided to suit the convenience of construction, but two or more locomotives can be coupled together and operated by a single motorman in the cab of the leading locomotive. While the steam locomotive, and especially the larger types as represented by the Mallet compound, is seriously handicapped by the difficulty and expense of stoking, the electric locomotive can be operated in groups of two or more by a single operator who has under his complete control the 2,000 or 3,000 h.p. concentrated in each of the several locomotives of the group. The possibilities opened up in this direction are enormous.

A steam locomotive is considered large when its boiler is capable of sustaining an output of from 1,500 to 2,000 i. h.p. The electric locomotive, on the other hand, as represented by the 3,400 type now operating on the New York Central, can give a sustained output of 2,200 h.p. rated with ample margin of overload in excess of this. It should be well understood also, that this 2,200 h.p. output of the motors is obtained with a total weight of something less than 100 tons, of which 68 tons is upon the drivers, and this locomotive was designed for a specified duty and does not in any way represent the maximum possibilities of electric locomotive construction.

It seems entirely practicable to construct an electric locomotive or a group of electric locomotives capable of delivering any drawbar pull permitted by the strength of the drawheads, and,. moreover, this drawbar pull can be delivered at any speed desired, in this respect far exceeding the possibilities of steam locomotive construction. This means that instead of operating trains downgrade at a maximum speed of from 25 to 30 miles an hour and up grade at a maximum speed of from 6 to 12 miles per hour, it is possible with electric locomotives to operate at any speed up grade that is consistent with the alignment of the track. In other words, the same schedule speed can be maintained up grade and down grade, thus greatly facilitating the movement of trains on heavy grade sections and vastly increasing the tonnage of the tracks.

Air brake equipments on all cars have contributed towards increasing the size of trains and safety in operation on mountain grade sections, but such operation is still handicapped by the limitations and dangers attending the holding of a heavy train on a downgrade of long extent. As the electric locomotive is a convertible piece of apparatus, changing electricity into mechanical power and vice versa with equal efficiency, it offers a means of relieving the air brake entirely or in part, and performing the functions of braking by returning electricity to the line. Elimination of air-brake shoe troubles and overheated tires, will be appreciated by steam railroad operators as soon as this valuable feature of the electric locomotive becomes well understood, and aside from the economic value of electric braking, it offers much towards the safety of carrying passenger trains over mountain grade sections.

This is peculiarly an age of engineering struggle and the battle between high-power guns and armor plate is equally reflected in railroading between the constructors of locomotives and the builders of roadbeds. The electrical engineers seem to have available a type of locomotive which can use existing roadbeds without subjecting them to additional burdens, at the same time ensuring material economies over steam locomotive operation. The initial step towards electrifying mountain divisions has already been taken by the Great Northern Ry. in equipping its Cascade Tunnel, and larger projects are under careful consideration by other roads, and will probably result in more electrified heavy-grade sections in the near future.

The Cambridge Bridge Over the Charles River.

The recent dedication of the Cambridge Bridge between Cambridge St., Boston, and Main St., Cambridge, which has been under construction for several years, is an event highly gratifying to those who believe that bridge work in this country is capable of a much higher artistic development than is generally permitted by those paying for the structures. The Cambridge Bridge has been in charge of a commission consisting of Dr. E. D. Leavitt and the mayors of the two cities it connects. To the public spirit of Dr. Leavitt is largely due the success of the commission's work, for through his influence it was determined at the outset that this bridge should not be a mere utilitarian structure, spanning the river between these two cities with a minimum expense for steel and masonry, but should be a structure worthy of the importance of the site and an ornament to the great parkways which have already been partly developed along the banks of the Charles River, and eventually will extend along both banks for a distance of over twenty miles, forming a water park of the first rank. The technical features of the work were assigned to Mr. Wm. Jackson, city engineer of Boston, and Mr. E. M. Wheelwright, the well-known Boston architect. The assistant engineer was the late John E. Cheney, who took a deep interest in it and left the imprint of his skill as a designer in all the structural details, some of which have already been illustrated in this journal.

Before any plans were prepared, Messrs. Jackson and Wheelwright visited Europe to become thoroughly familiar with the bridges in the important cities across the Atlantic. It may be recalled that The Engineering Record printed some years ago a series of large engravings from some fifty of the most interesting of the photographs these gentlemen gathered during their tour of inspection. It might be stated that before making this journey, Mr. Jackson had no preconceived ideas regarding the type of structure to be employed, although he was naturally enough glad to have an opportunity to design a bridge in which the question of dollars was relegated to a minor position as compared with artistic merit and harmony with surroundings. Mr. Wheelwright, on the other hand, visited Europe with the expectation of learning that stone arches were the only true solution of such a problem as that presented in this structure. After critically examining the important bridges of the Continent, it was apparent, however, that it was practicable to build steel structures possessing all elements of structural beauty, and that masonry not only had been forced from its old position as the leading material for artistic bridge-work, but had even been compelled to give way to steel for structures of the highest aesthetic rank under certain conditions. This fact was particularly evident from a study of the bridges in Dresden, illustrations of which were among those included in the series already referred to.

While the first suggestions for the bridge were being developed, the commission found it necessary to secure permission to build a structure without a draw span. At first it was believed that such a draw could be introduced without spoiling the effect of the structure as a whole, and it was proposed to make the central feature an artificial island with a channel cut through it at the draw. It was found impossible, however, to design a bridge having a draw span which would be satisfactory artistically and, accordingly the Massachusetts legislature was petioned to authorize the construction of a bridge without a draw, crossing the channel at a height sufficient to furnish a clear headroom of 26 ft. above mean high water at the central spans. This gives a sufficient height to allow tugs and vessels without masts to pass, and as there is no business to speak of above the bridge it was felt that the injury which might arise to a few riparian owners through the closing of the river navigation to larger vessels was more than counterbalanced by the gain in the character of the bridge. Unfortunately the War Department refused to agree to this opinion, and it was necessary to secure the passage of a bill in Congress and its approval by President McKinley in order to permit the construction of a drawless bridge. Two years were occupied in these legislative proceedings, but it was absolutely essential to carry them through in order to enable the engineer and architect to reach the best possible result, which alone would be acceptable in the case of the Cambridge Bridge.

Before the final design was adopted, about fifty carefully worked out studies had been made. Each of these was prepared to show the effect of some change in spans, piers, grades or points of structural emphasis, and every suggestion having any merit, structurally or artistically, was thoroughly discussed before decision was reached concerning it. It was learned early in this investigation that the best effect would be obtained by laying emphasis on the central portion of the bridge, increasing gradually the length of the arches from the shore to the center of the bridge and making the piers successively heavier as the central channel was reached. The length of the bridge between abutments is 1,767½ ft., and it has eleven spans, each of twelve steel ribs, varying from 101½ to 188½ ft. The height of the bridge at the center is about 48½ ft. above low water. The main effect of the structure is produced by the use of two large central piers, each having a foundation 201 ft. long by 67 ft. wide; these piers have ornamental stone towers rising to a height of 40 ft. above the roadway, and smaller stone towers have been built at the end of each abutment. In designing the masonry of these piers the purpose was to obtain the happiest possible expression of monumental dignity and not to keep the number of cubic yards down to the minimum consistent with strength. As a result, these great piers completely overshadow the masonry structures used on other bridges across the Charles River and demonstrate in a most striking manner the possibilities of stone masonry combined with structural steel for the expression of graceful strength. They also call attention to the fact that the bridge crosses the boundary line of two important cities.

Attention is particularly called to this structure because it is one that should be visited by all engineers and architects who have an opportunity to inspect the structure. It is the result of the most careful and painstaking attempt yet carried through to completion in this country to build a bridge which is artistically as well as structurally in perfect harmony with its position and with its purpose. Dr. Leavitt and Messrs. Jackson and Wheelwright are to be congratulated on the success of their work, which stands forth as one of the few really satisfactory American bridges from every point of view.

Large Reinforced Concrete Syphons.

The beginning of the construction of the Catskill Aqueduct for the additional water supply of the City of New York obviously brings into prominence many serious questions of design of the main features of the work. Among these important problems of design there is probably none requiring more serious consideration than that bearing upon the proper construction of syphons under the deep valleys crossed by the aqueduct line. The most evident forms of construction, those which most easily suggest themselves, are deep tunnels and riveted steel pipes. The deep tunnels are naturally carried to such depths as to pierce bedrock under the lowest points of the geologic valley crossed. This frequently necessitates the construction of shafts several hundred feet deep with the base of the tunnel carried still deeper. These pressure tunnels can usually be lined with comparative economy so as to make them actually or practically water-tight, and they serve their purpose admirably as structures if an excessive amount of water be not encountered in their construction. They need, however, provision for being pumped out at proper intervals for examination, cleaning and repairs, if necessary, all of which at such great depths involves inconvenience and expense.

The riveted steel pipe, on the other hand, aside from questions of relative cost, lies near the surface of the ground and is depressed to no greater depth than is necessary for suitable covering and protection. It is therefore subjected to a relatively low pressure no greater than the minimum required by the topographic features of the valley. This is a great advantage and reduces some important parts of care and maintenance, but it is offset by the perishable character of the metal, which can scarcely be completely protected against all corrosion. It is clear that the riveted steel pipe would be more suitable for a short syphon than a long one where the cost of shafts would be distributed over a comparatively long high pressure tunnel.

The obvious advantages of surface construction, or in some places of a type of aqueduct suitable to be carried across a valley on a masonry or other bridge structure, and, furthermore, of a more permanent character than that of a steel pipe gives much interest to the recent construction of a reinforced concrete syphon forming part of an irrigation canal in Spain, as described in "Le Genie Civil." This syphon has a length of about 3,200 ft., and consists of two tubes each 12.5 ft. in diameter. It may be contended, strictly speaking, that these tubes are mortar-lined and concrete coated steel pipe rather than reinforced concrete, and the contention would at least be reasonable, for each tube consists of a riveted steel pipe ⅛ inch thick reinforced on its exterior with steel ties. These steel pipes are coated with six inches of concrete on their exterior which encloses and imbeds the reinforcing ties. The interior of the pipe is lined with seven-eighths inch of mortar. The steel pipe is continuous throughout the length of the syphon, being fitted with expansion joints and thus affording a continuous water stop.

This is an interesting structure, especially in view of the large diameter of the tubes, at the same time it does not afford opportunity for learning much about what reinforced concrete would do in such a structure. A continuous steel

pipe of such a diameter lined with a thin interior layer of mortar and covered with but six inches of concrete is practically a series of comparatively thin cylindrical laminations. While water tightness is secured, it is at the cost of unity of the materials composing the syphon. It will be exceedingly difficult if not impossible to prevent the thin interior layers of mortar from cracking sufficiently to permit the water to come into contact with the steel, resulting in serious corrosion. In such a structure there is complete failure to secure that intimate and inter-structural combination which constitutes one of the most excellent features of reinforced concrete and without which failure of detail is invited.

The obvious reason for not using reinforced concrete for syphon tubes, aside from any matters of cost, is the lack of water-tightness of ordinary concrete. There has been, however, much advance made in securing this quality, so necessary for the purpose under consideration. Concrete sufficiently water-tight for aqueduct purposes, up to heads of sixty feet or more, has already been made, and experimental investigations indicate that it may be feasible to reach far greater heads. The maximum head on the Spanish syphon is eighty-five feet and there should be no serious difficulty in constructing a true reinforced concrete tube to meet the requirements of such conditions, nor would it be difficult to provide effectively against expansion and contraction with longitudinal steel.

Recent investigations have resulted encouragingly for the early attainment of concrete practically impermeable to water up to heads far beyond any hitherto considered. The intimate combination of the concrete and steel enables a sufficient mass to be used to eliminate any prejudicial effects of fine cracks. A properly designed and constructed reinforced concrete syphon would be as permanently enduring as any other first class masonry, and with all the advantages of complete accessibility, convenience and low cost of care and maintenance.

The Value of Small Drawings.

So much has been said about the value of small drawings in construction work that the subject would not be referred to at this time if evidence was not constantly proving the laxity of many companies in keeping their drawing office practice up-to-date, and their failure to realize that in probably half of all cases drawings for field use not larger than 11x14 in. are better than anything bigger. It should be needless to go over all the arguments against the custom of making single drawings for construction work big enough to convert into a suit of clothes. Sometimes, of course, a map must be drawn on so small a scale that the territory cannot be shown on less than 6 to 10 sq. ft. of paper, but if employers stopped to figure the cost of making large drawings and large prints, let alone the difficulty of filing them compactly, it is safe to say that fewer of those productions would be bulking big in the expensive office spaces of large cities.

An album of small drawings, multiplied as to details, is infinitely more convenient than several huge rolls in which details and general relations are all jumbled together. It can be kept up-to-date much easier, and at less expense. The cost of blue prints is not a negligible quantity under city conditions. Proper rotation and numbering, with suitable cross-references in the drawing index, are all that are needed to maintain the usefulness of the small data sheet. The picture plans required by non-technical clients and boards of directors can just as well be made on an 8 by 10 or 11x14 in. sheet in the majority of cases.

Obviously it costs money to keep drawings up-to-date, but it costs more in the long run to fail to do this. A prominent firm of engineers recently undertook the re-modelling of a power plant, and the expense for the new foundations was greatly increased on account of the fact that absolutely no record or definite knowledge existed as to the character of the foundation and soil under the plant. The knowledge was obtained finally, of course, by test borings and a long series of tabulations of data, but the expense to the client company was far beyond the cost of maintaining the necessary simple plans in the first place. It is poor policy for a company to be in such a hurry to start its plant that no time can be found to keep the proper records of the character of the construction, and the changes put in effect beyond the original design. From a hasty point of view the money expended on drawings and data in very large engineering undertakings by Federal, State or railroad authorities seems at times needlessly great, but a great system rarely gets through its first operating year without being benefitted in money saved far above the cost of the drawings and data, if the latter have only been kept up-to-date. Particularly in electrical work is there a field for the use of schematic diagrams in which on small sheets stripped of all superfluities, three phase circuits, for example, are shown by single lines, and apparatus by simple symbols. The value of drawings to an operating man is in direct proportion to their straightforward freedom from all draughting complications.

Notes and Comments.

The Rain-Water Run-off from populous districts is one of the most important subjects that the designers of sewerage systems have to consider. In spite of the attention that has been paid to it, surprisingly few absolutely definite data are available and for this reason the sanitary section of the Boston Society of Civil Engineers has appointed a committee to consider the whole subject. The committee is particularly desirous of collecting all records regarding it and engineers throughout the country who have information on the subject are requested to send it to Mr. Harrison P. Eddy, 14 Beacon St., Boston, who is the secretary of the committee. At the present time nothing is so necessary as the compilation and study of available data, and for this reason engineers will do well to assist the committee with whatever information they may possess, since the committee's work is done for the benefit of the whole profession.

A Gas Engine Test lasting two weeks was recently run at the works of the J. P. Eustis Mfg. Co., of Boston, by Messrs. P. R. Nichols and R. F. Knight, of the Massachusetts Institute of Technology. The test was made on a 55-h.p. engine direct-connected to a 30-kw. direct-current generator. The engine was of the vertical, twin cylinder, four-cycle type, the governing being effected by varying the richness of the explosive mixture. Cooling water was circulated by a motor-driven centrifugal pump and the engine was started by compressed air stored in two tanks which were kept filled by an air pump driven by a small motor. The gas used by the engine was taken from the street mains and averaged about 590 B. t. u. per cubic foot. During the two weeks' run, the total kilowatt-hours were 3,146, and the total gas used 92,900 cu. ft.; 31.9 kw. hr. were used in driving the pump, leaving 3,114 kw.-hr. as the net energy delivered during the run. At 70 cents per 1,000 cu. ft., the gas cost 2.09 cents per kw.-hr., the oil cost 0.029 cent, the labor at 2 hr. per day cost 0.193 cent, and the interest and depreciation, reckoned at 15 per cent. on $3,000, amounted to 0.555 cent, making the total cost of energy 2.87 cents per kilowatt-hour.

The Refuse Destructor and electric station described in The Engineering Record of Nov. 11, 1905, which was built by the City of New York to utilize the refuse of a portion of the Borough of Manhattan, has proved an unprofitable venture, so far as the generation of electricity is concerned. The current has been used for public bridge lighting, costing the Department of Water Supply, Gas and Electricity about $50,000 a year, while the local lighting company would do the same work for about half this sum. The trouble with the lighting end of the undertaking seems to have been that city refuse is a very uneven fuel, and the operation of the plant as an electric generating station is much more difficult than will be its operation as a refuse destructor simply. It is not unlikely that small amounts of current for various purposes will be furnished from it to the immediate vicinity, but it is not believed that any extensive system of public lighting can be safely undertaken.

Foundation Troubles at the Mt. Royal pumping station of the Baltimore water works are now being investigated and seem to be due to an unusual condition. One corner of the building has been underpinned and the pier which supported it has been laid bare by sinking a pit some 30 ft. deep. The concrete was found to be in a bad condition and the rock on which the pier rested was also somewhat decomposed. The earth in the vicinity was very warm and moist, and an examination showed that the concrete hot well had been leaking considerably. In addition to the presence of this hot water in the cinder fill which formed the site of this part of the building, return currents from the belt line tunnel of the Baltimore & Ohio R. R. were detected. It is understood that the condition of the concrete is not unlike that described by Mr. A. A. Knudson, in a paper read last winter before the American Institution of Electrical Engineers, concerning the electrolysis of steel embedded in concrete. The conditions at Baltimore are so unsual that when the examination is completed it is to be hoped that all the facts will be made public.

A Trade Catalogue Library has been established by the Technology Department of the Carnegie Library at Pittsburg, and an attempt is being made there to collect business pamphlets covering the entire engineering field These publications will be given a prominent place on the shelves, carefully catalogued under both firm name and subject, and made accessible to the public. A similar collection made at a Brooklyn library some time ago proved not only of value to the people using the library but also of service to the publishers of the catalogues. It goes without saying that a practically complete collection of trade publications in a library in a manufactoring city like Pittsburg has a reference value exceptionally high, and for this reason it is believed that manufacturers of supplies for engineers, architects and contractors will find it decidedly to their advantage to send their publications to Mr. H. W. Craver, who is in charge of the Technology Department of the Library at Pittsburg. The formation of such a collection in the public library of each manufacturing city is something that may very properly be investigated by its librarian. The time has gone by when the trade publication is merely a collection of claims for some product, stated without much regard for truth and published without regard to typographical appearance.

THE CONTRACTOR'S PLANT AND METHODS ON THE HARBOR WORK AT GARY, IND.

The construction of a harbor for the new plant of the United States Steel Corporation at Gary, Ind., is one of the most difficult and extensive of the engineering works required in building that plant. The site of the latter is at the extreme south end of Lake Michigan, 12 miles from the South Chicago plant of the steel corporation, and 20 miles from the central business district of Chicago, where an area of about one square mile, with a frontage of over a mile along the shore of the lake, has been provided. This area is covered with fine lake sand to a depth of from 40 to 60 ft. from the surface, which before construction started was formed by a series of alternate ridges and hollows parallel with the shore line. The ridges rose 15 to 40 ft. above the water in the lake, while the general elevation of the depression between them was about 10 ft. above that level. The Grand Calumet River, a sluggish stream that heads in swamps to the east of the site, extends along the rear side of the latter, parallel to the lake, into which it empties at South Chicago, 12 miles away. From South Chicago entirely around the lower end of the lake the shore line is a low, flat and practically unbroken sandy beach. This characteristic shore line existed at the site of the new plant, where the established minimum of 22 ft. in channel construction on the Great Lakes is not reached in the lake until about 2,000 ft. off shore.

General Arrangement of Harbor.—The provision of proper and sufficient harbor and docking facilities for the great number of the largest boats on the Great Lakes which will ply between the new plant and the terminals of the iron-mine railroads on Lake Superior, was rendered a project of unusual magnitude by these natural conditions. A slip, 250 ft. wide, approximately a mile in length and with a minimum depth of 22 ft. of water, is being built at right angles to the shore line to secure the necessary wharfage and habor room. This slip extends 2,000 ft. off-shore to the 22-ft. depth in the lake and 3,000 ft. inland. It is being closely lined along both sides with sheet piling to hold the sand in place, and will be dredged to the required depth.

The furnaces and stoves of the steel plant will be in single row along the west side of the slip, at a distance of about 750 ft. from the latter. Large traveling unloading machines will operate the length of the dock on that side and will convey the iron ore from the vessels to storage piles between the slip and the furnaces. These storage piles will be spanned by traveling bridges carrying grab buckets, which will handle the ore to stock piles or to cars for charging the furnaces, the general arrangement being the same as in several existing plants of the steel corporation.

The pier along the west side of the slip from the shore line to the inner end of the slip a distance of 3,000 ft., will have a concrete dock wall carried by heavy pile foundations. This wall extends from 3 ft. below Chicago city datum, the later being on an average about 2 ft below the lake level at Gary, to 10 ft. above that datum. It is 15 ft. wide at the bottom, has a vertical front face and is stepped on the rear face to a width of 5 ft. at the top. This wall rests on three longitudinal rows of piles spaced 6 ft. apart on centers, the piles in the rows being 3 ft. apart on centers. The piles in this portion of the pier are all at least 34 ft. long and are driven to at least 30 ft. below Chicago datum. The two outer rows are tied together at intervals of 6 ft. with heavy iron rods; the outer row on the slip side are also anchored by rods, 44 ft. long, at intervals of 6 ft., to a waling on a fourth row of piles under the footing for the unloader tracks. Immediately inside of the outer row of piles is a row of triple-lap Wakefield sheet piling. This piling consists of 3x12-in. Oregon fir in 34-ft. lengths and is driven to a penetration of at least 30 ft. The outer row of round piles are under the toe of the dock wall and are cut off at the level of the bottom of the latter, 3 ft. below the Chicago datum, and are capped with a 12x12-in oak timber. The other two rows of piles and the row of sheet piling are left with their tops protruding as they are driven and are imbedded in the lower part of the concrete wall.

The off-shore 2,000 ft. of the pier along the west side of the slip is a rock-filled timber and pile pier. For the first 600 ft. from the shore line this crib consists of two rows of closely-spaced, heavy, round timber piles with a minimum length of 45 ft. The rows are 12 ft. apart on centers and are tied together with two horizontal rows of iron rods attached to oak walings on the piles. A row of triple-lap Wakefield sheet-piling, consisting of 3x12-in. Oregon fir planks, 44 ft. long, is driven immediately outside of the row of round piles on the slip side. This sheet piling is protected by a third row of round piles, which are spaced 6 ft. apart on centers; these piles are capped with a 12x12-in. oak timber and are tied together near the top with a 12x12-in. oak waling piece, which also acts as a fender for the pier. The various rows of piles in the latter are driven to within about 12 ft. of the average water level in this section outside the natural shore line. The space between the two rows of closely driven piles is filled with broken stone from the natural bed of the lake to the top of the pier.

Beyond the 600 ft. of pier 12-ft. in width on this side of the slipe, is 700 ft. that is 18 ft. wide and beyond that 700 ft. that is 24 ft. wide. The construction of these wider sections is the same as that of the 12-ft section. At the outer end of this pier and the west side of the slip a rock-filled timber and pile pier, 2,000 ft. in length and 24 ft. wide, will be built to the west in the lake at right angles to the slip. This pier will be of the same construction as the off-shore portion of the pier along the west side of the slip, with the exception that the row of triple-lap sheet piling will be omitted in it. The space enclosed by the pier along the west side of the slip and by this outer pier was formerly covered with upwards of 22 ft. of water, but will be filled with sand to a height of 3 to 18 ft. above the water level and on this made ground will be erected a part of the steel plant.

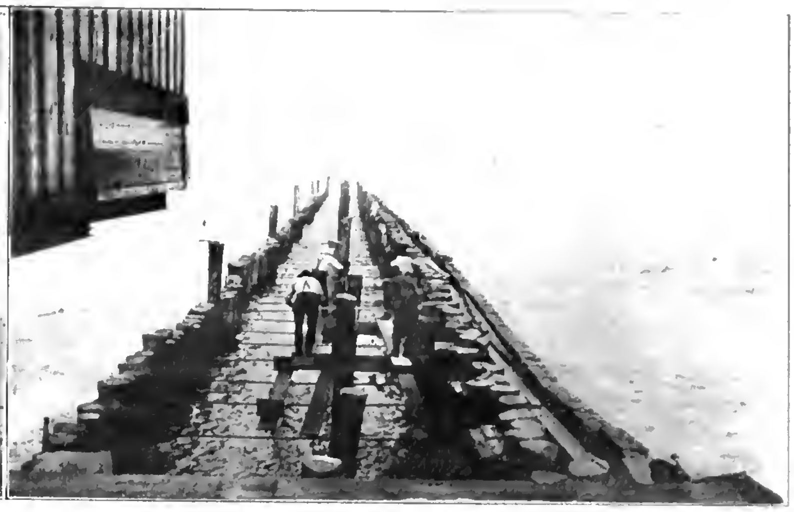
No dockage facilities will be provided along the east side of the slip, for the present. From 500 ft. off shore to the inner end of the slip, in a length of 3,500 ft., a row of triple-lap Wakefield sheet-piling, consisting of 3x12-in. Oregon fir planks, 44 ft. long, is driven as a lining to retain the sand. This sheeting is protected on the outer side by a row of heavy round piles, driven 6 ft. apart on centers, which are capped on top and are held together by a 12x12-in. oak waling piece along the side that also serves as a fender. The second 500 ft. off-shore of the lining on this side of the slip consists of a pier 12 ft. wide and of the same construction as the pier of that width on the west side; the next 300 ft. is 18 ft. and the remainder 24 ft. in width, all of the same construction as the pier of the same width on the west side. At the outer end of this pier, a return pier 24 ft. wide, is to extend 1,000 ft. to the east in the lake at right angles to the slip, and together with the pier along the east side of the latter will enclose an area of made ground, where the lake was originally as much as 22 ft. deep.

Section of Channel Showing Character of Sand.

Construction of Harbor.—The low, flat beach and the location of the site of the harbor at the south end of the lake, where it is exposed to the full force of the extremely severe northeast storms which sweep the latter, rendered the early construction work on the harbor particularly hazardous. The sand dunes that formed the site of the inshore portion of the slip rose 15 to 30 ft. above the level of the lake and were only sparsely covered with scraggly oak trees and scanty vegetation. The sand in which the slip has to be excavated is extremely fine, clean and free from pockets of gravel or loam. Although not exactly quicksand, it flows so freely when wet that it is confined with difficulty, and, in fact, is almost as hard to hold when dry.

Construction on the harbor was commenced in July, 1906, when the contractor for this work,

Off-Shore Piers under Construction.



Piles for Off-Shore Rock-Filled Pier.

the Great Lakes Dredge & Dock Co. of Chicago, excavated into the site of the slip from the lake with a hydraulic dredge. The piling for a 600-ft. length of the pier on the west side of the slip, extending into the lake from the shore line, were then driven with a land driver running on the finished work. A 500-ft. length of the pier on the east side, also extending into the lake from the shore line was built about the same time. A breakwater consisting of two rows of piles driven close together, the rows being about 12 ft. apart and filled between with rock, was then thrown about half way across the slip at the end of 600-ft. length of pier on the west side. It was expected that floating equipment could work readily in the temporary harbor thus formed. The unsually large number of heavy northeast storms which occurred during the past winter and spring, however, greatly interfered with the progress of the dredging and pile driving. In fact, at times the floating drivers and the dredge were in much danger from the high surf that prevailed on the flat beach and carried into the temporary harbor without much reduction in force. In order that the floating equipment could be better protected, the breakwater across the slip was extended 40 ft. farther and a short breakwater built into the slip from the completed portion of the east pier, this second breakwater being far enough toward the shore from the first so an entrance from the lake was provided between the two. With this final temporary harbor arrangement the floating equipment can work on the off-shore pier construction during good weather and on the piers of the inshore section of the slip when the lake is rough.

After the preliminary dredging had been done with a 15-in. hydraulic dredge and the temporary harbor finished, the hydraulic dredge New York was brought in and is being used to handle the excavation of the slip. This dredge has an all steel hull which has a 40-ft. beam, is 110 ft. long, over-all, and 12 ft. deep. The superstructure is also entirely of steel, so the dredge is practically fireproof, and, as a matter of fact, is believed to be the only dredge of this type on the Great Lakes that is so constructed. The suction pipe for the pump of the dredge is swung from a 36 ft. A-frame with a 65-ft. boom at the forward end of the hull, which permits this pipe to be lowered to 35 ft. below the water surface. In the fine loose sand in which the dredge is at present operating no cutter is necessary. The dredge is provided with a 6-ft. cutter, however, which is operated by a 250-h.p. motor driven by current generated by a dynamo in the engine room.

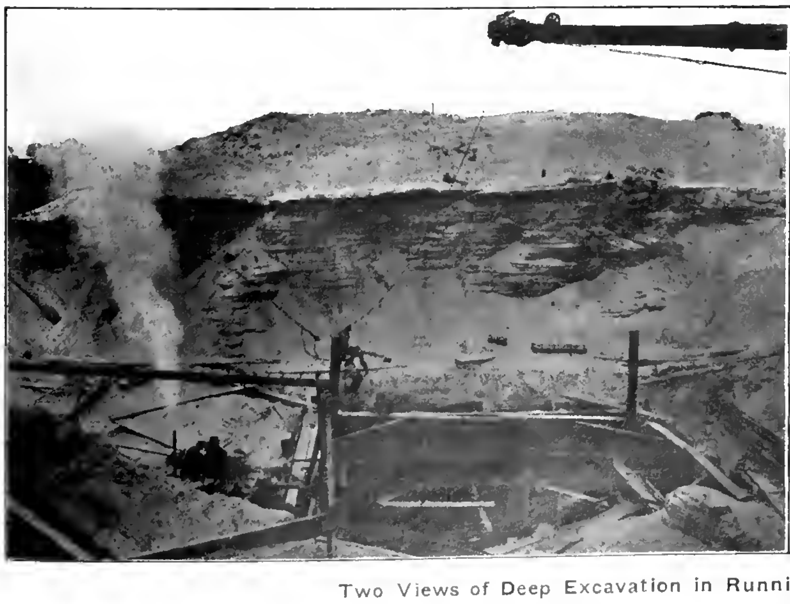
The dredge is equipped with a special centrifugal pump having a 24-in. suction and a 24-in. discharge. This pump is driven at 300 r.p.m. by a 17x30x42x30-in. triple-expansion marine engine. Steam is supplied to this engine and to the other steam consuming units by two 13x13-ft. Scotch marine boilers operating at 170 lb. pressure.

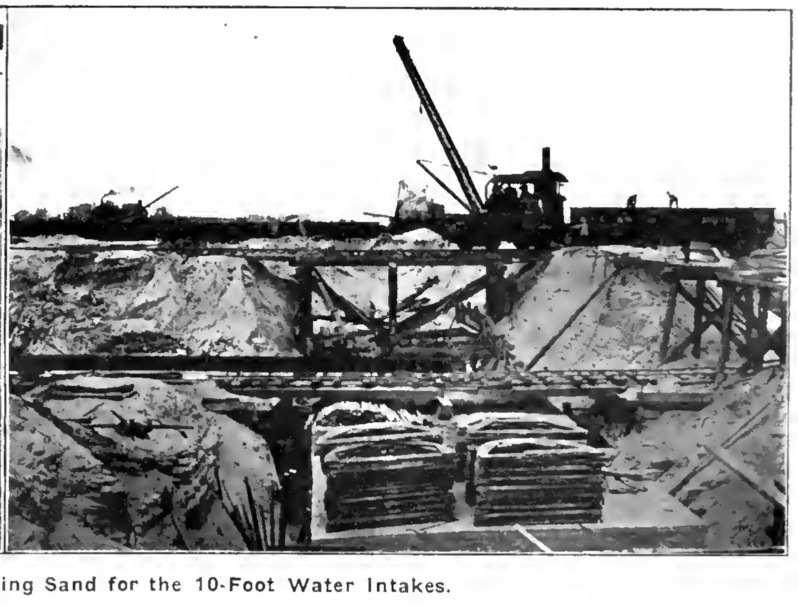
Two shifts are employed on the dredge in the present operations so that pumping may be carried on continuously. Quarters are provided on board for 40 men, 36 men being required to run the dredge.

The 24-in. pipe line that extends from the dredge to the point where the sand is being deposited for filling is carried on the water by pontoons consisting of hollow 24-in. cylinders built of boiler plates. These cylinders are made watertight and are built in lengths of 10 to 80 ft., depending on their location. They are used in pairs, one on each side of the pipe, the latter being swung from timbers attached to them. The pipe line is provided with flexible joints at intervals in order that bends may be made in the line without difficulty. The sand thus far has been pumped as much as 1,100 ft. from the dredge, the maximum distance to be reached by pumping being about 3,000 ft.

The preliminary plans covering the harbor construction estimated the excavation for the slip to require the removal of approximately 2,000,000 cu. yd. of material. Although under ordinary circumstances the dredge handles 8,000 to 12,,000 cu. yd. in 24 hr., when working on the excavation for the inshore section of the slip the roots of the small oak trees interfere to considerable extent with the operation of the pump. Small roots, 1-2 to 1 1-2 in. in diameter, are found to extend as much as 30 ft. from the surface to reach the water in the thick stratum of sand which makes up the site, fine shoots branching from these tap roots in the vicinity of the water. These fine roots cannot be kept out of the pump, but collect in the latter in considerable quantities and have to be removed.

The excavation for the slip is made somewhat wider at the water level than is required for the slip itself, in order to facilitate the construction of the piers. In all, over 16,000 round piles and 5,000,000 ft., board measure, of lumber will be used in the piers. The piles and the sheet piling are all being driven with the assistance of hydraulic jets. With the exception of the short length of each pier in which the piles were driven by land drivers, the work





Two Views of Deep Excavation in Running Sand for the 10-Foot Water Intakes.

is handled by four floating pile-driver outfits. Each of these outfits is equipped with a pump for operating a hydraulic jet at a pressure of up to 150 lb. per square inch. The sand in which the driving is done is of such nature that the jet can be put down first to loosen sand, and the pile or sheeting then dropped into this hole. A drop hammer in the leads of each outfit serves to carry the pile down into the loosened hole, and, if necessary, to hold it there momentarily until the sand has flowed back sufficiently to prevent it from floating, the nature of the sand being such as to remain very loose when stirred up under water.

The piles and timber for the dock work are mostly delivered on two switch tracks which extend the length of the land section of the slip parallel to and on the east side of the latter. The sheet piling is assembled on this side of the slip, dropped into the water and floated to place. The round piles for the east pier are also floated to place at present from storage piles along the east side. A standard-gauge track is laid the length of the west pier as it progresses in order that the piles and stone filling for that pier may be delivered on it. A track is also being laid on the off-shore section of the east pier to facilitate the delivery of material there.

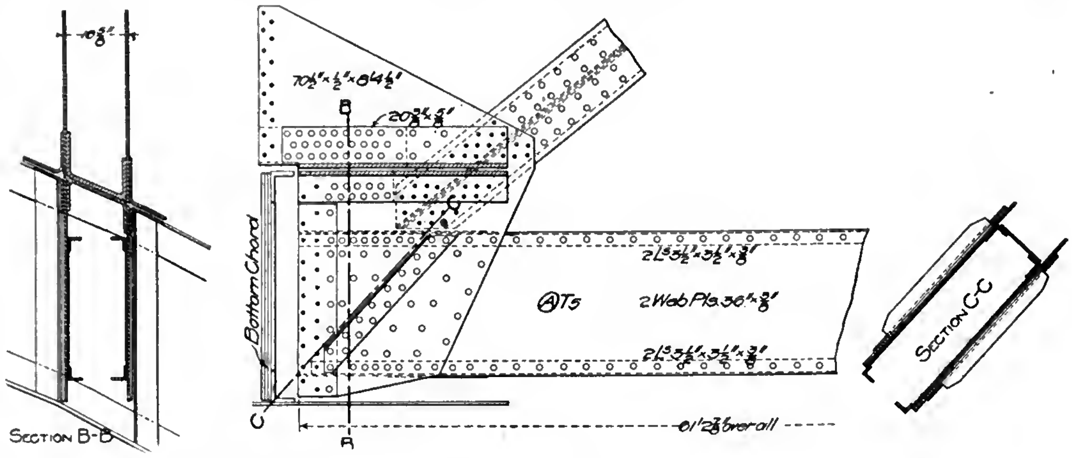
The concrete for the dock wall along the west side of the inshore portion of the slip is made in a mixing plant set up along the site of the wall and adjacent to a service track. A Drake continuous mixer is placed in a tower under storage bins for the concrete materials. The latter have heretofore been handled from cars on the service tracks to the bins in wheel barrows, but arrangements are being made to use a turntable A-frame derrick with a 1½-yd. clamshell bucket for this service. The mixer discharges into 1-yd. Koppel dump cars, which are pushed to place by hand on narrow gauge tracks laid on top of the wall forms.

Construction of Water Intakes.—The Great Lakes Dredge & Dock Co. also has the contract for building a pair of water intake conduits, each 10 ft. in diameter, which extend from an inlet in the concrete dock wall of the slip to a pumping station in the steel works, 750 ft. from the slip. The inverts of these two conduits are 25 to 26 ft. below the water level in the sand and 35 to 50 ft. below the surface, making their construction particularly difficult. The wide and deep excavation in the fine running sand required in building these conduits has been carried forward, successfully, however, by methods specially adapted to the work. The excavation is opened in lengths of 60 to 80 ft., the full width of the trench, a 1½-yd. McMyler clamshell bucket handled by a turntable A-frame derrick with a 65-ft. boom being used to remove the sand.

The sides of the excavation are lined with close horizontal sheeting as the sand is removed, until the water level is reached. A series of well-point strainers are then jetted down around the sides of the excavation to about the grade of the inverts of the conduits. These well-points range from 1½-in. to 2½-in. in diameter and are attached to pieces of wrought-iron pipe, which are threaded at the top and are screwed into 6-in. or 8-in. pipes laid horizontally around the sides of the excavation. These mains serve as suction pipes for several pumps set up around the excavation. Four to eight pumps are used in drawing water through this drainage system while excavating below the water line is in progress. This arrangement for keeping water out of the excavation has been so successful that the sand inside the limits of the suction mains is kept practically dry as long as desired, and the portion of the excavation below the water line does not require sheeting. The construction of the conduits is also carried on in the dry 25 to 26 ft. below the water level.

The concrete for the conduits, of which about 8 cu. yd. to the linear foot of the latter is required, is made in a Smith mixer set upon a platform on wheels running on a track laid along one side of the top of the excavation. Materials are supplied to the mixer from storage piles along a service track, or from cars on the track, by the clam-shell bucket handled by the turntable A-frame derrick. The mixer discharges into chutes which feed the concrete directly into place, the average output being about 120 cu. yd. a day when the outfit is in operation.

The construction of footings for the pumping station in which the two conduits terminate also involved deep excavations in the fine sand. The pumping station building is 45x153 ft. in plan.



Bottom Strut Connection in Floorbeam Truss, Quebec Bridge.

Part of the Work along the Site of the Ore Unloading Bridges.

The conduits end in a pump suction chamber, 8.5 ft. wide and 127 ft. long, the bottom of which is 25 ft. below Chicago city datum, or about 26.5 to 27 ft. below the lake level A 5-ft. layer of concrete was placed in the bottom of this chamber to insure against upward hydrostatic pressure. The pumping station provides room along one side of the top of the suction chamber for seven turbine pumps direct-connected to motors. A heavy base of concrete has been provided for these motor-pump sets, this base being carried down to about 20 ft. below the water level. The side walls of the building are carried by concrete footings 4 ft. thick which surround the suction chamber and pump base.

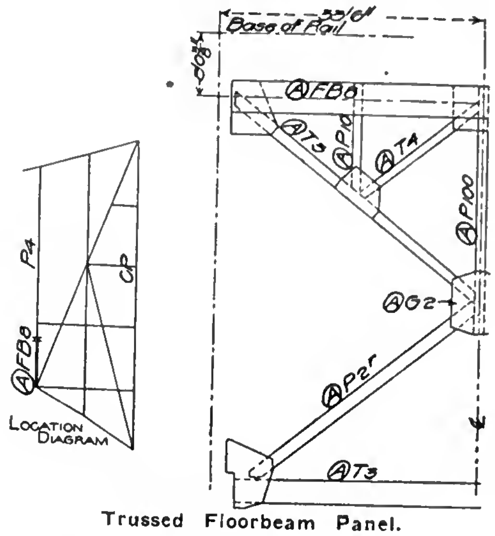
The wide and deep excavation in the sand for these heavy concrete footings was handled before the well-point pumping outfits had been adopted, heavy close sheeting and a large amount of pumping being required before the work was finished. The concrete was made in the same Smith mixer that is now being used on the conduits, over 6,000 cu. yd. being required.

The Great Lakes Dredge & Dock Co., the contractor for the harbor work and the intake conduits has the following plant now in operation: The 24-in hydraulic dredge New York; a land and four floating pile-driver outfits; four derrick scows; several flat scows; two standard-gauge turntable locomotive cranes; the A-frame turntable derrick; a light locomotive and train of dump cars; a large tug and various other equipment such as pumps, concrete mixers, air compressors and so forth. At present between 300 and 400 men are employed in the construction of these two portions of the new steel plant. They are housed and fed in model quarters by the contractor, on a cash co-operative basis.

The new steel plant was designed and is being constructed under the direction of Mr. G. G. Thorp, vice-president of the Indiana Steel Co., Mr. A. B. Neumann is chief engineer, and Mr. W. P. Gleason is superintendent of that company. The operations of the Great Lakes Dredge & Dock Co. are directed by Mr. T. C. Lutz, vice-president and general manager. Mr. John R. Williams is superintendent in immediate charge of the work at Gary.

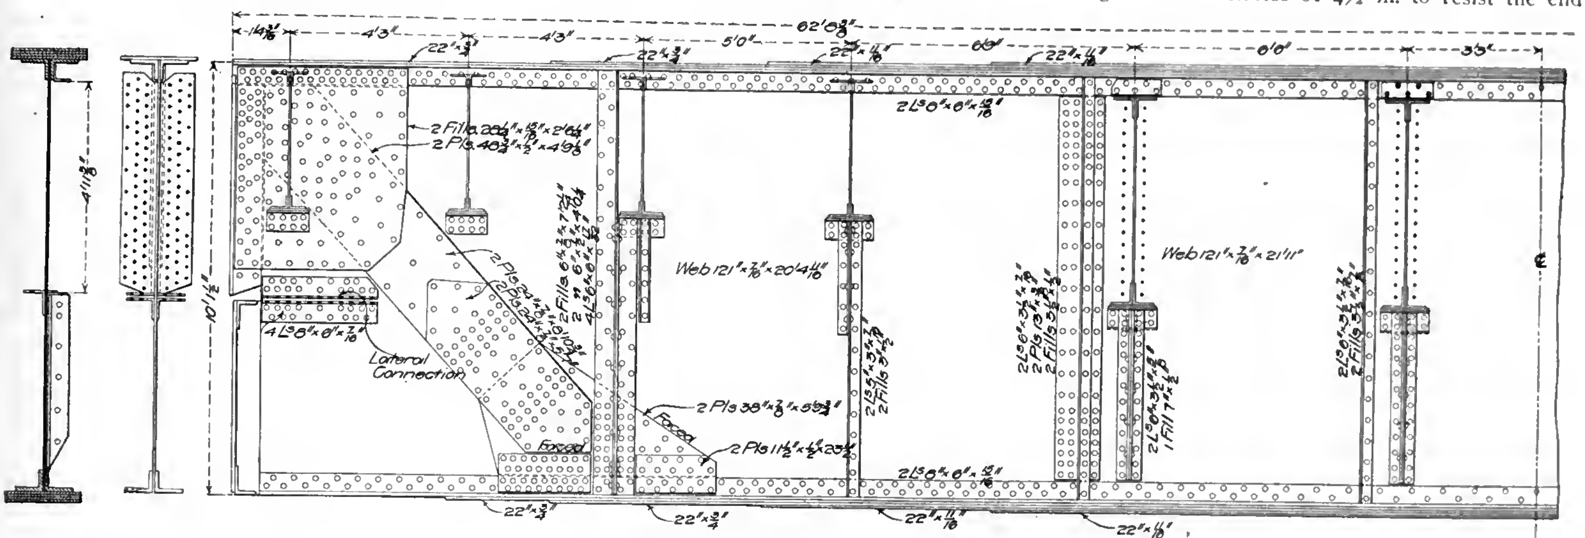
The Quebec Bridge Superstructure Details.—Part VIII.

Floor System.—The floor platform projects 5 ft. 3 in. beyond the centers of the trusses giving it a total width of 72 ft. 3 in. and provides for a live load consisting of two 140-ton locomotives on each track 6½ ft. from the axis of the bridge and for a continuous line of electric cars 30 ft. long, weighing 56,000 lb. each, 19 ft. each side of the bridge axis; and for a dead load of 6,200 lb. per lin. ft. due to floor construction alone. The railroad tracks are enclosed by vertical screens 7 ft. 4 in. high and the 17-ft. spaces between them and the truss clearances are floored with 4-in. diagonal planks spiked to 6x8-in. transverse joists, 18 in. apart on centers. Sidewalk platforms 5 ft. 1½ in. wide in the clear extend through the trusses beyond the outer edges of the roadway platforms and are protected by well-braced lattice girder hand-rails 4 ft. high. They have a flooring of 2-in. transverse planks elevated 6 in. above the top of the roadway planks and are carried by longitudinal timbers laid across the cantilever ends of transverse joists 7½ ft. apart.

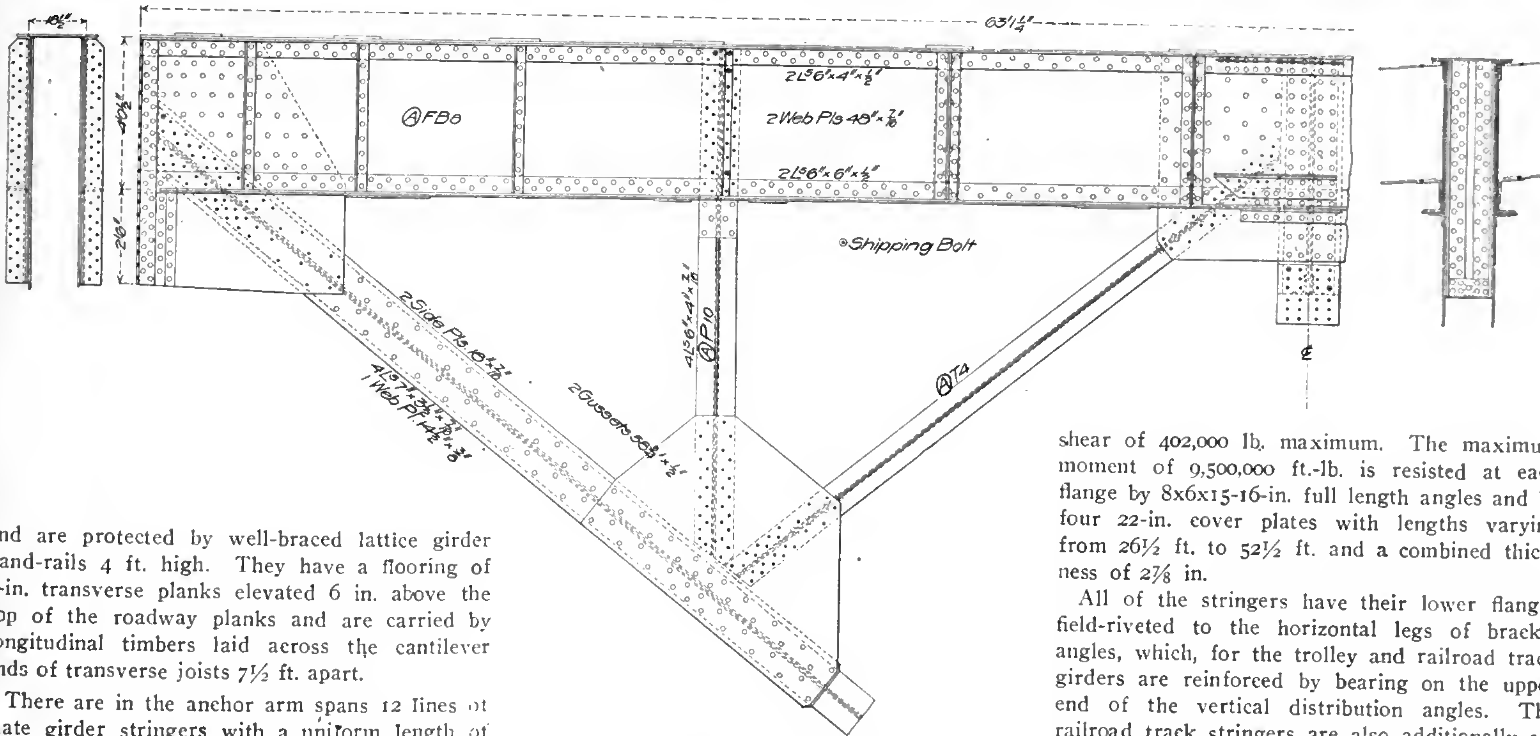


Trussed Floorbeam Panel.

the floor beam webs and provision is made for transmitting the lower flange stresses at an angle of 45 deg., to this point, through wide diagonal reinforcement plates riveted to the web plates in the sub-panels of the floor beams. These plates are thoroughly spliced to the bottom flange angles and although the latter are continued horizontally through the ends of the floor beam webs for the sake of stiffening them, the effect is substantially that of bending the flange angles up to the ends of the floor beams at this point. The floor beams at P1 and P2 resemble those at the adjacent intermediate panel points and have 7-16-in. web plates 10 ft. deep made in three sections, spliced together with four vertical rows of rivets to two 13x⅜-in. cover plates. The end is reinforced and already described by four diagonal 24x⅞-in. plates, and by two outside 48¾x½-in. plates in the upper corners, making a total thickness of 4½ in. to resist the end shear of 402,000 lb. maximum. The maximum moment of 9,500,000 ft.-lb. is resisted at each flange by 8x6x15-16-in. full length angles and by four 22-in. cover plates with lengths varying from 26½ ft. to 52½ ft. and a combined thickness of 2⅞ in.



Regular Floorbeam.



Half of Upper Part of Trussed Floorbeam.

There are in the anchor arm spans 12 lines of plate girder stringers with a uniform length of 50 ft., web connected to the floor beams with their top flanges just clearing the upper surface of the floor beam flanges. The four lines of railroad track stringers are 58 in. deep and are spaced 3 ft. 3 in. and 6 ft. 9 in. from the bridge axis. The 8 lines of roadway stringers 38 in. deep are spaced 5 ft. apart under the trolley tracks and 4 ft. 3 in. apart outside of them. The track, as well as the roadway stringers, are braced in the usual way with zigzag top and bottom flange lateral angles and transverse frames.

In the shore end panels of the anchor arm the lower chord is nearly horizontal and does not fall clear below the floor system; the deep, plate-girder floorbeams are therefore made in several cases to engage both the lower chord and the vertical posts, web-connected in the usual manner to the latter, notched slightly in the lower corner to clear the former and have their lower flanges flush with the lower flanges of the lower chord connected to them through the lateral connection plates. The effective connection is, however, made on the upper half of

All of the stringers have their lower flanges field-riveted to the horizontal legs of bracket angles, which, for the trolley and railroad track girders are reinforced by bearing on the upper end of the vertical distribution angles. The railroad track stringers are also additionally secured by top flange horizontal angle connections and by 30 field-driven rivets through vertical web-connection angles at each end. Each end of the floorbeam is connected to the vertical post by 106 field-driven rivets in six vertical rows of holes reamed to iron templates. The floorbeams weigh about 30 tons each and are shipped complete from the shop and handled in erection by special swiveling attachments which enable them to be delivered to the bridge parallel to its axis and to be revolved 90 deg. after being lifted from the cars by the overhang tackles, which swing them to position.

At post P3, where the bottom chord is clear of the lower flanges of the floorbeam, the latter is a simple plate girder 121 in. deep with webs and flanges like those already described for the end floorbeams except that the ends are not fitted around the lower chords and are set square and riveted to the vertical post through their full depth, the connection being made with a pair of 6x8x¾-in. vertical angles, having two rows of rivets to each flange. The lower flanges of the stringers are seated on and riveted to the top flange of the floorbeam.

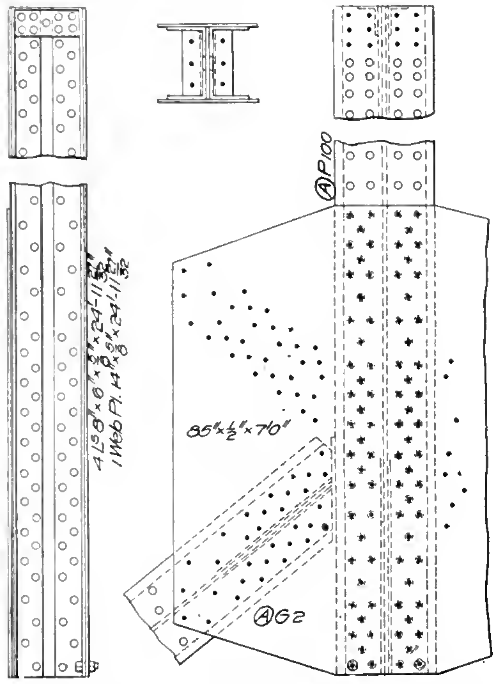
Near the river end of the anchor arm and the shore end of the cantilever arm the floorbeams virtually form the top chords of triangular trusses of which the bottom chords are formed by the main diagonals of the transverse braces below the floor. The floorbeams proper here consist of a box girder with two 48x7-16-in. full-length web plates, four 6x4x1½-in. flange angles, one full-length 26x1½-in. top flange cover plate and two full-length 7x1½-in. bottom flange cover plates. The stringers make butt joints on the center line of the top flange, where they are seated on riveted transverse plates. Pairs of 66x½-in. vertical gusset plates are riveted to the insides of the webs at the ends and centers of the girders and project below the lower flanges to form jaws receiving the field riveted connections of the diagonals and of the center vertical posts.

The upper ends of the intermediate vertical posts are inserted between the girder webs and are field riveted directly to them. The ends of the floorbeams have pairs of vertical connection angles 6½ ft. long, field riveted to the faces of the vertical posts or hangers. The main diagonals of the transverse bracing, which form the lower chords of the trussed floorbeams, have I-shaped cross section made with a 14½x⅜-in. web plate two pairs of 7x3½x5-16-in. flange angles and two 18x7-16-in. flange cover plates. They intersect at the center of the panel, where they are cut to clear the vertical post supporting the floorbeam at its center point, and are connected to it and spliced together by a pair of 85x½-in. flange cover plate, 7 ft. 10 in. long.

The lower ends of the main diagonals are connected to the feet of posts P4 with pairs of 70½x½ vertical gusset plates field riveted to the flanges of the vertical post and shop riveted on the outside of the web plate of the lower horizontal transverse strut, the ends are notched to clear the lower chord and they are connected above the strut with an oblique diaphragm made with a pair of plates back to back transferring the lateral stresses from the X-brace members in adjacent panels which are connected to corresponding double bent plates on both faces. The lower lateral strut has a rectangular cross section made with two vertical 26x⅜-in. side plates and four 3½x⅜-in. angles latticed top and bottom.

(To be Continued.)

Ventilation of Tunnel Workings during the Euston extension of the City & South London Ry. received the careful attention of the engineers and contractors, who commissioned Mr. Harvey Collingridge to make periodical examinations of the air at short intervals. Whenever these showed that the working conditions were not up to the standard deemed necessary, immediate steps were taken to remedy matters by exhausting the foul air and supplying fresh. As the impurity in the air at the working face generally was two or three times as much as in the body of the tunnel, a little distance back, it was found necessary to keep the point of air discharge close up to the shield. It sometimes happened, also, that foul air collected at other points in the tunnel workings, and accordingly the whole line of the construction was kept under observation.



Center Connection of Trussed Panel, Quebec Bridge.

Electric Operation on New Haven Line.

The recent beginning of regular electric operation of passenger trains of the New Haven R. R., running into New York was an engineering event of unusual importance, although trial and training runs had previously been made so often that there was no question about the success of the new system. This company was one of the earliest pioneers in the field of heavy electric traction, and operated six short branch lines in commercial service by electricity for a number of years. Three of them, aggregating 33 miles in length, were equipped for overhead contact, and three of them, aggregating 39½ miles in length, for third rail contact. All these lines were equipped with 500-volt, continuous current motors. The third rail was rather primitive in design and without protective devices, and so many injuries and fatalities followed its use that the company abandoned all third rail operation in Connecticut in consequence and returned to the use of steam locomotives. Improvements over the method it adopted formerly are now available, but it is safe to say that this unfortunate experience was one of the leading factors which determined the company to adopt the single-phase method of propulsion on its line. This selection of single phase after the New York Central authorities had chosen continuous current locomotives to haul trains into the same terminal station has aroused considerable interest, and on this account it is desirable at the outset to explain just why the choice was made, this explanation being based on information furnished by Vice-President McHenry, of the New York, New Haven & Hartford R. R.

Had the company been limited in its inquiry to the equipment of the terminal section leading into New York City, which is now electrically operated, considerations of expediency would doubtless have led it to select continuous current motors taking current from a third rail. The company, however, recognized the great importance of its decision upon future extensions of electric service to other parts of its system, and its final decision was accordingly based upon a study of the road as a whole rather than upon the solution of the New York terminal problem only. Its main problem, therefore, was the selection of a system of electric transmission best adapted to its condition, combining in the greatest measure efficiency, flexibility, simplicity and lowest first cost.

In the case of the New Haven road this problem was rather unusual for reasons which will appear at a glance at any map of its system. The latter comprises a net-work of lines which makes the transmission problem one to be worked out for areas rather than for lineal distances, reversing ordinary conditions. Under such circumstances the economic radius corresponding to any initial potential will be considerably extended and the practical value of high potential transmission will be much increased. The company finally adopted the single-phase system for a number of reasons. The efficiency which it showed was 95 per cent. between the bus bars in the power house and the collectors on the cars, whereas the customary continuous current motor system has an efficiency of but 75 per cent. The flexibility of the continuous or combination system is impaired by the limited radius of the low tension distribution, requiring sub-stations at frequent intervals, and still further by the limitations imposed by the use of a conductor rail. The position and height of this rail regarding the track rail must be rigidly maintained, while the overhead conductor used with the single phase system may vary 8 ft. in height and 4 ft. horizontally without causing inconvenience. It was also believed that the cost of the single phase installation would be much less than that of a continuous current system, although it is too early to furnish positive comparisons of cost of construction and operation at the present time.

The selection of the frequency and voltage of the transmission system was a decidedly interesting problem. The choice of frequency was practically fixed by the manufacturing companies at 15 or 25 cycles. The lower frequency afforded a material reduction in weight, size and cost of motors, a reduction in conductor losses and induction disturbances, together with an increase in the power factor of the motors. On the contrary its adoption would have materially impaired the commercial value of the system as a whole, in preventing its extension for many other uses incidental to railway operation. The standard power and railway frequency in general use is 25 cycles, and as the New Haven company already owned a number of power houses generating current at this frequency for trolley roads and, in addition, had equipped many of its shops with 25 cycle motors, the adoption of 15 cycles would have required the abandonment of a large amount of standard apparatus or the use of costly and inefficient frequency changes. The lighting of buildings was an important factor, also, for 25 cycles is the lowest frequency at which carbon filament lamps in general use can be satisfactorily operated. It was also considered desirable to provide for operation in parallel with the 25-cycle generators already adopted by the New York Central R. R. Accordingly the practical effect of a change from 25 to 15 cycle apparatus on the New Haven system would be substantially equivalent to a break in gauge and under existing conditions it was decided that the practical commercial value of the higher frequency outweighed the more theoretically merits of the lower one.

In the final selection of apparatus another interesting consideration was the determination of the generating and transmission electromotive force of the system. It was believed at first that the best results would be obtained by transmitting power at the highest initial voltage for which generators could be safely designed, about 22,000 volts, sub-stations being provided at suitable intervals for supplying current at 3,000-6,000 volts to secondary circuits. As the two motors in each electric locomotive truck are permanently connected in series, current must be supplied to them at 560 volts through the trans-

former which is a part of the locomotive's equipment. It was finally ascertained, however, that great simplicity would result from cutting out entirely the intermediate sub-stations and line transformers and reducing the initial electromotive force to 11,000 volts, raising the ratio of the locomotive transformer to correspond. This change has caused a reduction in capital and operating cost and an increase in electrcial efficiency which is most gratifying.

Before passing to some of the details of the equipment of the New York, New Haven & Hartford electrified line, attention may properly be called to a few statements given out by Mr. McHenry concerning the commercial aspects of electric traction. His investigations led him to believe that under favorable conditions there may be a sufficient saving in electric as compared with steam operation to pay interest and other fixed charges on the additional construction due to electrification and still leave a satisfactory margin to apply to dividends. Under general conditions, however, he believes it is altogether improbable that the direct saving resulting from the simple substitution of electric for steam power will be sufficient to justify the additional investment and financial risk.

In changing the method of motive power on existing railways, the conditions are by no means so simple as in the construction of new lines, for in the former case a great amount of capital already invested must be sacrificed and the problems of adaptation to existing conditions are particularly severe. The transition stage in bridging over the gap between steam and electric operation is both expensive and difficult, as the change affects train lighting and heating, telegraph and telephone service, signaling and track maintenance. To secure the fullest economy it is necessary to extend the new service over the whole length of the existing engine stage, and to include both passenger and freight trains, and in this connection it is interesting to note that in the case of the New Haven Co., the passenger train mileage forms so large a proportion of the whole that no additional generating and transmission capacity will be needed when electric traction is extended to freight service.

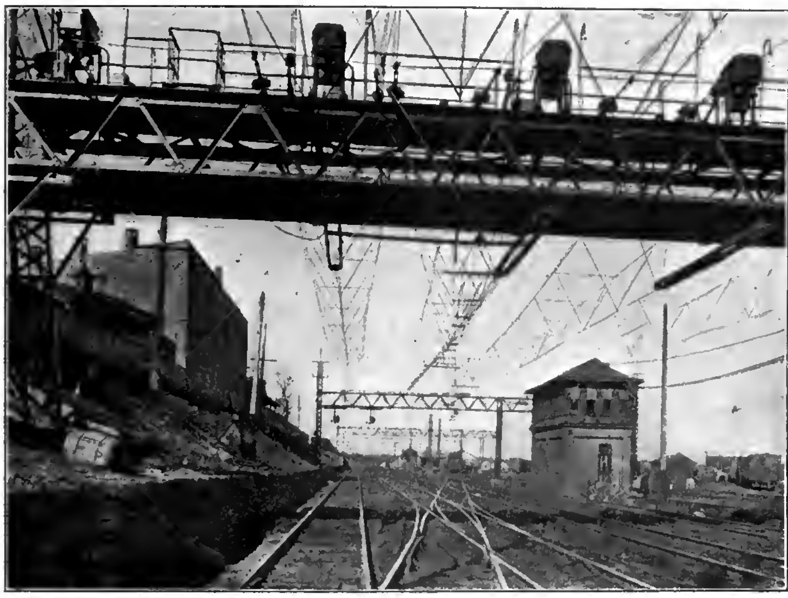
Mr. McHenry believes that the application of electric traction to heavy railway service will probably be governed by more important considerations than its mere relative cost as a motive power under similar conditions. In steam service the weight and speed of trains are limited by the horse-power capacity of the locomotive which generates its own power, and there are but few locomotives which can generate sufficient steam to utilize their full cylinder tractive power at speeds in excess of 12 miles an hour. Consequently any increase of speed beyond certain limits can only be attained by sacrificing train tonnage in a corresponding degree. A division of the train mile cost by the lesser number of tons increases the ton-mile proportionately. The high cost of fast freight service is principally due to this effect of a diminishing divisor, while it would seem that electric traction should permit high speed without sacrificing commercial tonnage, as, with a relatively unlimited source of power at command, the maximum draw-bar pull permitted by the motor design may be maintained at all speeds. The commercial value of high speed in freight and passenger service is so great that the prospect of escaping the present penalties accompanying reduced train capacity becomes doubly interesting.

Hardly less important is the opportunity afforded at the opposite end of the scale, for the economical operation of trains of minimum capacity. The train capacity cannot be reduced, without loss, below the point where the earnings equal the train-mile cost and if this cost cannot be reduced proportionately with reduced capacity, the inferior limit of capacity may be uneconomically large. In steam service the irreducible elements entering into the train-mile cost are so large that it is rarely possible to operate trains earning less than 40 to 50 cents per mile. On the other hand, electric service permits an extreme reduction of the train length to single car units, costing to operate but 10 to 15 cents per car mile. Hence the frequency of service may be increased and rates reduced, which in turn will react upon the volume of traffic, with a final result of increasing both gross and net earning. It may therefore be claimed for electric traction, in Mr. McHenry's opinion, that it will extend the limits of profitable operation of high speed heavy trains and also of light trains of low capacity.

A series of elaborate articles on all details of the electrical installation on the New Haven road is now appearing in the "Street Railway Journal," to which the reader is referred for complete official information in greater minuteness than is elsewhere available. The following notes are intended to give merely a general idea of the equipment.

The power plant is on the main line of the road on the bank of Mianus River, about one mile from Long Island Sound, and was designed and built by Westinghouse, Church, Kerr & Co. Coal can be delivered either by water or rail and an unlimited amount of salt water for condensing purposes is available from the river. By the erection of a dam about a mile upstream from the station, plenty of excellent boiler feed water has been obtained. The station is interesting as an example of plain-faced concrete blocks, made with crushed gneiss obtained in the excavation for the basement and condenser water flumes. In the boiler room the columns are steel, but all others are concrete. The runways for the traveling crane are of reinforced concrete. The boiler room is 160x110 ft., and the turbine room is 60x112 ft., the switchboard occupying a space 25x110 ft.

The current is supplied by three 3,000-kw. Westinghouse Parsons steam turbines and room is left for a fourth similar unit. The generators are wound for 3-phase current, but arranged to deliver both 3-phase and single-phase current. Their design was one of the most important technical problems of the entire undertaking. The former is required for delivery to the New York Central system to compensate for the energy required to operate the New Haven trains over the New York Central lines.



Overhead Lines at Cross-over.

Intermediate Bridge with Signals.

A separate condensing outfit is provided for each turbine, consisting of an Alberger 3-phase counter-current surface condenser, a 2-stage dry air pump, a centrifugal circulating pump direct-connected to a Westinghouse engine and a Monitor hotwell pump, the speed of which is automatically controlled by a float.

Condensing water is furnished by a single flume constructed of timber with a lining of creosoted lumber, from the intake at the face of the dock to the shore line, and of concrete for the remainder of its length. A similar discharge flume parallels the intake flume under the turbine room, and then diverges from it to the river. Each condenser is installed directly underneath the corresponding turbine and over the discharge flume, while the circulating pumps are located over the intake flume, thus making all connections as short as possible. The pipes leading from the condenser to the discharge flume have a submerged discharge, thus decreasing the head under which the circulation pumps work. To prevent electrolysis of the brass condenser tubes, a motor-generator set has been installed with suitable controlling apparatus maintaining in each condenser a counter electromotive force slightly in excess of the electromotive force due to the galvanic action and the stray currents.

Steam is furnished by twelve 525-h.p. Babcock & Wilcox water-tube boilers, set in batteries of

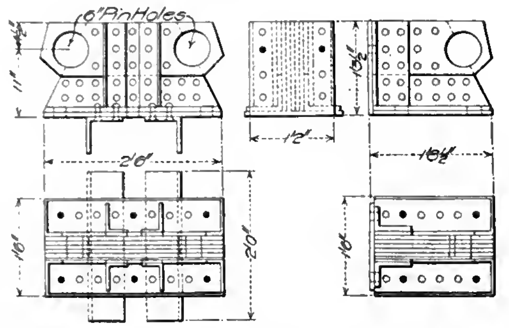
two each and arranged with eight boilers on one side and four on the other, separated by a 21-ft. firing floor. Provision is made for four additional boilers and to take care of the fourth turbo-generator which may be installed later. The boilers have Roney mechanical stokers and Babcock & Wilcox superheaters to deliver steam at 200 lb. pressure and 125° superheat. The boiler settings are completely enclosed in an external steel casing to render them impervious to air leakage. There are three Green fuel economizers.

Water is pumped at the dam at Mianus by means of two single acting vertical triplex pumps driven by 3-phase motors. One of these is able to supply the plant when it is running non-condensing and the other to supply all the fresh water needed when running condensing. Both pumps are operated by current from the power station. The water is forced through a 10-in. main to a circular reinforced concrete reservoir holding 600,000 gal., just outside the power house. From it the make-up water flows by gravity to two 13,000-gal. feed water tanks in the basement of the boiler room, which also receives the discharge from the hotwell pumps. The water is then drawn from these tanks by the pumps and delivered through the feed water heaters and economizers into the boilers. An auxiliary supply may also be obtained from a main of the Greenwich Water Co.

Coal received by water is unloaded from the barges by a clam-shell bucket which raises it into a hopper of 15 tons capacity at a height of 55 ft. above the dock. From the hopper it drops by gravity into a crusher and from the latter drops into steel cars in which it is weighed. The cars are drawn by cable up an inclined single-track railway of 13 per cent. grade into the top of the boiler room. There the coal is discharged into a hopper, whence it is delivered to two flight conveyors running the length of the boiler room. Openings in the bottom of the conveyors discharge coal through spouts to the stoker hoppers of the boilers. The flight conveyors have a capacity in excess of the coal required for the boilers and the surplus fuel is discharged at the further end of the boiler room into a storage bin below the boiler floor. Coal received by rail is dumped directly through a chute into this bin. When the boilers are supplied from this bin, the coal is discharged from it by gravity into a crusher, thence into a bucket conveyor in a tunnel below the bin, by which it is delivered to the flight conveyors above the boilers, and thence through the chute to the stoker hoppers. The ashes are dropped by gravity from the dumping grates of the stokers into chutes leading to cars running on tracks in the basement. These cars at present carry the ashes for use as a filling of the low ground in the neighborhood of the station.

A steam main is carried over the boilers on each side of the boiler house, each of the two mains crossing over to the opposite side at the center of the boiler room; provision is made for cross-connecting these two mains. From the boiler room the mains extend through the partition wall into the turbine room, thence downward into the basement where they connect to a header under the floor. A separate main is provided for the steam-driven auxiliaries, which are all designed to use superheated steam.

The main cables from each generator are run up to the switchboard gallery and thence through circuit breakers down to the high-tension busses under the gallery. One bus supplies the 3-phase current to the Port Morris feeders and the other principally single-phase currents for the New Haven locomotives. When a bus section, or the entire bus is used for supplying single-phase propulsion current, one leg is grounded directly to the track rails of the right-of-way through suitable switches; another leg supplies the outgoing feeders, which are run in duplicate, connecting directly to the trolley and forming the complete single-phase circuit; the third leg of this bus is also connected to a feeder carried along the right-of-way to supply power for local purposes, and completing the 3-phase circuit along the line.



Skewback Hinge Pedestals, Plate Girder Arch.

The locomotives used for hauling the trains were designed jointly by the engineers of the Westinghouse Electric & Mfg. Co., the Baldwin Locomotive Co. and the New York, New Haven & Hartford R. R. Co. They have two 4-wheel trucks, spaced 14½ ft. apart between centers, each truck having four 62-in. driving wheels. The motors, one for each axle, are of the gearless type and the methods of suspending them and transmitting the torque to the drivers are unusual. The armature winding is of a well-known direct current type, but is closed on itself and indirectly connected to the commutator through preventive leads, which are a feature of the Westinghouse design of single-phase motors. These leads serve the same function as the preventive coil used in alternating current work when passing from one tap to another of a transformer. The two armatures on each truck, with their corresponding compensating field coils, are joined permanently in series and operated at all times as a unit. For direct-current work, the two motor units of each locomotive are connected in series at starting and in parallel at full speed, while for alternating current work the two units are operated separately from the secondaries of the step-down transformers at variable voltage, so that they are practically joined and parallel at all times. The locomotives may be controlled from either end by a master controller. On the New Haven portion of the line, current is taken from the overhead trolley line by means of a pantagraph collector, while on the New York Central portion of the route provision is made for a lower overhead direct current pantagraph trolley and third rail shoes. The locomotive measures 36 ft. 4 in. over the bumpers and weighs approximately 85 tons. It is capable of handling a 200-ton train in local service on a schedule speed of 26 miles per hour, with stops averaging 2 miles apart, making in such service a maximum speed of about 45 miles. It can also handle a 250-ton train on through service with a maximum speed of about 60 miles per hour. With heavier trains it is planned to couple two or more locomotives together and operate them in multiple. Details of the locomotive were explained at considerable length in The Engineering Record of March 24, 1906.

The overhead construction is shown in the accompanying illustrations. It is carried by supporting bridges of various lengths, accommodating 4 to 12 lines without intervening posts between tracks, and by heavier anchor bridges of which details have already been published in this journal. The main conductors are paralleled by two auxiliary feeder wires, for feeding around any section that may be cut out of service, and provision is made for two power feeders connected to the third phase of the generating system, and, on top of each post, for a three-phase circuit. The bridges are uniformly 300 ft. apart, and on sharp curves guy poles and pull-over wires are used to give the necessary curvature at intermediate points.

100-Foot Plate Girder Arch Spans over Carnegie Lake.

Snails in the Water Mains of some districts in Chicago have been causing considerable trouble. Evidently these snails originally entered from the lake and are now living in those pipes, which have only a small flow through them. In many cases service pipes have been stopped up by the shells, which have become tightly wedged inside them. These service pipes have been pumped out by force pumps and the main flushed through fire hydrants. In this way a large number of the shells have been removed. Blow-off branches to the sewers and screens on the mains will be tried as remedies.

A Plate Girder Highway Arch Bridge.

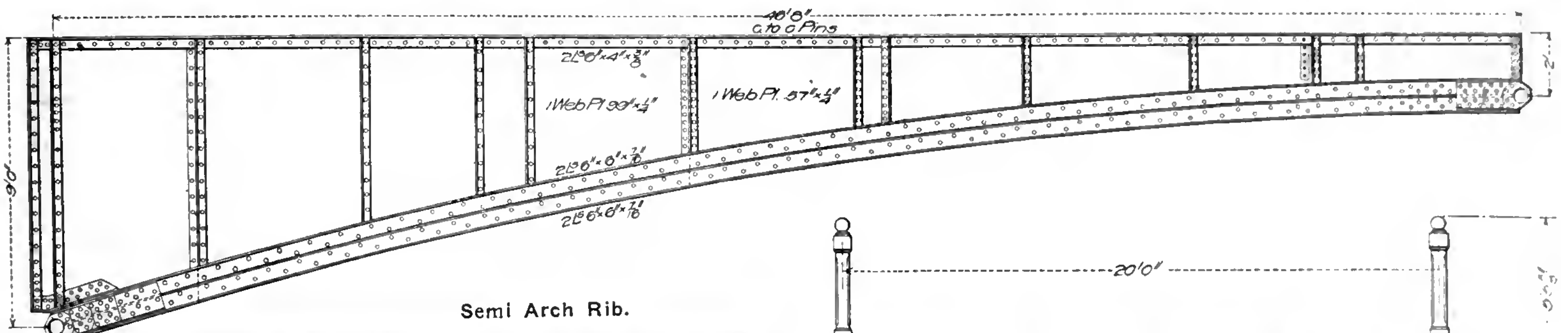
Harrison St., in Princeton, N. J., is carried across Carnegie Lake at a height of about 14 ft. above water level on a bridge of four three-hinge plate girder arch spans of 93 ft. 4 in. Several alternative designs for the superstructure were considered, and estimates were made for ordinary plate girders and for lattice girders, but the arches were adopted on account of the increased headway secured by their use, for the minimum elevation, and because of the much more attractive apeparance presented by them. The weight, although somewhat less than for ordinary plate girders is a little larger than for lattice girders of the same span.

The spans are duplicate and are independent of each other except that the pedestals on the three intermediate piers are continuous. Each span has two 3-hinge arch ribs 20 ft. apart on centers which have a rise of 7 ft. from the skewback pins and a depth of 2 ft. at the crown and 9 ft. at the skewbacks. Each semi-arch rib was shop riveted complete, forming a single unit about 47 ft. long and weighing about 9,500 lb. 26 in. deep are web connected to the arch ribs with their top flanges under the top flanges of the ribs. They carry three lines of 12-in. I-beam stringers with shelf and web connections and support the continuous reinforced concrete floor slabs which also rest on the top flanges of the arch ribs and project a few inches beyond them. The slab is made with 1:2:4 concrete reinforced with a single layer of No. 10 expanded metal of 3-in. mesh. It has a uniform depth of 6 in. except over the stringers where it has a 1-in. extension to rest on their top flanges and at both edges where it is integral with the curbs in which the hand rail cast-iron posts are firmly embedded. The slab is covered with macadam, crowned to a thickness of 5 in. on the center line.

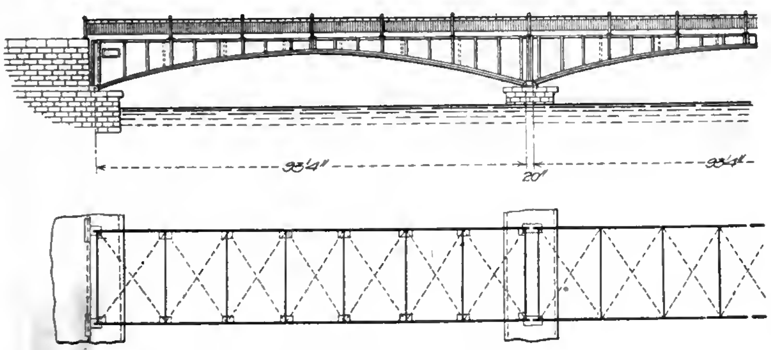
The skewback pins engage half holes in single-web pedestals which, on the intermediate piers, are symmetrical about the center line and receive both adjacent spans, to which they are locked by single projecting reinforcement plates with full holes. A pair of 6 x 6 x 5/8-in. angles 2 ft. long are riveted across the base plate with their vertical legs projecting downward and embedded of 17,000 lb. in tension and 10,000 lb. shear on web plates. The dead load per lin. ft. consists of 800 lb. of steel and 2,200 lb. of floor, while the live load is calculated at 100 lb. per square foot or for a 15-ton road roller.

When the bridge was erected there was no water under it except a small creek between two of the piers. Two ginpoles were set up on the dry lake bottom and erected the semi-arch ribs, holding them in position until connected and braced to be self-supporting and stable. All materials were delivered by wagons at the feet of the piers and hoisted by the gin poles or by hand.

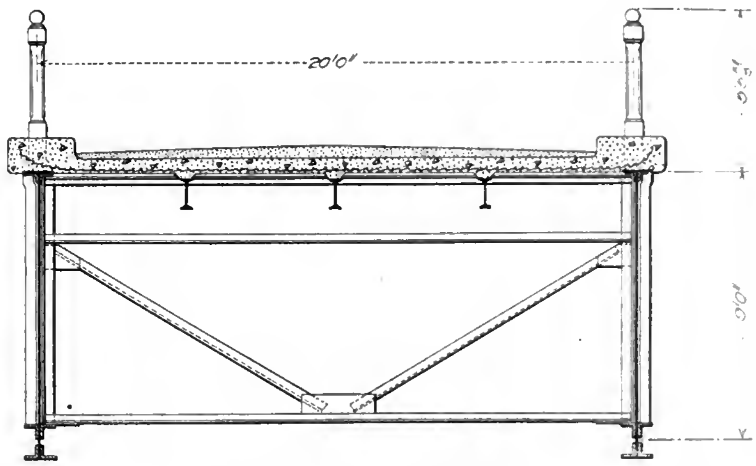
The bridge was designed by the American Bridge Co., and was fabricated in its Trenton plant. The United Construction Co., Albany, N. Y., was the contractor for the erection of the superstructure.



Semi Arch Rib.



Three-Hinge Arch Span.



Cross Section at Crown of Arch.

It really corresponds to a spandrel braced arch truss in which the effective member is the curved lower chord which is the segment of a parabola. It has an H-shaped cross section with a uniform area built up with four 6 x 6 x 7/16-in. full length flange angles and a 1/4-in. web plate which, forming the spandrel bracing, projects beyond the lower chord to the horizontal upper flange of the arch rib which is made with two 6 x 4 x 3/8-in. angles.

The web is spliced by double vertical rows of rivets through pairs of 6 x 3/8-in. cover plates and is divided into panels about 5 1/4 ft. long by pairs of 3 x 3-in. vertical web stiffener angles. The arch rib is reinforced at both ends by pairs of pin plates to give the required bearing for the 6-in. skewback pins and the 5-in. crown pins. The bearings are made with half holes, except that the outside reinforcement plate is continued far enough beyond the end of the rib to receive a full hole and lock it to the pin.

The arch ribs are connected at both ends and at six equidistant intermediate points by lower horizontal struts and vertical transverse X-bracing of the ordinary type made with single light angles riveted to vertical web stiffener angles adjacent to those at the regular panel points. The panels between have X-brace lateral angles in the plane of the lower flange. The plate girder floor beams

in the concrete so as to develop considerable resistance to any unbalanced horizontal thrust which might temporarily occur during erection or from very irregular loading. Since the horizontal component of the reaction is greater than the vertical component, the pedestals at the abutment ends of the bridge, which receive only one skewback hinge each, are made with both vertical and horizontal bearing plates and the former engages the outer flanges of a grillage of three 6-in. I-beams 4 ft. long embedded horizontally in the concrete abutment.

The thickness of the floor slab is increased at the ends to 7 in. and rests and slides freely on a seat moulded in the top of the abutment back wall with its surface and that of the floor slabs thoroughly painted with hot asphalt to prevent adhesion and to facilitate longitudinal motion. The roadway is protected by neat fences in the planes of the arch ribs which have at panel points cast-iron posts carrying the 2 x 3/8-in. top and bottom bars, 33 in. apart, the 3/4-in. square vertical bars 5 1/4 in. apart and a top rail made of a 3 1/2-in. pipe, with a horizontal 2-in. channel, flanges up, riveted to it.

The bridge is made of railway bridge grade open hearth steel corresponding to the requirements of the manufacturer's standard specifications and proportioned for maximum unit stresses

The Protection of Concrete and Iron.

The protection of concrete and iron exposed to the portion of the water of Frankfort, Germany, drawn from driven wells is necessary on account of the large amount of oxygen and free acids in the supply. These have a destructive effect on iron and other metals, the iron undergoing a softening change which continues to such a point that it can finally be cut with a knife. The concrete walls of a large reservoir having a dense surface coat of cement mortar were also attacked by this water, and the department accordingly undertook an elaborate series of investigations to determine the degree of protection against such action afforded by various compounds on the market. After experimenting for some time, none was found sufficiently resisting to this peculiar water, but Dr. Carl Roth, the chemist engaged on the investigation, devised a compound which gave much more satisfaction, lasting without apparent injury long after other substances had completely failed. The success of this compound has led to its being placed on the market under the name of "Inertol" by Mr. Paul Lechler, of Stuttgart. The concrete is best rubbed off with felt disks rather than steel trowels, and must be perfectly dry and preferably warmed before the inertol is applied. The latter should be given an opportunity to dry thoroughly before water is allowed to come in contact with it, for otherwise the water will acquire the odor of carbolic acid and consequently be spoiled for drinking purposes.

A Low-Cost Concrete Railway Culvert.

In line with the policy of the Nashville, Chattanooga & St. Louis Ry. to fill all trestles instead of rebuilding them, whenever possible to construct culverts for the waterway required, it was decided in 1905 to fill Trestle 55.7 on the Nashville Division.

This trestle, known as Yellow Bank trestle, has a total length of 922 ft., with the track at an elevation of 76 ft. above the valley. There is no stream under the trestle except during the wet season, when a large volumne of water passes through. After making a survey of the drainage area above the trestle to determine the size of waterway required, a 12-ft. full-centered concrete arch culvert, with 6-ft. side walls, was decided upon as being ample, and plans were prepared for the same.

In designing the plant for building the culvert, advantage was taken of the height of track above the valley, so that as nearly as possible all material moved by gravity from the cars in which it was shipped until finally placed in position in the wall. Slag and sand were shipped in drop-bottom cars and unloaded into bins constructed in the trestle. These bins were built with hopper bottoms, ending in chutes that led to a wheeling platform, which occupied the space between two of the tresle bents and extended over a concrete mixer placed just outside of the trestle. A cement house was erected alongside the trestle, level with and adjoining the platform. An inclined chute led up from the opposite end of the cement house to an unloading platform at track level, so that the cement, which was shipped in sacks, could be handled directly from the cars to the chute, and thence by gravity into the house.

The sand and slag were fed by gravity into wheelbarrows through gates controlled by levers to regulate the amount taken, and were then dumped into a hopper directly above the mixer. Two men wheeled slag to the mixer, one man wheeled sand, and one man wheeled cement. With the mixer in operation these men had to load the barrows and make a round trip, including dumping the load into the hopper, in about one minute's time. The maximum wheeling distance from the chute to the hopper was 23 ft.

A water supply was secured by sinking a well in the drainage channel just below the trestle, the water from this well being pumped by means of a gasoline engine into a tank placed on the trestle. From the tank a continuous stream of water was fed into the mixer through a flexible connection, a valve so regulating the flow that the necessary amount was delivered in the time required to mix a batch.

A drop-bottom car of 1 cu. yd. capacity, running on 30-in. gauge tram tracks, conveyed all concrete from the mixer to the wall. The hinged bottom doors of this car were held closed with a latch, which was withdrawn by means of a lever at the side of the car to dump the load. After dumping, the bottom doors closed automatically, and were latched by the lever above referred to.

A trestle spanning the entire culvert was constructed out of old car sills, with the deck at a sufficient height to clear the top of the arch when completed, and longitudinal tracks were built on the same directly above each wall. This arrangement permitted dumping the concrete into its final position in the wall without rehandling. Two small turntables connected the longitudinal tracks with a cross track that extended to the mixer. Three men were required to handle the car, and they made the round trip when going to the extreme end of the culvert in about 3 min., the mixer in the meantime discharging into a small hopper, which discharged into the car upon its return.

In order to provide expansion joints, the culvert was built in three sections, both walls of a section being brought up together. After reaching a point 2 ft. above the spring line, one of the tracks was removed and the other shifted to a position directly above the center of the arch, so as to reduce the handling of concrete to a minimum.

The concrete consisted of a 1:3:6 mixture, slag and stone being used as the aggregate. It was intended to use slag exclusively, but delays in shipment of the same necessitated substituting stone for about one-third of the work.

All excavating for the foundation, unloading of material, mixing and placing of the concrete, was done by one of the regular concrete forces of the railway, consisting of four white men and thirteen negroes, the rate of pay being as follows: 1 foreman, $3.50; 1 mason, $3.50; 1 carpenter, $2.25; 1 blacksmith, $2.05; 5 laborers, $1.20; 8 laborers, $1.10; a total of $26.10 per day. Usually this gang builds the forms as well as doing all other work; but owing to the size of the culvert and the haste to complete concreting before cold weather, the forms, arch centering, bins, tram trestle, and working platforms were erected by a bridge crew of white men, whose pay ranged from $1.75 to $2.25 per day. This slightly increased the cost of building forms, but secured rapid construction of the culvert.

The concrete gang moved to the work on Sept. 12, excavated 853 cu. yd. of earth, unloaded the material for and mixed and placed 1,217 cu. yd. of concrete, removed the forms and bins, loaded all timber used in construction, and moved away on November 9. During this time they lost three days on account of rain and closed down one day for lack of material.

The mixer was in operation 194 hours, and mixed 7,702 batches, or at the rate of one batch every 87 sec. during the entire time it was in operation. During the last ten days it mixed a batch every 78 sec. while running. The best short record made was 291 batches in 5 hours, being one batch every 63 sec., or at the rate of 58 batches, equal to 9.2 cu. yd. of concrete in place per hour. This is about equal to the capacity of the machine, one-half minute being required to mix the concrete, and at least that much time in charging and discharging it.

A No. 5 Chicago improved cube mixer, operated by a Bates & Edmunds Motor Co. gasoline engine, was used, and gave satisfaction; but a larger size would have been more economical, as all cement had to be measured, the amount required for each batch being two-thirds of a sack. This measuring required one additional man.

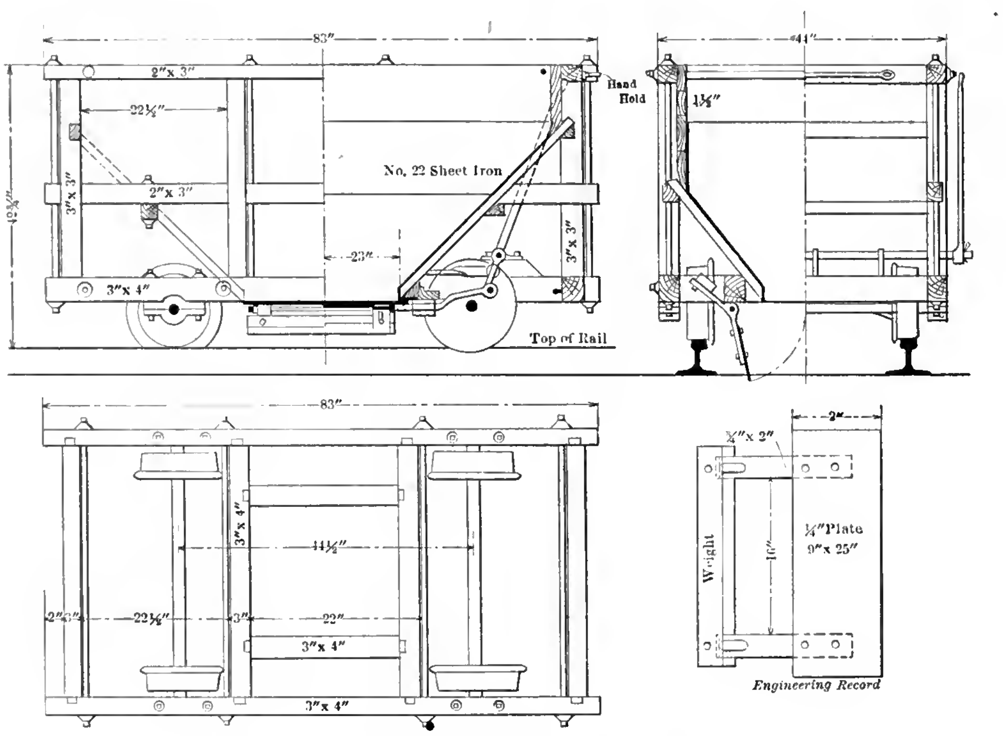
Another objectionable feature of the small machine is the size of the charging hopper, which causes a tendency to choke if the entire contents of a wheelbarrow are dumped into it instantaneously. To the cost of one man required to keep the hopper open should be added the delay in charging the mixer, which materially reduces the daily output of the same.

A comparison of the cost of this culvert with those of culverts on the same road built under quite similar conditions shows a large saving both in the labor and material items, the saving in the latter case being due to the use of slag. The concrete amounts to 1,217 cu. yd. and cost on an average $4.32 per yard, as against $5.88 per yard for the next lowest cost culvert which contained 406 cu. yd. of concrete, and $6.27 per yd. for a culvert containing 986 yards. The cost of the labor for the Yellow Bank culvert was $1.64 per cubic yard, for the second culvert $2.97, and for the third $2.97. These costs include excavation, mixing and placing concrete, building and removing the forms, and the back filling.

The cost of the concrete alone including forms, material, and labor of unloading, mixing and placing was $3.71 per cubic yard for the Yellow Bank culvert, $5.16 for the second one, and $4.96 for the third, the labor items in these amounts being respectively $1.08, $2.11 and $1.67 per cubic yard of concrete.

The reduction in labor cost was due largely to the use of a mechanical mixer, although the large yardage and the economical methods of handling material were factors in bringing about the reduction. The total cost of the culvert was $5,258.13.

The account of the work here given was presented in a paper by Mr. W. H. Whorley to the Engineering Association of the South.



Concrete Car Used on Nashville, Chattanooga & St. Louis Ry.

The Kern River No. 1 Power Plant of the Edison Electric Co., Los Angeles.—Part II.

By C. W. Whitney.

Power House.—The pressure tunnel emerges from the side of Mt. Breckenridge at an elevation above the sea level of 1061.95 ft. Directly in front of this point and slightly up-stream there was a boulder-covered wash protected by a bend of the river and bordered by a large mass of bed rock standing at the edge of the main channel of the river. This space was chosen as the power house site. The intake of the Power Transit & Light Co., of Bakersfield, is directly across the river and it is necessary to discharge the water from the wheels in such a direction and at such an elevation that it will flow by gravity into their intake.

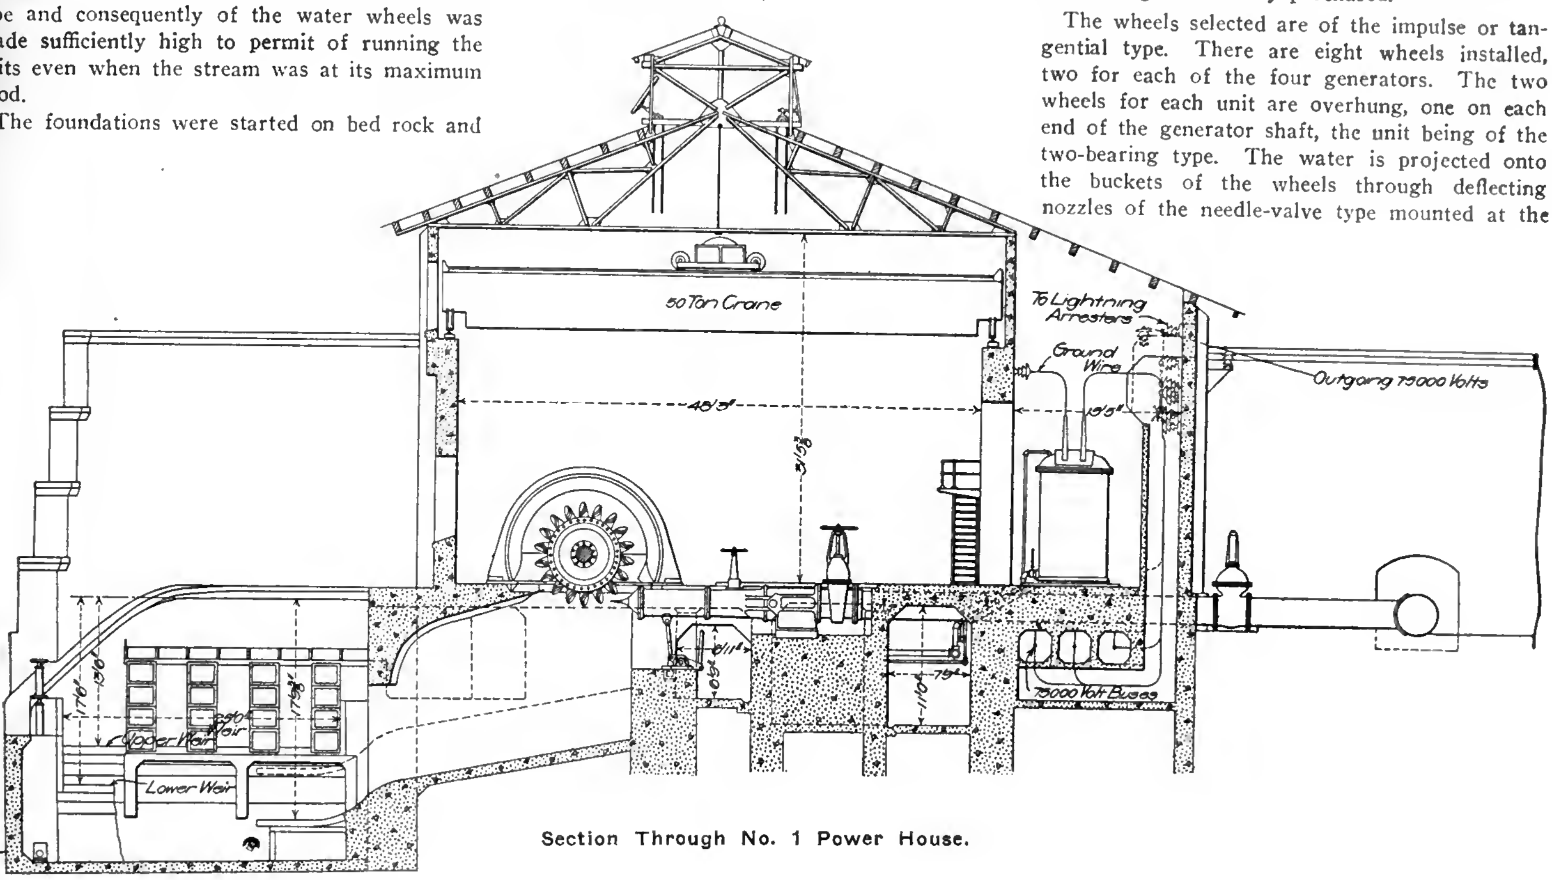
The Kern River is subject at times to very considerable floods and the elevation of the header pipe and consequently of the water wheels was made sufficiently high to permit of running the units even when the stream was at its maximum flood.

The foundations were started on bed rock and cemented boulders, low enough to avoid any possibility of the power house being undercut by floods and were carried up as walls in such a manner that no important machinery rested on floors placed on backfill. All spaces between these walls except those which could not be utilized on account of their falling so low as to be subject to flood, were filled in with compact backfill from other portions of the work.

The available area was so crowded that it was necessary to make a deep excavation in the hillside to accommodate the inner or eastern end of the building. The débris from the cut and from the tail-races was wasted on the south side of the building as a dump upon which the header and branch piping from the pressure mains were placed. On the north side of the station the spoil bank filled in a triangular area of the flat wash, raising its entire area above maximum high water and producing a bulkhead which will protect the power house from any possible flood.

The foundations proper are of monolithic concrete. The rock and part of the sand for the aggregate were secured by crushing granite boulders excavated from the site, as well as a large amount of rock which was lying on the pressure tunnel dump. Additional sand was secured for a time from various small bars in the river adjacent to the power house. These were, however, covered by exceptionally high water early in the year and after that time all necessary make-up sand was hauled from the mouth of the canyon about 2½ miles distant.

The upper part of the machine foundations carries a small amount of reinforcement. The large block of masonry back of each water-wheel deflector is heavily reinforced and tied into the main foundation blocks. The crane rail arches for the interior wall are reinforced concrete beams, with the exception of the long span above the switchboard, which contains an I-beam girder. By reason of the length of the building and the importance of the work no account was taken in its construction of the additional strength resulting from the continuity of the beams, the bridging effect of the crane rail, and its cushioning timbers, nor was any allowance made for the 12-in. curtain walls which fill in in places below this beam. The north wall, however, is a 12-in. curtain wall reinforced with heavy pilasters and this contains only sufficient reinforcement to render it reasonably secure against shock and vibration. The south wall of the building is of a cellular construction for about two-thirds of its height in order to provide wiring ducts for the 60,000 volt wiring connections. This wall also contains only nominal reinforcement. Between this wall and the interior crane wall, a space 15 ft. wide, a series of transverse partitions break up the area into transformer, switch and switch-board rooms. The transformer rooms are open up to the crane beam to permit of wheeling the transformers out under the main crane. The crane rail columns are not highly stressed and have no hooping whatever. A 50-ton electric traveling crane with a 50-ft. span, built by Maris Bros., serves the entire machine room. The switch-board space carries a deck 8 ft. 6 in. above the main floor level upon which the control board is mounted.



Section Through No. 1 Power House.

The roof of the building is of galvanized iron laid on wooden purlins, which are carried on steel roof trusses of 52 ft. 1 in. clear span. The internal length of the machine room is 164 ft. and its clear width 66 ft. 6 in. The generating units are located along the north side of the station 78 ft. from the center of the pressure header.

Water Wheels.—At the time tunnel work on the Kern River No. 1 plant was commenced five years ago, no plant of its size had been constructed for impulse wheel work. Units exceeding 2,000 kw. in output were extremely rare and for a long time it was supposed that 2,500 kw. units would be selected for this station. When, however, specifications were issued many larger units were in successful operation and prices were requested on machines of 4,000 and 5,000 kw. normal output. No difficulty was anticipated nor was any experienced in securing generators of this size. Considerable attention was given to the water-wheel equipment. Some manufacturers were willing to undertake the building of wheels having an output of 10,000 h.p. each from a single nozzle, but the large size required and the extremely crowded placing of the buckets rendered necessary if the unit was to be of reasonable dimensions, seemed to the officials to indicate that such a construction would be less efficient than the arrangement finally purchased.

The wheels selected are of the impulse or tangential type. There are eight wheels installed, two for each of the four generators. The two wheels for each unit are overhung, one on each end of the generator shaft, the unit being of the two-bearing type. The water is projected onto the buckets of the wheels through deflecting nozzles of the needle-valve type mounted at the end of the 28-in. branch pipe. By means of these deflecting nozzles and needle valves the discharge from the tip of each nozzle can be accurately regulated without altering the form of the jet to any appreciable extent. The wheels are designed to run at 250 r.p.m., and the two wheels on each unit are guaranteed to deliver 10,750 h.p. to the generator shaft.

The nozzles are provided with hand-adjustable needles and are arranged to be deflected by the governor automatically, or by the latter's hand-regulating device. By deflecting the jet, instead of regulating its discharge by adjusting the needle with the governor, it is possible to secure a constant velocity of water in the pipe line, as well as a constant discharge of water into the tail-race, even when the plant is operating with heavy fluctuations of the commercial load.

The nozzles are of the best quality of cast steel. Special attention may here be called to the design, which has a number of new features. Each nozzle consists of two Y pipes, flanged together in such a way that the whole nozzle has a diamond or bifurcated shape. The up-stream end of the nozzle forms the movable part of the knuckle or ball joint, and the down-stream end carries the nozzle tip. By making the nozzle diamond-shaped, the following advantages are claimed by the manufacturers:

1. The center of the jet corresponds to the center of the inlet pipe, therefore any reaction from the jet upon the needle and nozzle is not eccentric. This is of importance with deflecting nozzles, where any variable reaction upon the governor should be avoided.

2. As the two branches of the Y join at an ample distance from the nozzle tip, the water has time to gather concentrically around the needle under an absolutely uniform pressure. The result is that the jet leaves the nozzle tip at a high velocity and without disturbance.

3. Due to the fact that the jet leaves the nozzle tip uniformly, the needle is axially balanced and not subject to any vibration.

4. The needle stem, not being subject to any bending, need not be made slender and flexible, but is made of very substantial form. The end of the stem projecting through the front Y pipe is of smaller diameter than the stem. The differential room thus formed can be put under adjustable water pressure. This pressure tends to close the needle and puts all pins and links of the connection to the hand adjustment under slight pressure in the closing direction. By this any rattling of the needle is prevented.

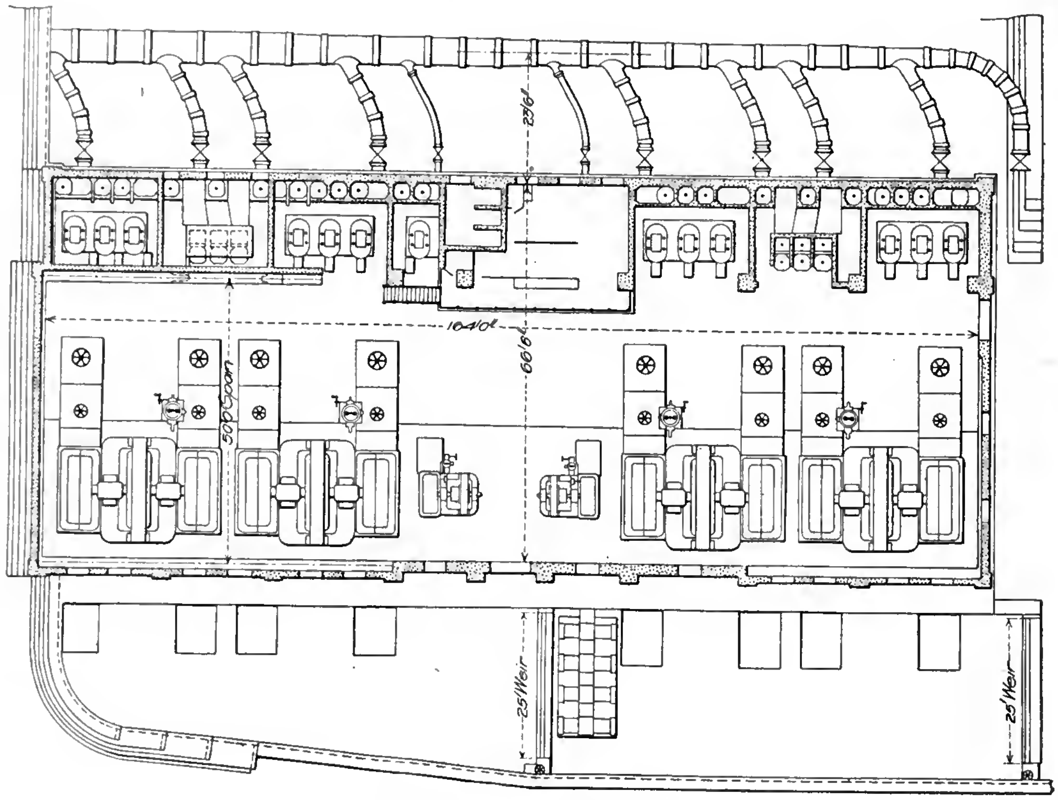
The up-stream end of the nozzle, forming the movable part of the ball joint, is hooked into the stationary part, or swivel head. This swivel head is heavily bolted to the concrete foundation, as it has to take up the full pressure of 375,000 lb., tending to pull the nozzle away downstream. This pressure is taken up by two steel trunnion pins carefully fitted into their bearings and provided with suitable lubrication.

The nozzles are equipped with needles for adjusting the size of the stream by hand. For convenience in construction and to permit of balancing them for back-thrust the needles are straight backed, running through a guide-sleeve of their full diameter into a balancing chamber supplied with water from the pressure side. The needle then reduces to a stem and passes through a second stuffing box beyond which the control links are attached. The needles are topedo shaped, being 8 ft. long 12 in. in diameter at their maximum and 8½ in. in diameter at the stem. The tip is about 25 in. long and is carried down to a blunt point on straight lines. The needle is operated by means of a hand wheel on the main floor, the wheel-stand also supporting a pressure gauge connecting with the nozzle and the two pipes connecting the two sides of the nozzle body with the balancing chamber of the needle. Each nozzle throws a jet 7⅜ in. in diameter at full opening. Part of the nozzle tips are of cast steel. Some cast iron tips have, however, been supplied, and it is expected that they will wear as satisfactorily as the steel ones.

Each of the revolving elements of the wheel is 9 ft. 8 in. in diameter and consists of a cast-steel rim to which are bolted 18 bronze buckets. These buckets are 27½ in. wide and are not radically different in form from modern buckets used elsewhere on the Pacific Coast, being in general of an ellipsoidal shape with a straight front wall and a dividing wedge that dips down toward the front of the bucket. The housings of the wheels are of cast-iron with graceful lines, and where the shaft enters are fitted with compound baffle plates or water guards to prevent water escaping from the housing. The sides of the housing have extensions into the wheel pit of removable steel plates, which protect the concrete walls against the impact of the discharging water.

The mechanical and hydraulic design of these wheels was carefully checked by the engineers of the Edison Electric Co., before the manufacturers were allowed to proceed with their construction. The combined moment of inertia of the revolving element in the two water wheels and generators of each unit is WR^2=1,800,000 lb.-ft.², by means of which regulation at 100 per cent. load variations is obtained within less than 8 per cent. when the units are carrying 50 per cent. overload and within less than 5⅓ per cent. variation of speed when running at normal load. The efficiency guarantee requires that the water wheel proper shall develop an efficiency at rated loads of 82½ per cent., which guarantee is to be substantiated by tests conducted by the company. For sudden changes of load, amounting to 25 per cent., 50 per cent. and 100 per cent. it is guaranteed that the speed variations will not exceed 1.7 per cent., 3.5 per cent. and 7.8 per cent. respectively.

There are two exciter units, each being of the two bearing type, with an impulse water wheel on one end and a heavy fly-wheel designed to give the units close regulation on the other end of the shaft. The exciter wheels are operated from stationary needle nozzles, the needles being of the same straight form used on the main wheels.



Plan of No. 1 Power House.

Regulation is obtained by governors which operate stream deflectors that are pulled up into the stream from below as the load on the unit decreases, thus deflecting a part or all of the stream into the tail-race. The exciter wheels are of a construction similar to the large wheels, having 20 bronze buckets 9⅜ in. wide bolted to the rim of the runner.

Governors.—Each turbine with its respective governor forms an independent unit. Although the available operating water pressure of 370 lb. from the force main is ample to operate governors, it was preferred to substitute oil governors. The governors are not fed from a central system, but each is absolutely self-contained. The oil pressure is 125 lb.

Special attention was paid to the safe operation of the units, avoiding from the beginning any tendency to run away. For this purpose the arrangement of the generator, as well as the exciter governor was made in such a manner that the jets will be automatically deflected from the buckets whenever the oil pressure in the governor should fail.

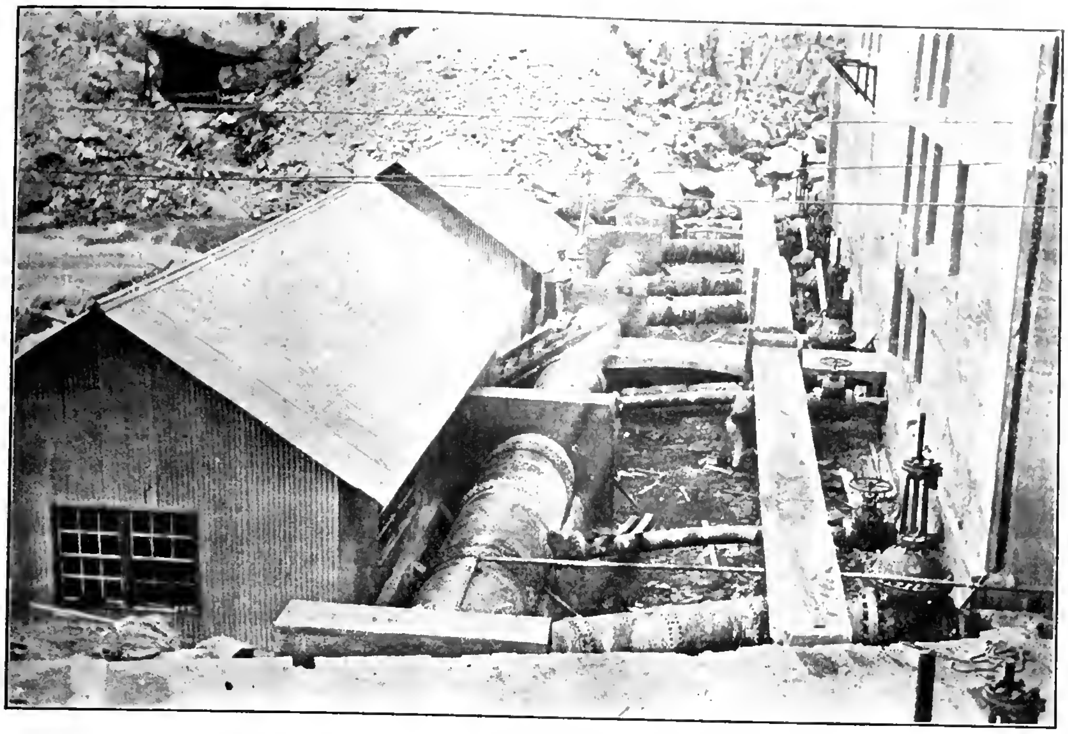
The weight of the two deflecting nozzles for each unit is partly carried by a hydraulic balancing piston placed midway between the nozzles, which receives water pressure directly from the force main. The governor arm connects by means of a link to a common rock shaft, which in turn actuates the two nozzles by means of rocker arms. These shafts are below the main floor and are accessible through a longitudinal alley or tunnel 5 ft. wide, and having a clear head room of 6 ft. 9 in. The governors are driven by a Morse silent-running chain driven from their respective wheel shafts.

The main casing contains the main operating cylinder with piston and mechanical hand-regulating device. The oil pump is attached to the casing and immersed in the oil reservoir. It is of the rotary type. The main pump shaft also carries the bevel gear which drives the fly balls operating the pilot valve over the regulating lever. The pilot valve is self-contained between opposing pressures, and any reaction upon the fly balls is eliminated. It is evident that this is a principal condition for exact regulation. The pilot valve distributes the oil pressure in the regulating cylinder. The motion of the regulating piston is reversedly transmitted to the regulating valve by means of a combined compensation. The leverage of this compensation is adjustable, so that the governor may be set to any change of speed between no load and full load, from 16 per cent. to absolutely constant speed.

The governors are equipped with four regulating devices which can be used at any time: 1. Mechanical hand regulation (without oil pressure). 2. Automatic regulation with fly balls. 3. Hand regulation with oil pressure (fly balls disconnected by a clutch coupling inserted between pump shaft and fly ball shaft). 4. Hand regulation with oil pressure and electric motor operated from the switchboard. (Synchronizing attachment.)

The exciter governors are of similar design, except that they are not provided for electric hand regulation. All the water wheel equipment mentioned above was supplied by the Allis-Chalmers Company.

The Lombard Governor Co. has furnished for the plant one of its type N governors for operating one of the main units and a type Q governor for one of the exciters. The governors are of the vertical oil pressure type and the order includes the necessary reservoirs, pumps, and similar equipment. The Edison Electric Co. has used Lombard governors in its other hydro-electric plants and is desirous of determining the relative

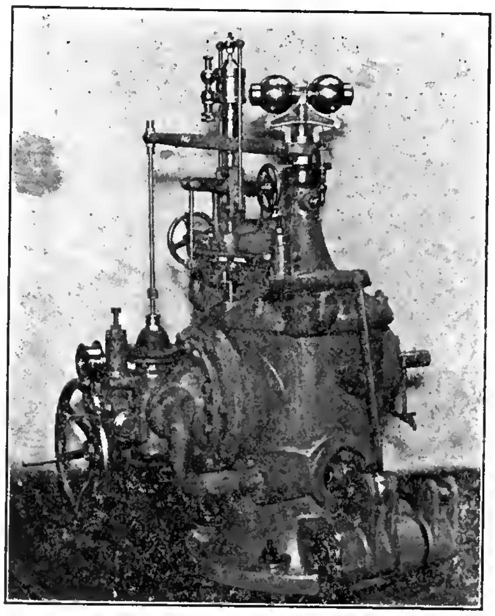


Pressure Header and Branch Piping at No. 1 Power House.

performance of the two types of governors in the new plant.

Tailrace.—Another feature of the water-wheel installation deserves mention on account of its novelty. As already mentioned, the regulation of the wheels is effected by a governor which deflects the jets of the two nozzles. The needles are adjusted by hand and are usually set to that maximum size of jet which will be sufficient to develop the maximum peak loads expected for that period of setting of the needles. In other words, there is always a maximum amount of water leaving the nozzles. The governor adjusts the deflecting nozzles in such a way that only as much water is directed upon the buckets as is needed for the load for the time being. The balance discharges below the buckets into the tailrace. Each jet has a maximum diameter of 7⅜ in. and leaves the nozzle tip at a velocity exceeding 225 ft. per second. It was necessary to provide means of receiving this tremendous power and deflecting the jet into the tailrace in such a way that its impact would not be detrimental to the structure against which it is directed.

The arrangement designed consists of a pair of heavy deflector plates onto which the jet is diverted. These plates are curved as shown in the elevation of the power house, their design being such as to turn the water through two right angles before it is allowed to pass into the tail race, thus reducing the force of the water so that it can do no damage. The upper of these plates consists of a channel heavily ribbed and bolted to the concrete foundation. The channel at its upper end is slightly more inclined than the deflected jet. Thus the jet strikes the bottom of the channel at a small angle, and therefore tends to spread and fill the section. The channel gradually widens and the jet is consequently offered a larger resistance area. The lower part of the channel is curved and at its end the jet discharges almost perpendicularly downward. The bottom plate is *S* shaped, its upper end being flush with the bottom of the wheel pit, the lower end practically level. The jet strikes the bottom plate almost in the turn of the *S* and under a small angle. Thus the jet is again forced to spread and follow the base of the bottom plate. The deflectors are lined with removable steel plates wherever the surfaces are exposed to the flow of the deflected jet, being held in position by lag screws. The plates are 7 ft. wide and the lower one projects out into the tailrace 8 ft.



Allis-Chalmers Exciter Governor.

The wheel races are lined with steel on both sides and fitted with steel back plates just back of the nozzle tips to keep the splash water out of the shaft alley.

The tailrace is 29 ft. wide and extends the length of the power house. It is fitted with two 25-ft. steel plate weirs, the lower weir at the end of the tail race being 4 ft. below the level of the upper weir, which has its crest 13 ft. 6 in. below the line of the nozzles.

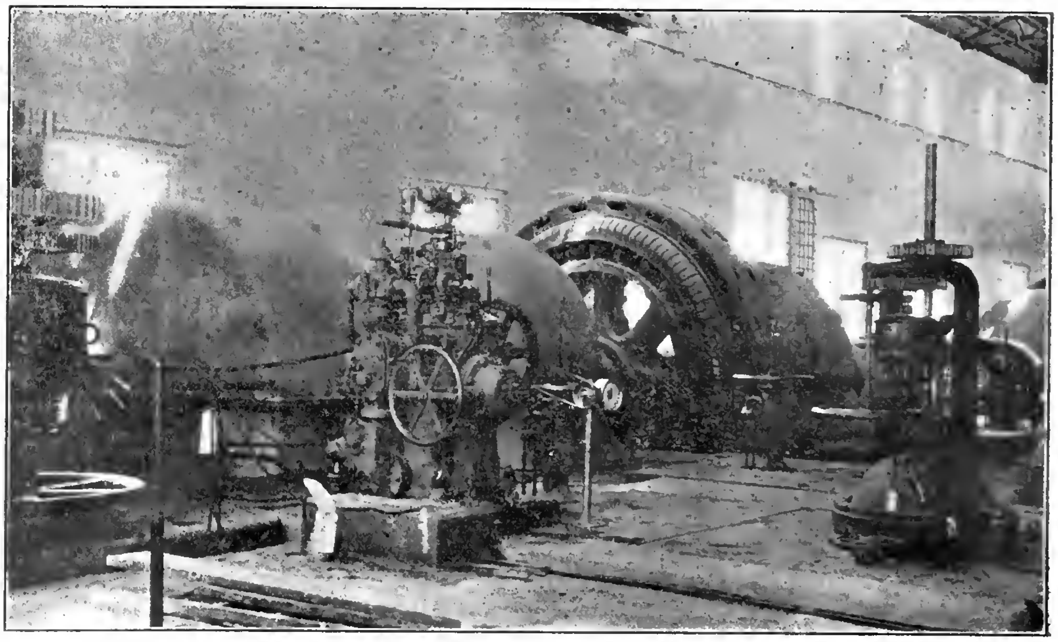
The water wheel branch pipes enter the power house at the south side and after passing across the transformer rooms and before joining the nozzle bases connect to 28 in. cast-steel gate valves. These valves are of a special design and are each operated from the control switchboard by a 1.2-h.p. 120-volt Allis-Chalmers motor. These motors are mounted vertically and operate at 460 r.p.m. It requires 7½ min. to open or close a valve by means of the motor. All of the gate valves are equipped with 4 in. by-passes.

In the machine room of the power house is installed a Dibble reservoir gate equipped with an indicating dial and a registering chart for measuring the water in the forebay.

Capacity of the Plant.—The normal rated capacity of the Kern River No. 1 power plant is 20,000 kw., or 26,667 electrical horse power. The machinery is all tested to operate under 50 per cent. overload for peak load service, thus making the ultimate capacity of the installation 30,000 kw., or 40,000 electrical horse power.

Generators and Electrical Equipment.—The main generators are of the standard General Electric A. T. B. type, form S, and have a rated capacity of 50,000 kw. The stationary armature is bar wound for 2,300 volts 3-phase 50-cycles. The main units are each carried on two 16x48-in. babbitted bearings, each fitted with six oil rings for flooding them with oil from the cellars contained in their pedestals. In the pedestals the oil is cooled by means of water coils built into them. Each bearing also has in its lower portion a number of small openings which are connected to a triplex motor-driven pump capable of circulating the lubricating oil under a pressure of 1,000 lb. to the square inch. The generator shaft is flared out at each end to form a flange to which is bolted the wheel disc. The shaft is also enlarged at the center to carry the cast-steel pole rim and spider. This latter is a single casting weighing 26 tons. The pole pieces are wedged to the exterior of this rim.

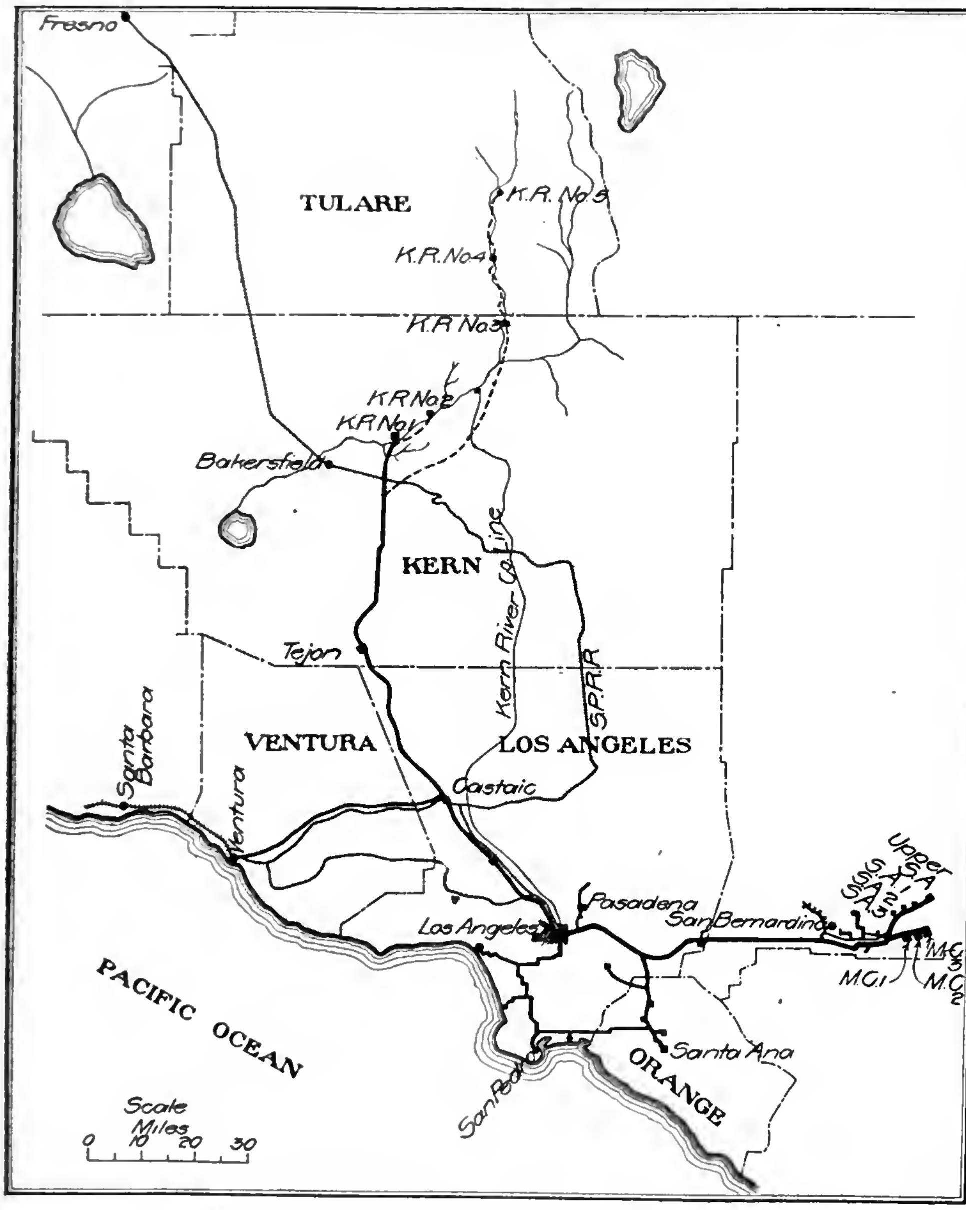
The exciter units are standard 225 kw. direct current machines generating at 125 volts, running at 430 r.p.m. and having ordinary self-adjusting



Unit No. 2, Governor and Top of Motor-Operated Gate Valve.

bearings. Sufficient space has been left between the two exciters to permit the installation of a large induction motor at some future time should it be found necessary. This motor would be designed for good speed regulation and arranged so that it could be connected by means of a pair of clutches to either of the exciters.

The station contains thirteen 50-cycle, 1,667 kw. oil-filled shell-type oil-circulated transformers in boiler iron cases. These transformers are grouped in 4 banks of 3 each with 1 pair to receive energy at 2,300 volts delta from the generators and to supply it to the line at 75,000 volts Y. Taps are also provided for the intermediate voltages of 56,250 and 37,500. These transformers instead of having internal water cooling coils are so built that when the oil is supplied to them under a slight pressure it will automatically distribute itself throughout their windings and return by gravity to the waste pipe. The piping and connections for this circulation are placed in the basement of the power house in a tunnel 7 ft. 9 in. wide and 11 ft. high, extending the length of the building.



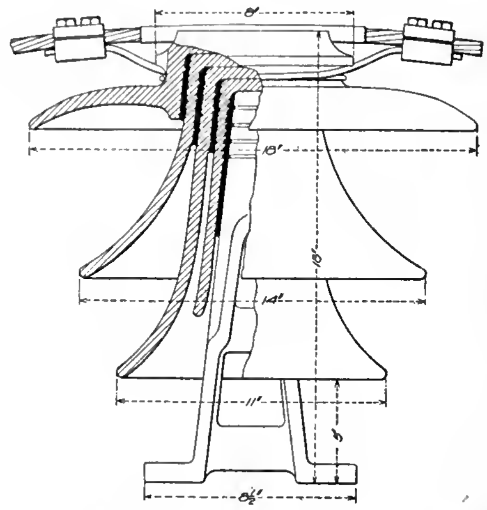
Map Showing Power Plants and Transmission Lines.

The oil coming from the transformers enters a receiving drum from which it is drawn by two 5-in. centrifugal pumps, motor-driven by 15-h.p. variable-speed shunt-wound direct-current motors. Either pump can supply the entire equipment of transformers in an emergency. These pumps force the oil through a set of boiler tube coolers, set over the tail-race and consisting of a series of 2-in. pipes, 10 ft. long, made up in four sections containing 1,008 tubes and having a total area of 4,500 sq. ft. Only two of these sections are at present installed. From these cooling coils the oil returns to the pressure line which supplies the transformers. As the system is under pressure from the time the oil enters the pump, any leakage will be outward and there will be no possibility of the water leaking into the oil, as is the case where the water coils under pressure are placed in oil filled transformers. Another advantage of this system is that the cost of installation is somewhat less than for a similar installation using water cooling. Water for the cooling section is by-passed from one or both of the exciter tail-races into a flume built across the top of the coolers.

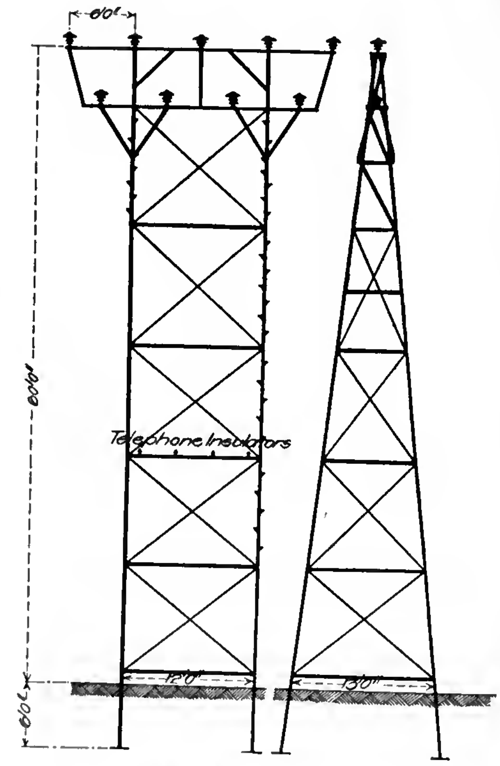
The generator leads pass through ducts under the station floor to the generator switches and thence to the low tension side of the transformer bank. The station is equipped in such a manner that in case of necessity any generator can be transferred to any single transformer bank or in case of absolute necessity run in multiples with some other generator on a single transformer bank, or if desired the entire station can be tied together and operated as a single unit.

The transformer banks connect on their high-tension sides to knife blade switches to a single bus bar from which the two outgoing transmission circuits are tapped off. The 2,300 volt oil switches are installed in concrete cells with concrete barrier walls and tops. The disconnecting switches for them are also separated by barrier walls where possible. The 75,000 volt oil switches are not only installed in concrete cells in accordance with standard practice but are each of them enclosed in a separate concrete room containing no additional apparatus except lightning arresters.

The control switchboard is mounted on a gallery overlooking the machine room. It is built of black slate and is a combination bench and panel board consisting of nine divisions. One of the panels controls the station auxiliaries, two of them the exciter circuits, four the generator units, one the auxiliary feeder and the remaining panel is at present left blank. These panels are equipped with the necessary meters and switches. The bench of the switchboard has controlling switches with red and green signal lamps for each



Insulator for 60,000-Volt Line.



Transmission Line Tower.

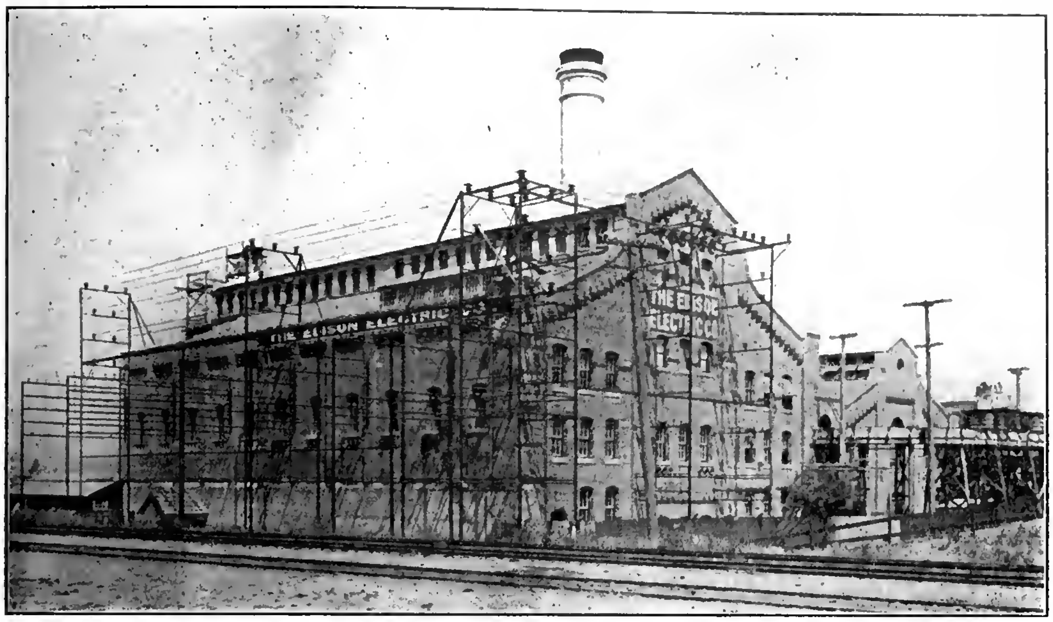
of the four generators, and control switches are also provided for the feeder switches, the bus sections and the outgoing line switches.

All the electrical equipment in the station including generators, exciters, transformers, oil switches and switchboards were supplied by the General Electric Co.

The high tension wiring is run in 4-ft. square ducts throughout. The lightning arresters are of the General Electric Co.'s multiplex type, consisting of alternate carbon spark gaps and resistance. They are mounted in concrete wall cells and are so completely isolated from each other by the intervening main line ducts that an arc starting on any single arrester could not by any possibility be transferred to any second bank. The leads after passing the choke coils and taps for the lightning arresters pass out of the south

wall of the building through rectangular openings located immediately below the eaves. From the eaves of the building, the leads converge onto the first tower of the transmission line.

The transmission voltage now used is 60,000, but 75,000 volts will be substituted later. The transmission line, 117 miles long, is carried on galvanized steel towers ranging from 30 to 60 ft. high. They are made of galvanized angles, bolted with galvanized bolts and held in shape by means of tension rods. All portions of the tower are figured to be safe under a wind pressure of 30 lb. per square foot on the tower and on the wire of a 700-ft. span. The towers will also withstand absolute failure of any single wire even though none of the resulting strain in transmitted to adjacent wires. They were furnished by the U. S. Wind Engine & Pump Co., Batavia, Ill.



Los Angeles No. 3 Receiving Station.

The transmission line is designed to consist of 3 circuits with the wiring spaced symmetrically on 6-ft. centers. The wire is 7-strand, 4/0 hard drawn copper havihg an elastic limit exceeding 35,000 lb., and an ultimate strength of 62,400 lb. It was furnished by J. A. Roebling's Sons Co., National Conduit & Cable Co., and the American Electrical Works. About two and a half million pounds of cable were used on the line.

The insulators used on the transmission line are the largest yet made for commercial transmission purposes. They are 18 in. high and 8 in. in diameter at the grooved top. The top section is 18 in. in diameter and the two lower petticoats are respectively 14 in. and 11 in. in diameter. The specifications for the insulators call for a guarantee of a 100,000-volt test from the groove to the pin for half an hour under a precipitation of 1 in. in 5 min. at an angle of 30 deg. from the vertical. The assembled insulator was required to stand under a wet test a potential of 150,000 volts for 30 sec., and the separate parts are guaranteed to stand a voltage 25 per cent. in excess of the normal proportion of over voltage test.

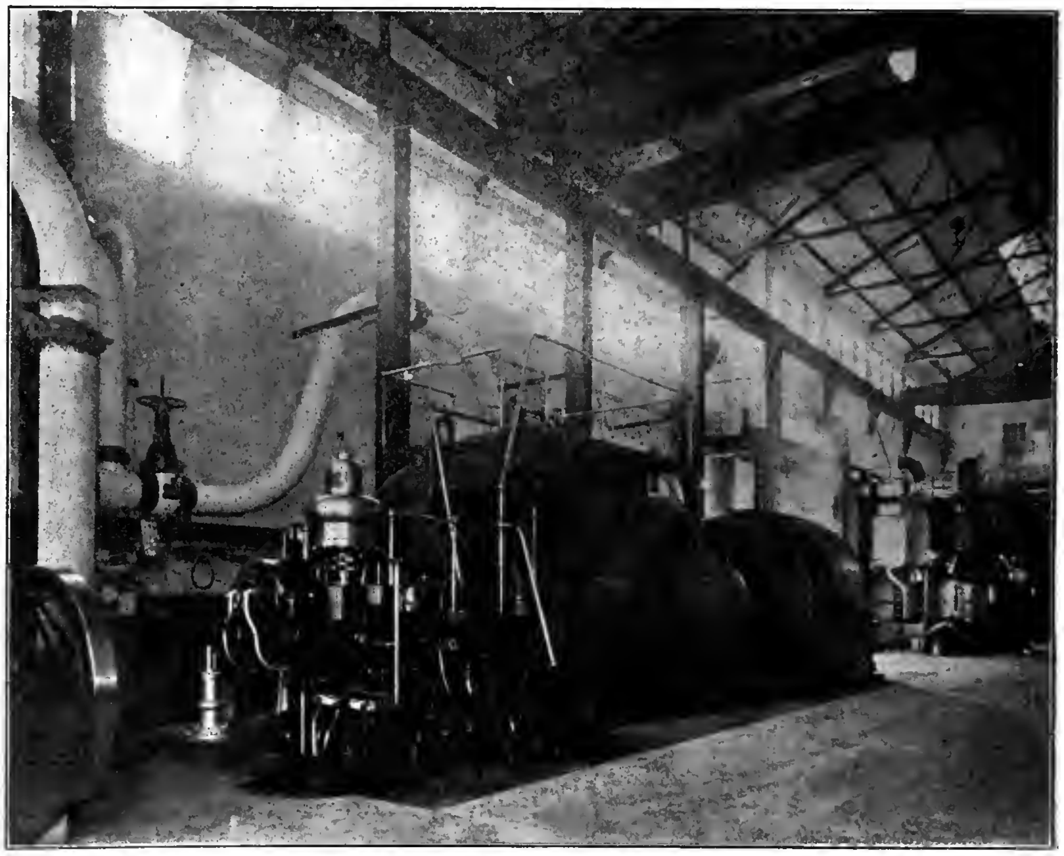
A telephone circuit is carried the entire length of the transmission line, being supported on the towers about 20 ft. above the ground. Between towers the wires are held up by wooden poles, 2 poles being necessary between towers for an average 700-ft. span. Switching stations are located on the transmission line at Tejon, Castaic and San Fernando, the latter two also containing transformer sub-stations.

Construction.—The first preliminary survey for location of the plant was made in the Spring of 1901. After that time it became necessary to obtain rights-of-way across private property and the Sierra forest reserve which required more than one year. The final location survey began in the summer of 1902, and construction was commenced near the close of that year. Continuous construction work was prosecuted vigorously during 1903, but in 1904 was slackened up owing to the fact that the company had two other power plants to construct at that time. During that year, however, the work was prosecuted on some of the longest tunnels, there being about four tunnel faces kept in operation the whole year. In the early part of 1905 work was again resumed with vigor and prosecuted until finally completed about May 10, 1907.

A construction plant generating 300 kw. at normal capacity was installed for furnishing the power used in driving tunnels, mixing concrete, transporting material and similar construction work. This plant was located at Frenchtown, or Camp 5, power being developed by means of a flume about 800 ft. in length which supplies water under 40-ft. head to McCormick reaction turbines each operating one 150-kw., 2,300 volt generator. This plant furnished all the energy required while the work was in progress and was only abandoned after the completion of the main plant. It frequently and for long periods operated at 50 per cent. overload. From the construction plant, power was transmitted at 10,000 volts to all parts of the work over a temporary transmission line, the power being used not only for the construction work, but for lighting both in the tunnels and in the camp quarters occupied by the men.

For driving the tunnels compressed air was generated by electrical power, transmitted from the construction plant, and was piped into the various tunnels for operating the pneumatic drills. The ventilating blowers for supplying fresh air at the face of the tunnel and for removing the fumes after a blast were also operated by electric motors. In the construction of the diverting a dam a complete system of cableways designed by the company's engineers was installed by means of which material was transported and placed in position in the dam. In the construction of the power house the handling of materials as well as the crushing of rock and mixing of concrete was carried on by means of equipment operated by electric motors. The hoisting engines for the aerial tramways used at Camp No. 1 and other camps for hoisting material to the tunnels were also operated by electric motors.

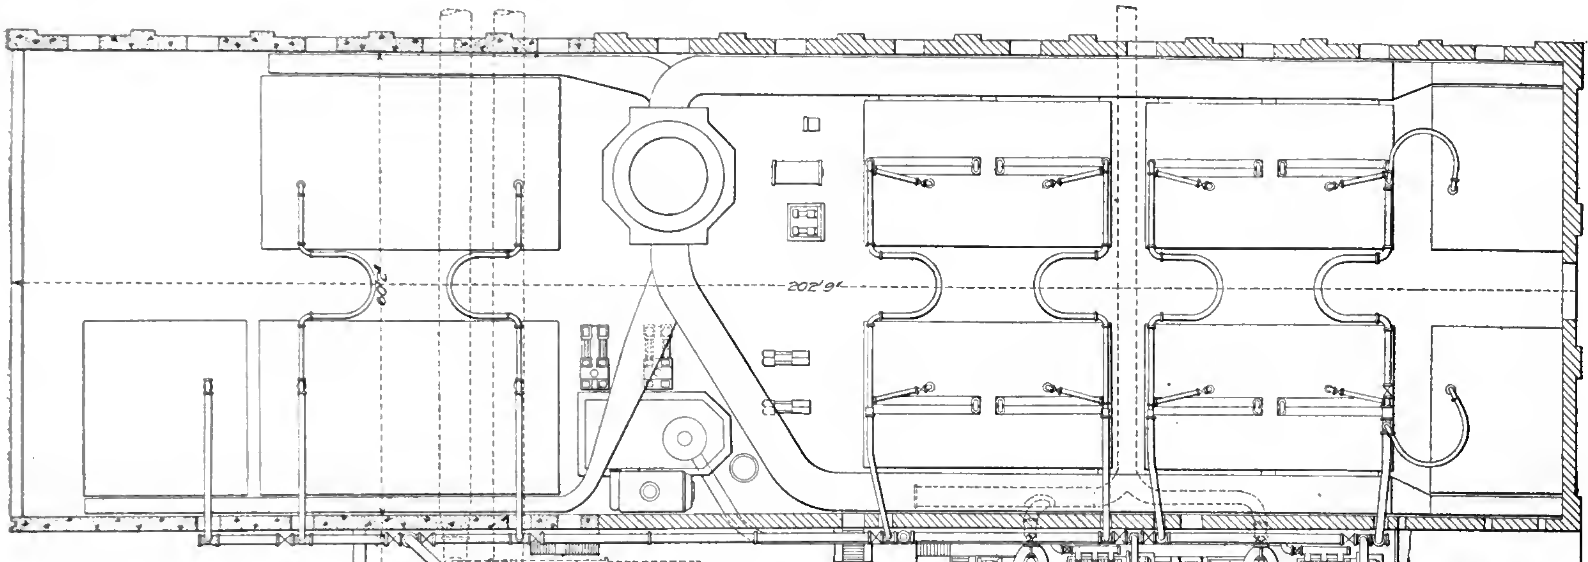
The station was placed in operation under the direction of Mr. H. H. Sinclair, one of the vice-presidents of the company. Water was first turned into the tunnels on May 11th, when it was wasted out at the Starr Creek flume. On the following day about 300 miner's inches of water were turned into the entire tunnel, the first water being carried through the pressure mains and sluiced out of the ends of the power house header into the river. On May 13, full prsssure, 380 lb., was placed on the plant and the first unit and one of the exciter units started up. After a few days of necessary drying out on May 19th, power was first put on the line from the station end and 2,500 kw. transmitted to Los Angeles. The first

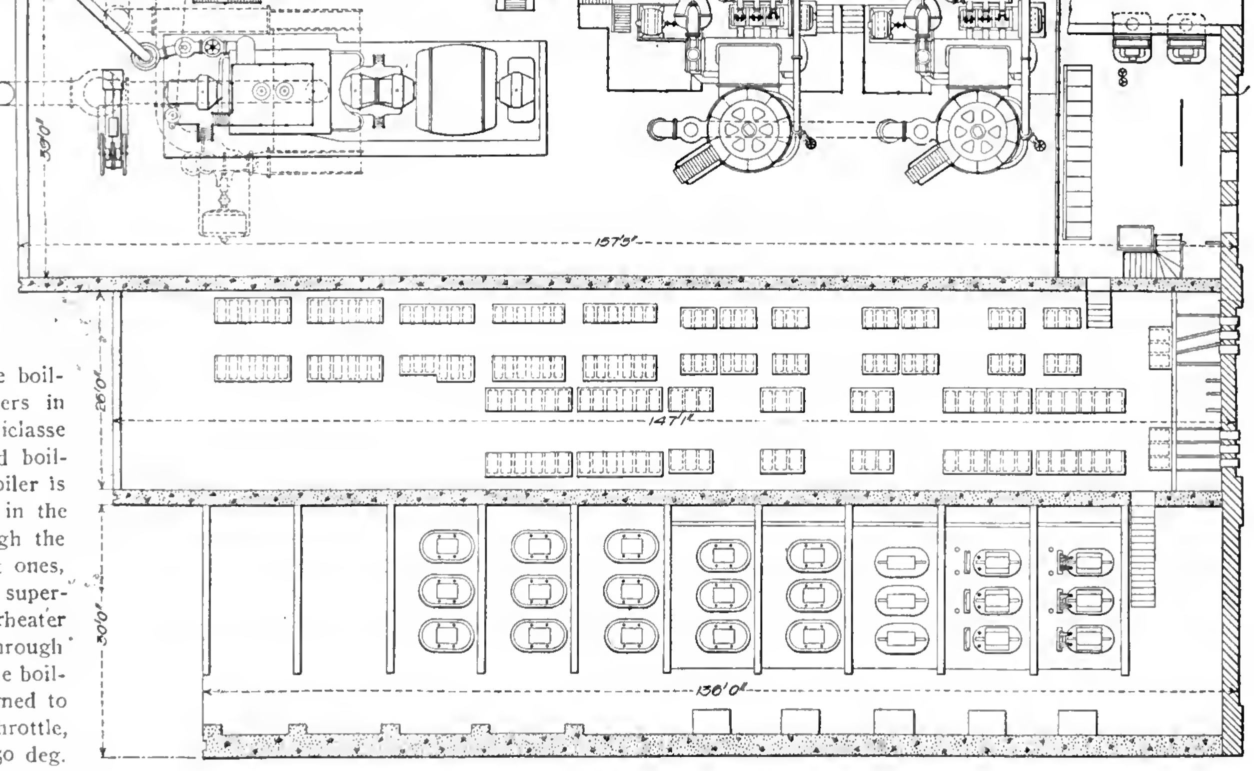


Westinghouse-Parsons 7,500 Kw. Turbo-Alternator in Receiving Station.

unit has been operating continuously since that date, and the other three units will be started up as soon as their installation is completed, some of the machinery having been delayed in transit.

Los Angeles Receiving Station.—The transmission lines from the new plant terminate at the steam and transformer station known as Los Angeles No. 3, which receives, transforms and distributes to the local sub-stations power received from the company's water power plants at Santa Ana River, Mill Creek, Lytle Creek and Kern River and also contains a large steam auxiliary plant to supplement the water-generated power.





Plan of Los Angeles No. 3 Receiving Station.

In the steam end of this plant there was installed in 1903 two 2,000-kw. 2,300-volt Curtis turba-alternators with 4,000 h.p. of Sterling boilers in units of 500 h.p. each. When it became necessary to order an extension for the plant in 1905 larger size apparatus was determined upon throughout. An additional 5,250 h.p. of boilers in 750-h.p. units were installed. These boilers were fitted with superheaters in the middle drum instead of Niclasse superheaters as used in the old boilers. The construction of the boiler is such that cold water entering in the back drums passes down through the back tubes up through the front ones, across into one end of the superheater drum, through the superheater tubes to the other end, and out through the super-heated steam line. The boilers in the old plant were designed to give 125 deg. superheat at the throttle, while the new ones produced 150 deg. The new boilers have heavy drums and are fitted in every way to carry 175 lb. pressure, although the plant is now operated with 165 lb. at the boiler.

The turbine installation in the new plant consists of a single 6,000 kw. Westinghouse-Parsons turbo alternator with Worthington condensing equipment. The steam end is of the Westinghouse standard construction receiving steam through an intermittent valve. This steam before reaching the machine passes through a separator, an automatic butterfly valve and a hand-operated throttle valve. The unit is 4-stage single-flow and is operated at 27½ to 28-in. vacuum. Thus far loads up to 10,000 kw. have been carried on the machine without any indication of its maxmum load being approached. The by-pass throttle does not open until 9,000-kw. load is reached under normal steam and vacuum conditions.

Steam from the exhaust end of the turbine passes to the atmosphere during warming up through an automatic release valve. After the machine is up to speed, 750 r. p. m., the steam is condensed into a 24,000-sq.-ft. condenser and the water of condensation returns to the hotwell by a 2-stage motor-driven centrifugal pump. The vacuum space is cleared of entrained air by means of a steam-driven dry vacuum pump. Forty-nine second feet of condensing water are forced through the condenser by means of a 30-in. volute centrifugal pump direct connected to a 450-h.p. induction motor, driven from the 2,300-volt main.

Circulating water leaving the condenser passes beneath the boiler room in a steel lined concrete duct to the edge of the cooling tower where it rises through a steel pipe to the top of the tower. The new portion of the tower installed for the Westinghouse unit is 73x150 ft. in floor plan and the water has a clear fall of 27 ft. This gives a tower area of 6,100 cu. ft. per second foot of water and with a humidity of 58 per cent, and a wind velocity of 6 miles per hour the water temperature is reduced from 102 deg. to 85 deg. Fahr. The tower framing consists of 4x4-in. posts, 2x4-in. intermediates, 1x2-in. horizontals and 1x3-in. bracing. The main flume is carried on 6x6-in. posts and is itself built of 1½-in. redwood. The distribution troughs are galvanized iron of rectangular cross section with round holes punched in their bottoms. Their headers are also galvanized iron with wooden sliding gates. Strips 18-in. wide of galvanized iron mesh screen are placed at 3-ft. intervals through the depth of the tower. The reservoir is of concrete 6 ft. deep and 12 ft. wider than the tower. Water passes from it into the concrete suction pipes through close-set grizzles. Its flow can be shut off when necessary by a 38-in. iron motor-driven gate placed in the engine room basement.

The Westinghouse turbo-alternator unit was put in service in October, 1906, and has been run ever since without any shut-down due to the turbine and without any serious shut-down whatever. The preliminary acceptance test gave results materially better than the manufacturers' guarantee.

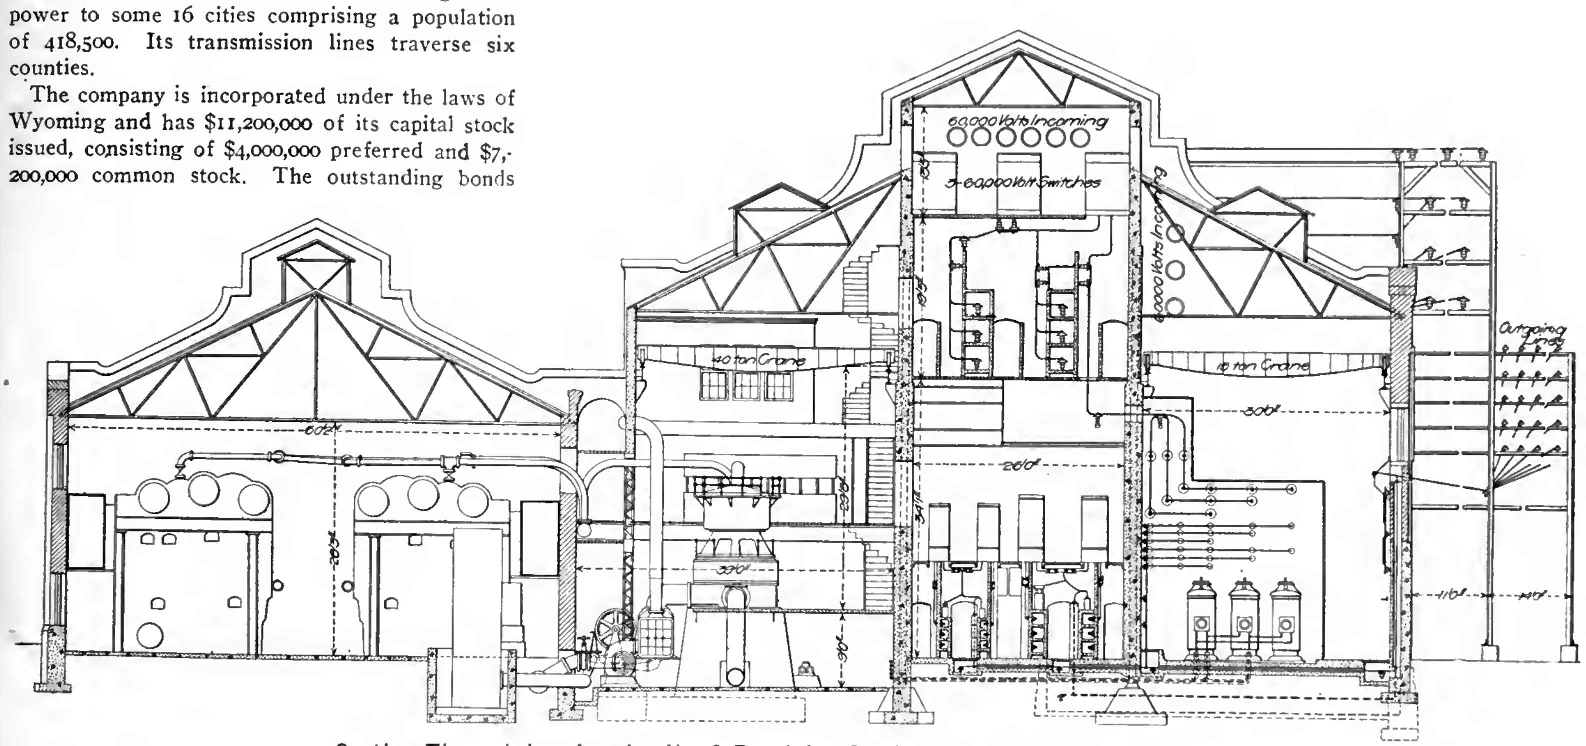
Extent of the Company's System.—In addition to the Kern River No. 1 Plant the Edison Electric Co., controls sites for four other plants on the Kern River, all of them above the plant just completed. They cover the entire length of the river 160 miles from the mouth of the canyon to the head works with the exception of the plant of the Power, Transit & Light Co., at the mouth, and the Kern River Company's plant about 30 miles above. The four additional plants will have a total capacity of 46,600 kw., and will be developed as the demand for power arises. The next plant to be constructed will be Kern River No. 2, the power house for which will be located immediately above the intake of the No. 1 plant.

Its diversion works will be 15 miles above, just below the Kern River Company's station. With the 317-ft. net head which will be available, this plant will develop a total of 11,600 h. p. with 400 second feet of water. Some work has already been done on this plant and the construction will soon be pushed ahead actively. In addition to the Kern River power locations which the company owns in entirety, it has a 2/3 interest in five excellent power sites on the Kings River, where 95,000 kw. can be developed.

The company is now operating 7 plants, including the one described in this article. The 6 earlier plants have a total capacity of 8,700 kw., the steam generating plant a capacity of 14,075 kw.; and it is expected that the Kern River plant will be able to deliver in Los Angeles a maximum of 23,000 kw. Thus far the company's maximum peak load has been about 20,000 kw. Judging by past experience it is probable that the new power will be contracted for as fast as it is available. The company now supplies current for light and power to some 16 cities comprising a population of 418,500. Its transmission lines traverse six counties.

The company is incorporated under the laws of Wyoming and has $11,200,000 of its capital stock issued, consisting of $4,000,000 preferred and $7,200,000 common stock. The outstanding bonds and debentures of the company amount to $10,895,000. The officers of the company are: President, John B. Miller, Pasadena; Vice-presidents, Henry Fisher, Redlands, Wm. R. Staats, Los Angeles, H. H. Sinclair, Pasadena, John W. Edminson, Los Angeles; Secretary, R. H. Ballard, Los Angeles; Treasurer, W. L. Percey, Pasadena; General Manager, A. L. Selig, Los Angeles.

The construction of the Kern River No. 1 Power Plant was prosecuted under the general supervision of Mr. H. H. Sinclair, vice-president of the company who originally located the power site on the Kern River and on most of the other streams whose power supplies are controlled by the company. The hydraulic features of the Kern River work including the dams, gravity tunnels, pressure tunnels and many of the details of the water wheel equipment were designed under the supervision of Mr. F. C. Finkle, chief hydraulic engineer and now consulting engineer for the company. Mr. F. E. Miller, as superintendent of power development, had charge of, and at times direct supervision over the construction work. The electrical details were looked after by Mr. Ralph Bennett, and Mr. R. J. C. Wood. Mr. G. E. Decker represented the company in the installation of the machinery. Mr. John Taylor formerly chief operator at the Santa Ana No. 1 plant has been placed in charge of the operation of the new plant. To these gentlemen the writer is indebted for many courtesies, for the furnishing of the drawings and much of the data which have made this article possible.



Section Through Los Angeles No. 3 Receiving Station of the Edison Electric Co.

The Tarring of Highways.

The increased attention which is being devoted in the United States to allaying the dust nuisance on our highways and to decreasing their disintegration under motor traffic makes a report which has recently appeared in the "Annales des Ponts et Chausses," by the secretary of a commission appointed by the French Minister of Public Works to consider this subject, of much interest.

The report classifies the various processes which have been employed, disregarding sprinkling with pure water, into four classes: 1, Surface tarring, either hot or cold; 2, treatment with petroleum oil or similar processes; 3, sprinkling with water to which various substances have been added; 4, several processes which cannot be included in the preceding classes.

Tarring.—After a historical note upon the subject, showing that the tarring of roads only reached any extent in 1902, the author describes the two methods which are in use to-day, the one cold, by thinning the tar with 10 per cent. of heavy or dead oil so that it can be absorbed, and the other by applying the tar hot. It is shown that in order to obtain satisfactory results it is necessary to allow the tar to soak into the road as long as possible before admitting traffic, and that if the absorption is not complete a light application of sand, or of the dust which has been originally swept from the road should be applied.

The conditions to be realized in order to meet with success are as follows:

1. To operate upon a road recently put in order, well rounded and sufficiently drained. Tar lasts much less time upon a flat surface, while from one which is moist at the time of spreading it scales off and disappears rapidly.

2. To carefully clean the street from the dust and filth which cover it and to expose the mosaic of stone in a way that will permit the layer of tar to penetrate into the road and, so to speak, anchor itself there thoroughly.

3. To operate only in dry weather and, if possible, only in hot weather.

4. To spread the tar in such a manner that it covers the entire surface without lack of continuity.

5. To let the tar dry out sufficiently, so that the wheels of vehicles will not pick it up nor skin off the coating.

From the information obtained through inquiries of various engineers by the Commission the report draws certain conclusions in regard to work done in summer as compared with that done in autumn and winter.

Summer Work.—There is a complete agreement that tarring, when done in the summer, is always satisfactory. Dust is suppressed, or at least notably diminished, and damage to the roadway is largely checked. These results are dependent upon the nature and the intensity of the traffic, the exposure of the road, the quality of the material of which it is constructed, as well as the manner of application, whether hot or cold.

The protection of the roadway upon routes travelled by motor vehicles is particularly striking.

Autumn and Winter Work.—Experimenters are of different opinions in regard to tarring done in autumn and winter. All agree that it lasts well upon rounded streets of good exposure, subjected to not too heavy traffic. As one or the other of these conditions is not fulfilled, the superficial coating of tar disappears at the end of a longer or shorter time, and it is rare that it lasts to the end of winter, at least on the crown of the road. Very often, if traffic is heavy, it has disappeared at the beginning of winter.

The tar, moreover, in the act of disappearing during bad weather, produces a very disagreeable mud, and one which is much more abundant than that from roads which have not been tarred. The majority of experimenters are agreed that with roads carrying a heavy and active traffic, as much as 600 to 700 collars, this result is, without doubt, to be expected. According to a minority, on the contrary, but who include the highest authorities, the diminution of the mud is quite sensible in winter, even on moist sections of road and those subjected to a heavy circulation.

These differences seem to pertain to the nature of the macadam and to the material of which it is composed. It is difficult to discover, from the answers to the questions, why this is so, as the replies do not give the details in

regard to the manner and care with which the tarring has been carried out.

It is beyond doubt that as long as the coating of tar lasts the roadway is guaranteed to a great extent against disintegration, but it must be remembered that the coating is a superficial one and not entirely continuous. The stone pierces it in many places and the exposed particles are worn down under traffic. The coating, on account of its plasticity, again covers these and other projections appear. There is always a certain wearing away of the stone by percussion or lateral friction, notwithstanding the bituminous material which supports them. It appears, then, that the tarred road is not entirely shielded from disintegration. If the coating of tar resolves itself into mud this mud retains water more easily, is more mobile and the road goes to pieces more readily. The general impression of all experimenters is, however, that tarring prolongs the life of the road; to what degree this takes place the observers are not agreed and do not dare give any definite value.

Tar Employed Per Square Yard.—This will depend upon the porosity of the road and the judgment of the operator. The first essential condition is that the tar shall cover the surface entirely. Upon a very absorbent surface, as one composed of dry silicious rocks thoroughly compacted, one would necessarily employ more tar than on a smooth and less permeable roadway of porphyry. In the same way a street which has been tarred the year before calls for less than one which is being treated for the first time. The minimum quantity is, then, a function of the state of the road, but in any case not less than 2 lbs. per square yard should be used. This amount can be increased according to the judgment of the operator. In the experiments made in France it has varied between 1.6 and 1.8 to 8.0 lbs. per square yard, with a mean in the neighborhood of 3.0 lbs. Experience has shown that it is advisable to avoid too thick a coat, which might prove slippery and provoke the formation of mud in winter. It seems that 4.0 lb. per square yard should be regarded as a maximum, beyond which it is not advisable to go. This means something less than one-half of a gallon.

Penetration.—The penetration of the tar into the surface should be carefully looked into to determine that the coating is well anchored. In well-conducted work the penetration should reach easily 1.25 to 1.6 in.

Effect of Temperature and Grade.—Frost does not seem to have any injurious effects upon tarred roads, in spite of the fears that have been entertained in regard to it. Excessive heat may soften it and even render it slippery. This is, however, rare, and is generally due to poor execution of the work and insufficient penetration.

One generally hesitates to tar a road having a grade of over 3 per cent., and a recent experiment at Aix-les-Bains on a 5 per cent. grade seems to demonstrate this.

Effect of Water.—Summer rain is favorable to tarred roads, as it cleans them, drying rapidly, and does not contribute to their disintegration. The washing of such streets with quantities of water, as in the manner carried out in cities, has the same effect. It is necessary, however, not to abuse this custom, especially on streets of heavy traffic, for the enemy of tar is persistent humidity.

Cost.—The cost depends on: 1, the quantity of material employed; 2, the price of this material; 3, the system of spreading adopted and the capacity of the plant.

An application of 3 lbs. of tar at a price of $10 per ton should not cost for material more than 1.3 to 1.5 cents per square yard. Labor for heating, spreading and sanding costs in France in the neighborhood of 1 cent per square yard. The Commission considers that the entire cost of tarring in France is, in the mean, between 2 and 3 cents per square yard, this, of course, for the first treatment. Subsequent treatment will cost less.

Methods of Treatment.—Tarring with hot tar, without any addition, is the method most frequently employed. A mixture of ordinary tar with 10 per cent. of dead oil has been practiced upon a considerable scale in various departments, especially at Havre, while some experiments have been conducted in Paris and in the Department of the Rhone. As far as can be judged, the two systems are identical in their results in both summer and winter, but in point of view of execution of the work the cold method does away with many inconveniences and the necessity for heating. The apparatus is less costly, the spreading is much facilitated, since no attention must be given to the temperature of the material, while the presence of dead oil has a happy drying effect. As a matter of economy the cost of heating is compensated by the greater cost of the heavy dead oil. Whether one system or another is to be adopted will depend upon local conditions. The use of crude tar without anything to make it more liquid is not to be recommended. It penetrates but a small distance into the roadway, especially in winter, remains upon the surface and dries badly.

Certain patented materials containing special driers, process Rimini, Pulveranto, d'Auch, Lassailly and Vinsonneau, are still in the experimental stage, as are particular methods of application, such as heating the tar after it has been placed upon the surface. More will have to be known of the success of these processes before they will be adopted in America.

Oiling Roads.—California seems to be recognized in the report as initiating the method of laying dust by oiling roads with a suitable oil. As no oil similar to the California petroleum is available abroad, mazout, the residuum from the distillation of Russian petroleum, has been used in France.

The report of the Commission gives few data in regard to the results obtained, but states that the difficulty with the use of this material is the high tax, $18 per ton, to which it is liable.

Sprinkling with Water Containing Other Materials.—The report considers the sprinkling of roads with solutions of deliquescent salts, and with mixtures of water and oil, such as westrumite and various other patented products. The results with these materials are in any case only temporary and last at the most for fifteen days and do not seem to be favorably regarded.

The Rio das Lages Hydro-Electric Station of the Rio Janeiro Tramway, Light & Power Co., is being constructed rapidly and before the end of the year it is expected that six generators will be in place. The falls supplying the power are 56 miles from the city, and a concrete dam has been constructed at their crest, which is 115 ft. high and 92 ft. thick at the base. From this reservoir water passes through a series of steel pipes about 6,000 ft. long to distribution receivers immediately above the power house. From the receivers six 36-in. pipes about 1,900 ft. long, are carried down to the six turbines. The receivers are about 900 ft. above the power station and the pipes leading to the turbines are on a steep grade. The total head when the reservoir is full is about 1,030 ft. from the level of the spillway on the dams to the nozzles of the turbines. Each of the six main wheels will develop about 9,000 h.-p., and will drive a three-phase, 50-cycle, 6,000-volt generator. It is proposed to step up the voltage of the current to 80,000 volts for transmission to Rio Janeiro.

Mechanical Equipment of the New City Hall at Newark, N. J.—I.

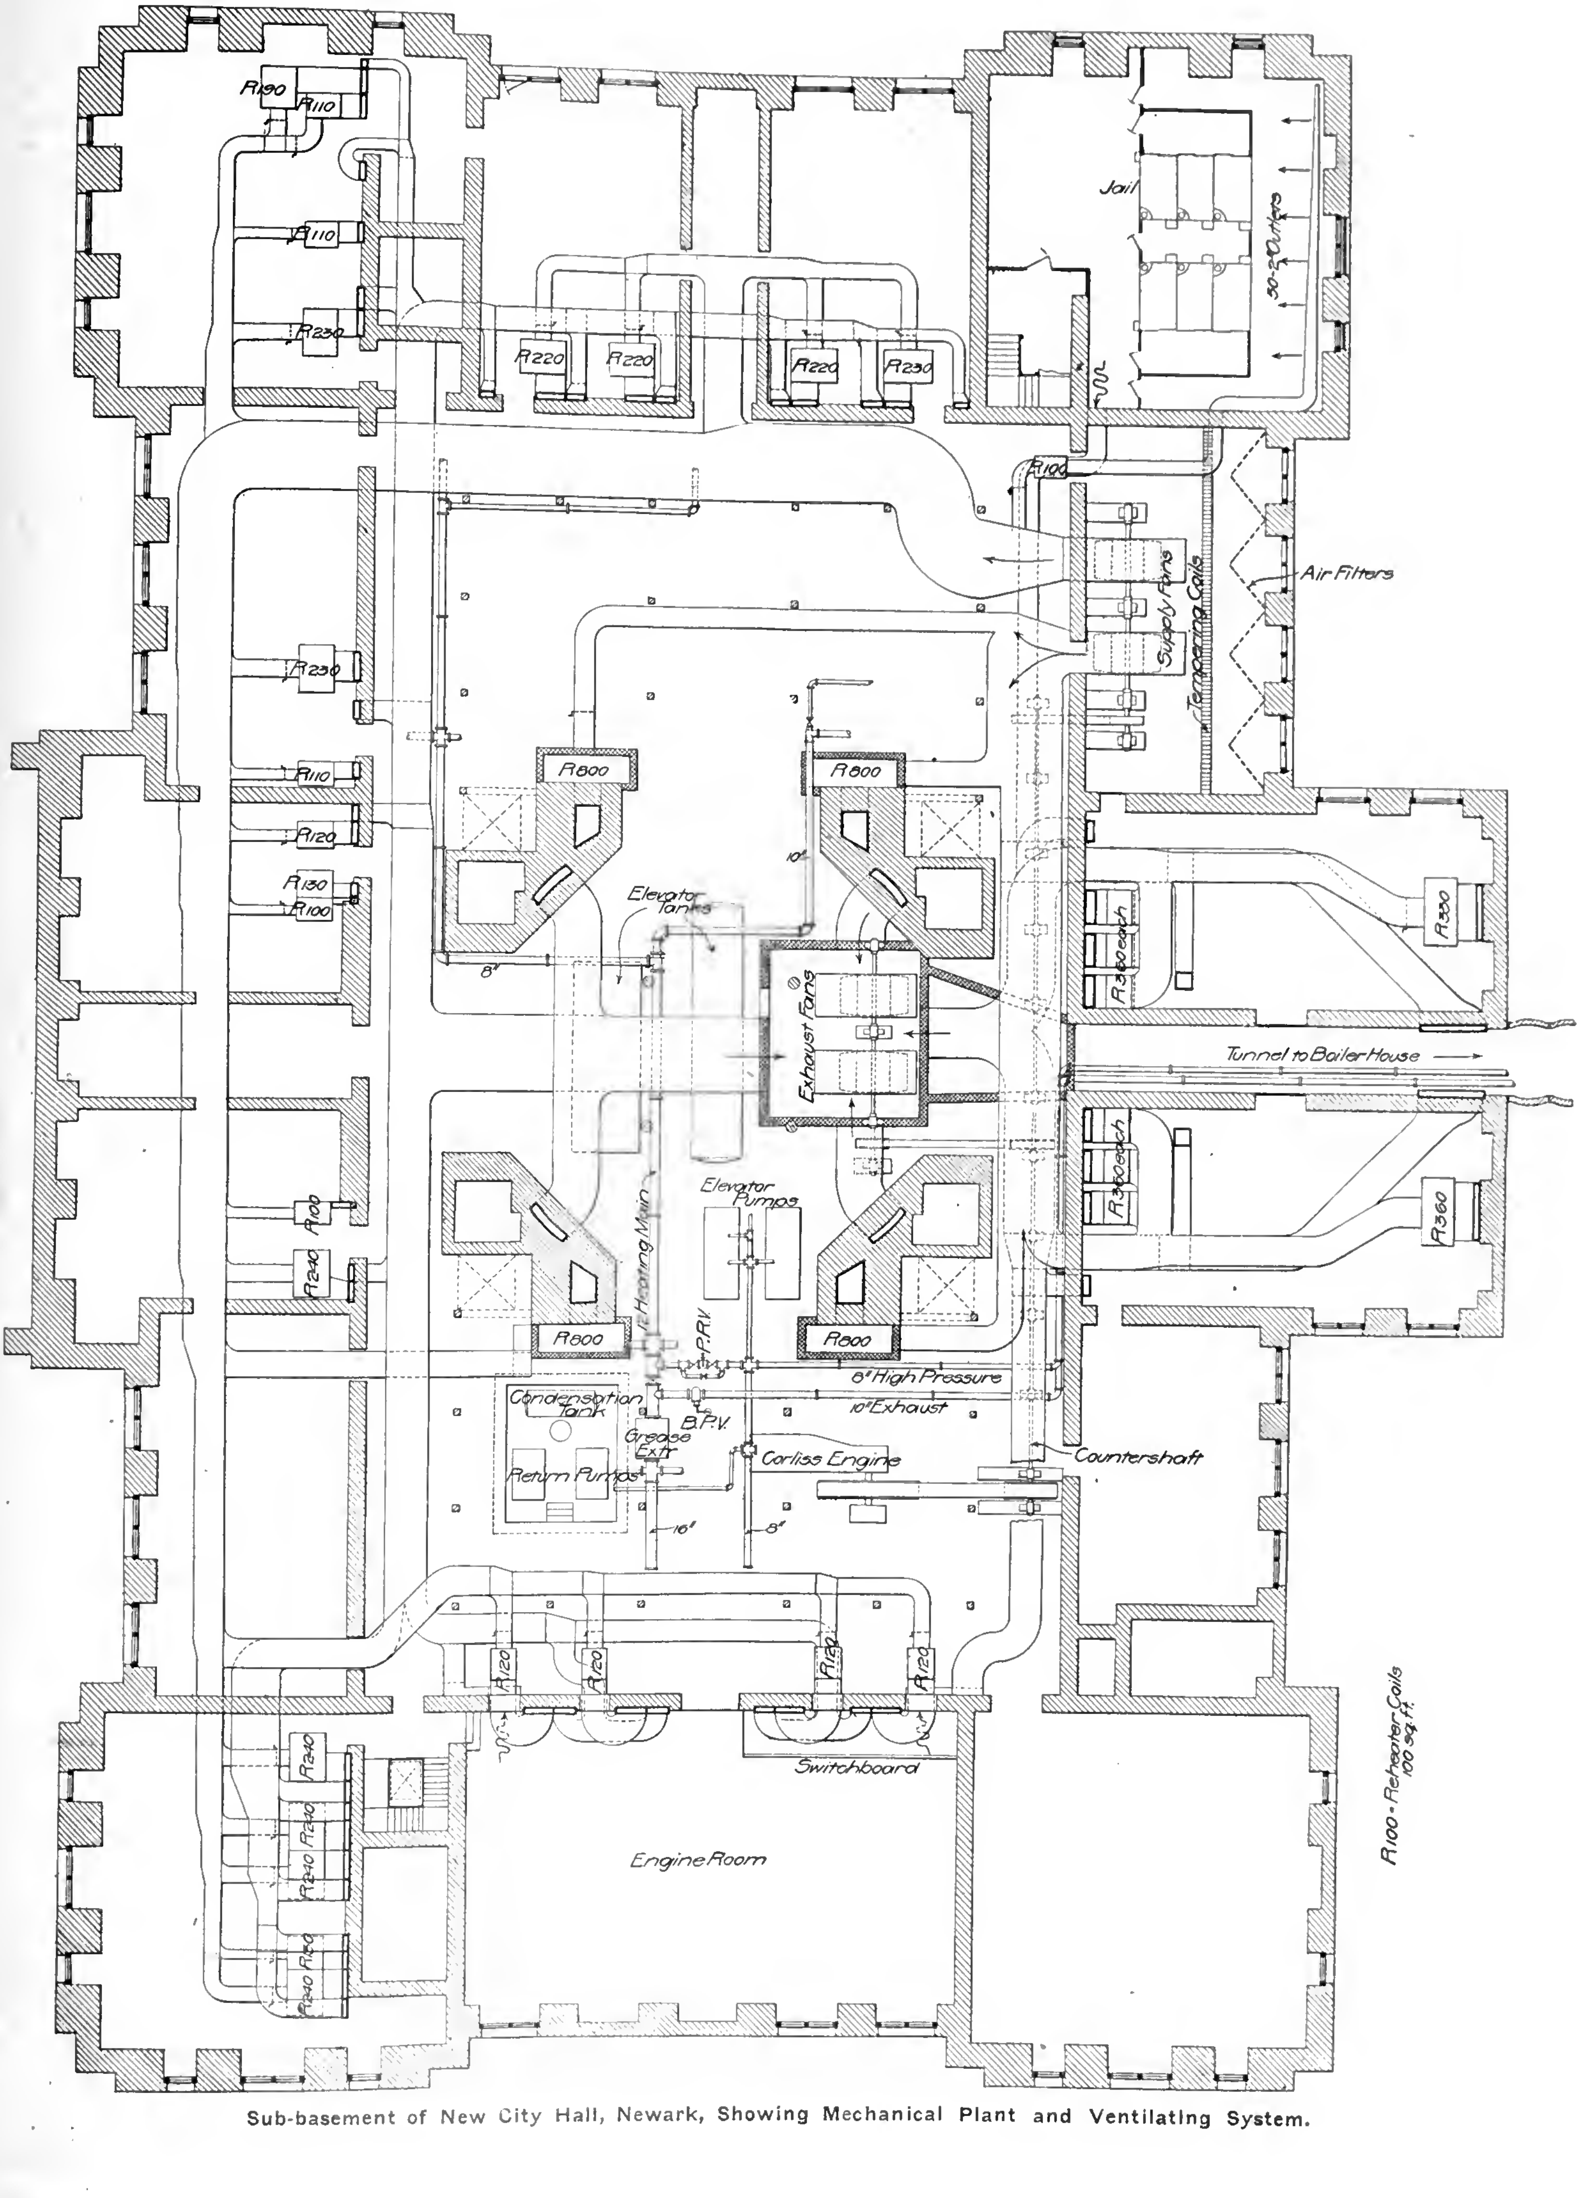
The City of Newark, N. J., has recently occupied an attractive new building for its municipal departments and offices which has a novel interior arrangement and an unusual heating and ventilating equipment. It has four stories and a basement and is surmounted by a central dome rising 135 ft. above street level. The structure is 175x240 ft. in plan and has an 83x152 ft. interior court surrounded by balconies forming the corridors of the various floors. In the center of this court is the structural work supporting the dome and elevator shafts, which has a most pleasing architectural treatment.

Current for lighting and a limited amount of power is purchased from the local public lighting company, but provisions have been made for a complete generating plant if it should be desired in the future. Provision has been made for ample ventilation of all rooms which are to be publicly occupied to any extent and also systems of exhaust from all toilet rooms. The heat and discomfort attendant upon a boiler plant in the basement of the building is avoided by having an independent boiler house at the rear of the grounds, with tunnel for steam and piping connections. This auxiliary building houses, however, only the boilers, the remainder of the mechanical equipment being installed in the sub-basement of the main building.

The general arrangment of the mechanical plant is shown in the accompanying plan of the sub-basement. The greater portion of the equipment is accommodated in the central portion under the interior court, the elevator equipment and exhaust fans occupying the circular portion under the dome, while a number of condensation tanks, pumps and piping, together with the engine which drives the ventilating equipment, are in the westerly portion of this area. The spaces surrounding this central area are for the greater part utilized as store rooms for the city departments, with the exception of that under the easterly wing which is occupied by the tunnel and a large amount of duct work for the fresh air supply system, and 21x44-ft. space adjoining this which contains the air intake and filter chamber, and the fresh air fans. A 35x60-ft. room at the westerly end of the sub-basement is reserved for possible future use as an engine room, and now contains the distribution switchboard for the electric lighting and power service, which has been so arranged that the addition of the necessary switch-board equipment for generating machinery will not be difficult.

The boiler house is 45x65 ft. in size and situated 50 ft. to the rear of the main building. This building has its floor 7 ft. below sidewalk level, and is connected with the main building by a brick tunnel 8 ft. square and 14 ft. under the surface, the tunnel entering slightly below the level of the sub-basement floor, which is 10 ft. below the sidewalk level. At the boiler house end, piping connections are carried up through a vertical shaft which rises to the roof in the corner of this building as a ventilation shaft.

Boilers.—Steam is furnished by three horizontal return tubular boilers in a single setting at one end of the boiler house facing a 35-ft. space in front, about 30 ft. wide, which serves both as firing floor and fuel storage. There is a 4-ft. space at the rear of the settings for access to blow-off connections and dampers, and 12 ft. at one side, provides for blow-off tanks and auxiliaries and also the addition of a fourth boiler unit if future demands for power should require. A convenient drive-way from the street facilitates the handling of coal, wagons being dumped directly through the large doorway at



Sub-basement of New City Hall, Newark, Showing Mechanical Plant and Ventilating System.

the front into the storage space, where fully 100 tons can be stored without restricting the firing floor space. Ashes are elevated to the driveway level for removal in carts by a small hydraulic four-can ash hoist of the sidewalk elevator type, which is operated by the hydraulic elevator system of the main building; the hoist is located just outside the front of the building and rises to the level of the driveway. Although the floor level is depressed some 7 ft. below the sidewalk, it is still above that of sewers in the adjoining streets which facilitates drainage from the floors and from the blow-off tank.

The boilers are 150-h.-p. units with 6½-ft. shells, 20 ft. in length, containing eighty-four 4-in. tubes and were built by the Coatesville Boiler Works, Coatesville, Pa. They have ½-in. shells with quadruple riveted double butt strap seams and ⅝-in. tube sheets, and were designed for 125 lb. pressure. They are without domes, ample space being provided above the tubes for a low water line and large steam liberation surface, and in this space there is a dry pipe 84 in. in length, 9 in. deep by 8 in. across at the top, which connects with a 6-in. nozzle in the center of the front sheet. Five-inch safety valve nozzles are fitted to the center of the middle sheet of each shell. The boiler setting has 24-in. outside walls and 28-in. division walls and the boilers are supported on roller bearing rests. The settings have flush fronts, and are designed for three passes of the products of combustion, the third pass being from the boiler fronts over the tops of the shells to the smoke connection on top of the settings at the rear. The furnaces are hand fired, being fitted with McClave shaking grates for the burning of fine grades of anthracite coal, and the fronts of the setting are fitted with water arches over the fire doors through which the feed water is passed for preheating before entering the boiler.

The products of combustion are removed by a 150-ft. circular brick stack just outside the rear of the building and connected to the boiler flues by a 48x72-in. breeching at the level of the top of the settings. The stack has a 66-in. clear inside diameter to the top, the lower 22-ft. of the stack being square in section, while the upper portion is circular and is capped by a cast-iron cap cemented in position. The stack was erected by M. W. Kellogg & Co., New York. The boiler branches from the breeching are 3½ ft. square over each shell, changing thence to 2 by 8 ft. at the front. The flues are fire-brick throughout, supported on cast-iron T-bars and specially designed to prevent cracking. The draft from the stack is controlled by a Locke damper regulator mounted at the front of the boilers and operating the dampers through a shaft extended back to the flue connections at the rear; this shaft is mounted on ball bearings and operates a working damper in the flue connection to each boiler. There is also a large damper in the main flue connection to the stack arranged for hand control from the rear of the settings.

The boilers are fed by two Worthington duplex pumps in duplicate, each having 7½ and 4½-in. cylinders with 10-in. stroke. They have suction from a 42x96-in. cylindrical steel receiving tank mounted on the sidewall about 6 ft. above them to which condensation, returned from the heating system of the building, is delivered and through which the make-up water is added from the city mains when required. These pumps are not fitted with a governor but are placed under the control of a fireman, there being necessarily one man always on duty in the boiler room. The pumps deliver to the boilers through a 3-in. feed main which leads first to the feed water heater with by-pass around the latter, and thence along the boiler fronts, where 2½-in. branches are led through controlling valves to the water arches above the furnaces; from these arches the feed is delivered to the boilers through perforated pipes extending through the shells longitudinally just above the tubes.

The feed heater is a 32-in. by 10-ft. Berryman closed heater with 1¼-in. brass tubing, presenting a tube heating surface of 150 sq. ft. The shell has 10-in. connections at the bottom and top to which the exhaust main that is carried over from the power plant in the main building basement is connected; this exhaust main bypasses the heater and is carried up to an exhaust head above the roof line, so that exhaust steam may be passed through the heater or by-passed directly to the exhaust head as desired. The back-pressure valve, usually provided between the feed heater and the exhaust head, is in this plant located in the basement of the main building. In the winter there is insufficient exhaust from the steam-using machinery to provide for adequate heating; at such times no steam escapes to the feed water heater and it is cut out of service, this being practicable as the condensation returned from the heating system is delivered to the feed pumps at a high temperature and furthermore the feed is delivered to the boilers through the furnace water arches for additional heating. This back-pressure valve is a 10-in. Jenkins excelsior straightway valve.

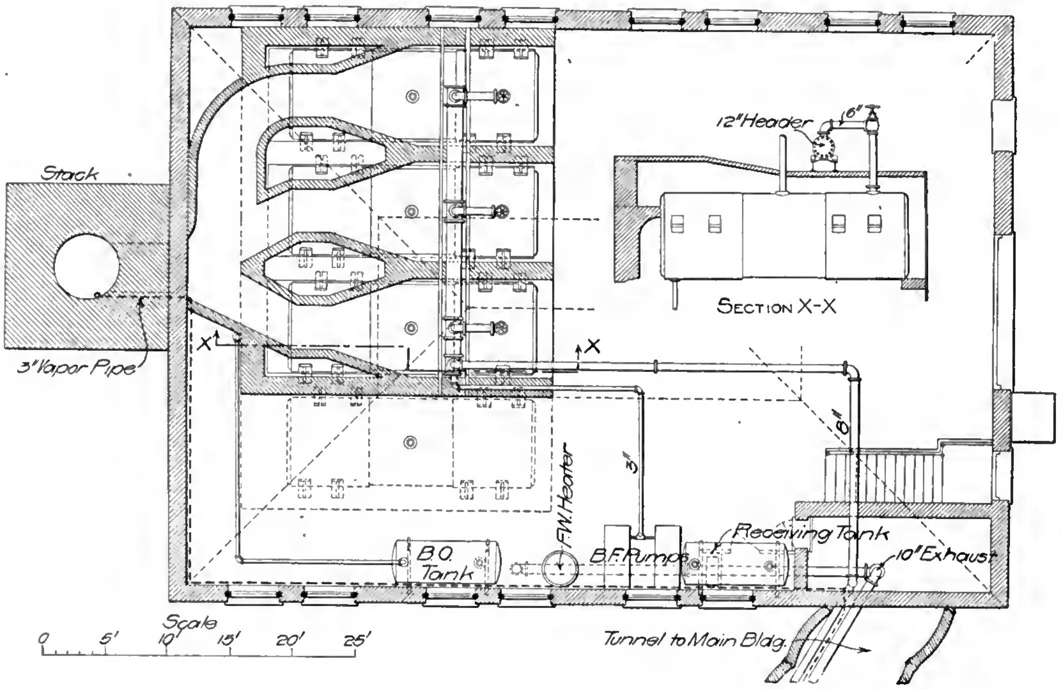
The blow-off system consists of a 3-in. blow-off main at the rear of the settings with 2½-in. branches to each shell, which main delivers into a 42x96-in. cylindrical steel tank at the side of the boiler room. This tank is above the sewer level, so that free drainage to the sewer is permitted, but the discharge connection is so made that the tank is maintained about half filled with water for the purpose of cooling the discharge received from the boilers. A 4-in. vapor pipe is carried up from the shell of this tank to the roof for removal of steam escaping from the hot discharge.

Steam Piping.—The steam piping of the plant is simply arranged, consisting of a 12-in. boiler room header over the boiler setting, from which a 3-in. branch extends to supply the feed pumps in the boiler house and an 8-in. line is carried through the tunnel to the power plant in the basement of the main building. From the steam-using machinery in the power plant a 10-in. exhaust line is extended through the tunnel back to the boiler house, where it connects with the feed-water heater and atmospheric riser to the roof exhaust head. The steam piping is all extra heavy wrought-iron with flanged connections, that for high pressure being designed for 200 lb. The high pressure piping is covered throughout with Keasbey & Mattison 85 per cent. magnesia covering while the low pressure piping is covered with H. W. Johns-Manville felt, all 1½-in. thick with a canvas jacketing. The arrangement of connections to the tunnel pipe line is such that expansion is easily provided for, there being right angle turns at both top and bottom of the shaft at the boiler house ends, while a 30-deg. bend of the tunnel near the main building introduces an additional bend which permits contraction and expansion.

Spacious quarters are provided for the machinery in the sub-basement of the main building as shown in the plan. The ventilation ducts are in all cases carried on the ceiling and practically all of piping is also on the ceiling, there being no trenches or pits except a 13x16-ft. pit in the westerly portion of the sub-basement, depressed 3 ft. below normal floor level to accommodate the condensation receiving tank of the heating system, the pump governor, return pumps and a cesspool.

The steam-using equipment in this section consists at present of the elevator pumps, two house pumps, two condensation return pumps, the Corliss engine for operating the ventilating fans, and the radiation of the heating system. To supply this equipment with steam, the 8-in. high pressure line carried over from the boiler house extends to the central portion of the machinery section, where, near the Corliss engine, it ends in a cross with a 5-in. connection to supply the elevator pumps, an 8-in. connection to the heating system, and an 8-in. branch blanked for future extension to the engine room when required. From this last extension a 6-in. branch is taken to supply the Corliss engine and a 3-in. branch to supply the condensation return pumps, while from the branch to the elevator pumps, a 1¼-in. line is extended to the hot water heating tank in the opposite end of the basement. The live steam connection to the heating system is made through a 6x8-in. Foster pressure-reducing valve with 4-in. by-pass, which connects directly to the 16-in. low-pressure header of the heating system.

The exhaust steam system which forms the basis of the steam heating system, is similarly planned to facilitate the addition of electrical generating machinery without change in the present installation. It consists of a 16-in. exhaust header which extends in the direction of the future en-



Plan of Detached Boiler House of the Newark City Hall.

gine room to a blanked flange, into which header all of the present steam-using machinery exhausts. The connections consists of an 8-in. line from the Corliss engine and the elevator pumps and a 3-in. line from the house pumps and condensation return pumps in the pit. The exhaust steam passes from the header to the heating supply main through a 16-in. Peerless grease extractor, furnished by Hussey, McCann & Co., New York, for the removal of lubricating oil. The extractor is mounted on the ceiling for convenience of connection to the header and supported by a substantial brick pier, the dirty drips from the receiver being discharged through a Heinz steam trap to the adjoining cesspool. Beyond the grease extractor, connection is made to the 10-in. line that extends through the tunnel to the boiler house for heating feed water when excess exhaust steam is available for that purpose. Between the latter connection and that for live steam supplementary supply, a gate valve is inserted to permit separation of the header into two divisions, permitting the heating system to be supplied solely by live steam, if desired, when the exhaust steam will be discharged from the header through the 10-in. line to the boiler house roof exhaust head.

Elevators.—The elevator system is hydraulically operated, the pressure for which is supplied by two 14 and 20x10x15-in. Worthington compound duplex pumps located with the necessary piping and tanks in the space within the dome foundations. Each pump is supplied with steam through a 2½-in. connection, with a Ford governor for control by the hydraulic pressure. The pumps draw through 8-in. suction connections from a large open discharge tank and deliver through 8-in. connection to a cylindrical steel pressure tank, from which the hydraulic pressure is supplied to the elevator control valves. The pressure tank is a 30-ft. steel tank 6 ft. in diameter, designed to withstand the operating pressure of 150 lb., and is maintained half filled with air for air chamber equalization of fluctuations of load. The discharge tank is an open steel tank 6x32 ft. in size and 6 ft. deep, into which the various discharge lines from the elevator control valves discharge. There are five passenger elevators in the main building and one as hoist in the boiler houses, all of the plunger type and installed by the Otis Elevator Co., New York. The five passenger elevators are arranged to run from the basement to the fourth floor, a total rise of approximately 70 ft. The four machines under the dome are designed to carry maximum loads of 3,000 lb. at a speed of travel of 300 ft. per min., while the fifth elevator, in the northwest corner of the court, is designed to carry 1,500 lb., at the same speed. The four larger machines have 7½-in. plungers, while the smaller elevator has a 5½-in. plunger. The ash hoist has a rise of about 10 ft. and a capacity of 1,500 lb.

Electrical Equipment.—The electrical installation is unusually extensive, decorative lighting and special illuminating features forming an important part of the building's equipment. A liberal use is made of studded ceiling and cove lighting, avoiding in general the use of large and complicated chandelier designs. The wiring system has been designed for abundant lighting of all rooms and departments of the building, there being a connected load of nearly 8,000 incandescent lamps, the greater part of which are, however, 8 c.-p. lamps in the decorative ceiling lighting scheme. But two motors are used in the building, driving ventilating fans on the roof.

The scheme of illumination is a practically general application of studded ceiling lighting by rows of 8 c. p. lamps. The corridors encircling the open interior court have rows of ceiling lamps on 12-in centers lining the cornices on the sides opposite from the court. All of the large offices and assembly rooms and many of the smaller offices are similarly illuminated, the lamps being very generally in rows bordering the cornices and distributed on 24-in. centers. In the council chamber and dome over the central portion of the corridor, special lighting schemes are attempted in which studded lighting is utilized with striking effect. The location and distribution of lamps are in all cases carefully proportioned for effective general illumination, the intensity of which may be varied by operating different combinations of lamp groups. This method of illumination rendered the wiring scheme very extensive and necessitated a very large number of outlets, the system providing in all 7,467 outlets for lamp connections. Of these over 1,400 are on the first floor, over 2,000 on the second floor, 1,460 on the third floor, 1,430 on the fourth floor, while the remainder are in the sub-basement and boiler house. The current supply of this lighting equipment is distributed by forty main feeders which vary in size from No. 1 to No. 0000 and extend from the main switchboard in the engine room to local distributing panel boards in various parts of the building.

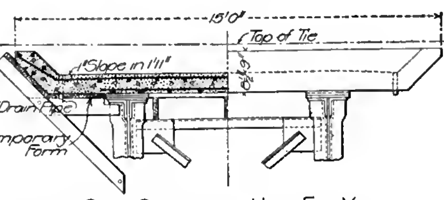
The wiring of the building is divided in general into four divisions, embracing the four sides of the building encircling the court, which greatly facilitated the running of the main feeders from the swithboard to central distributing boards on every floor. There is thus a panel distributing board on each floor near the middle of the corridor on each side facing the court, making six rows of boards on each of the four sides, all served by a single group of riser lines, or 24 boards in all, which together with two additional boards for special service, make 26 panel boards supplied by independent feeders, each under separate fuse and circuit-breaker control at the main switch-board. The feeders are extended to the groups of riser lines of panel boxes on the upper floors through lines of large conduits under the sub-basement floor which spread out into large convenient pull boxes at the base of each riser. These boxes are of heavy cast-iron with bottoms 1 ft. above the sub-basement floor and have heavy doors to enclose connections. A separate conduit is provided for each feeder, so that both the initial installation and subsequent access to any feeder for examination or repairs is greatly facilitated. All of the wiring for both feeder and distribution circuits is installed in concealed loricated conduit run on the loop system throughout. The main feeder cables are lead-sheathed from the switchboard to the pull box connections, beyond which standard rubber-covered wire is used throughout.

The switchboard is a six panel board of white marble, 25 ft. in length, mounted on an angle iron frame. It is at present enclosed in a glass partition for protection from dust and dirst in case the engine room is used for storage purposes. The board has eleven 400-ampere knife switches and circuit breakers, ten of 200 ampere capacity, two of 600 ampere capacity and two of 3,000 ampere capacity; a 5,000-ampere General Electric wattmeter, a 150-volt Thomson inclined-coil voltmeter and a ground detecter switch, no apparatus having as yet been installed for use in connection with generating apparatus. . The present current supply is at 120 volts alternating current, on the two-wire system, from the local lighting company.

The new City Hall was designed and its equipment selected by and installed under the supervision of Messrs. John H. and Wilson C. Ely, architects, Newark, N. J., and Mowbray & Uffinger, New York. The details of the mechanical equipment were designed by Mr. James H. Seymour, Jr., Newark.

(To be Continued.)

A Solid Floor for Plate-Girder Spans.



Burlington Bridge Floor.

Some features of plate girder design have recently been revised for standard construction on the Chicago, Burlington & Quincy Ry., where no bridge is considered up-to-date without a ballasted floor, and both deck and through plate girder spans are designed to receive reinforced concrete floors, although wooden floors may be used with them if desired. In a 75-ft. through span there are two girders 15 ft. 6 in. apart on centres and 8 ft. 4¼ in. deep, back to back of flange angles. Two lines of horizontal angles 18 in. apart in the clear are field riveted to the inner faces of the webs, with vertical legs inside, to form connections for the concrete floor construction, the top of the lower 4 x 4 ⅜-in. angle being flush with the top flanges of the stringers. With this construction the height from the top of the tie to the masonry is 3 ft. 10¼ in., and with the open floor it is 3 ft. 2 in. From the top of tie to clearance line is 3 ft. 3¼ in. and with the open floor it is 2 ft. 7 in.

Four deck spans have floors 15 ft. wide over all, with concrete slabs 8½ in. thick reinforced with transverse and longitudinal bars in the upper and lower surfaces. The outer edges of the slab are inclined upward at an angle of 30 deg. to make flanges 9 in. deep to retain their ballast. The top lateral system and the top angles of the sway brace frames are lowered clear of the top flange angles of the girders, to permit the forms for the concrete to be set with greater ease and to be supported on the transverse frames and lateral angles. The outstanding flanges of the vertical web stiffener angles in such girders are punched for connecting bolts to the knee-braces of concrete forms. A 75-ft. deck span weighs 95,800 lb. and one girder weighs 17,900 lb. For a 75-ft. through span the corresponding weights are 144,400 lb. and 40,860 lb. A 105-ft. deck span over Pope Creek on the Galesburg division weighs 208,000 lb. Its concrete floor weighs about 1.2 tons per lineal foot and raises the allowed unit stress from 4.86 tons allowed for ordinary floors to 5.5 tons.

All designs are made and the construction supervised by the Engineering Department of the railroad, Mr. W. L. Breckenridge, chief engineer, Mr. C. H. Cartlidge, bridge engineer. The Morava Construction Co., Chicago, was the contractor for the Pope Creek Bridge.

THE FLORIDA EAST COAST CANAL has been cut through from St. Augustine to Miami and work will shortly begin on its extension northward to the St. Johns River, affording a connection with Jacksonville. The construction has been under way for many years, backed mainly by Boston capital. The portion of the canal now completed is 55 ft. wide at the bottom and has from 6½ to 7½ ft. of water. Steamboats will be placed in regular service by the Florida East Coast Line & Transportation Co., which is constructing the canal, and it is expected that the long stretch of attractive land-locked water-way will bring many small yachts and house-boats. In addition it will furnish a useful method of transportation for every one along this noted portion of the Atlantic coast.

The Chateau des Beaux-Arts on Huntington Bay.

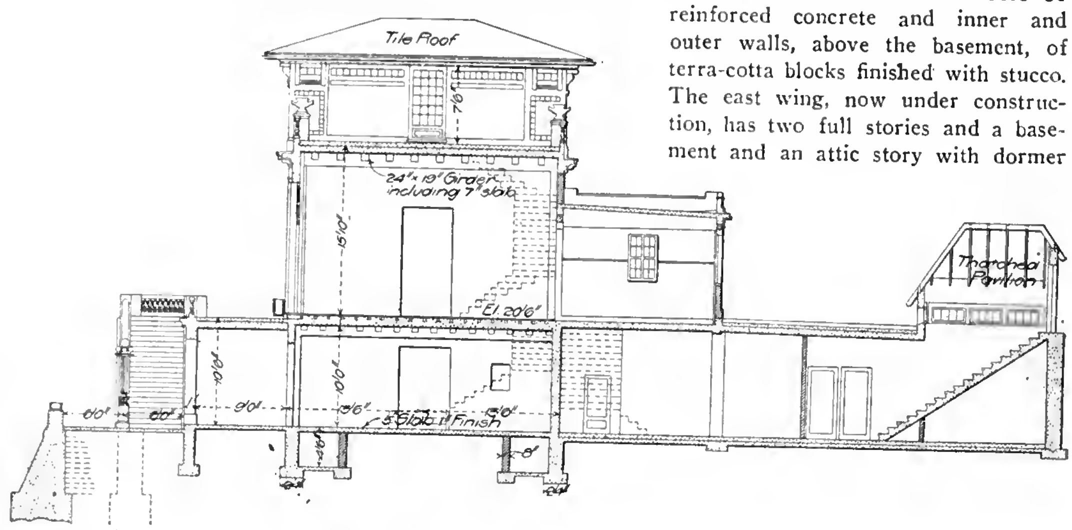
In the construction of the Chateaux des Beaux-Arts, a large summer resort now being built on the south shore of Huntington Bay, Long Island, concrete has been used almost exclusively, not only as a structural material, but also in forming the exterior and interior architectural ornament for the various buildings. The structures contemplated in the general scheme are: A large 3-story and basement central hotel building, with a 145x51-ft., 60-room wing on each end; a 135x36-ft. casino, with public and private dining rooms, billiard rooms and a roof garden; a garage to accommodate fifty automobiles; bathing pavilions and grounds for polo, tennis, golf and other sports. It is expected that ultimately a number of villas will be built on the rising ground in the rear of the hotel to be rented to summer occupants. The casino is now practically completed and the east wing of the hotel is well under way. These buildings and the garage will be available for the present season. The west hotel wing will be built next year and the central hotel building and other structures as soon as they are needed. The site of the main hotel building is now occupied by a 3-story frame hotel formerly known as Locust Lodge. This will be used as the main building at present and later will be moved to another site where it will serve as an overflow annex.

Where this development is in progress the land overlooking the bay rises sharply from the narrow beach, which is wholly covered at flood tide, to a height of about 20 ft., and then slopes gently back for about half a mile. A sea-wall of plain concrete is being built along the toe of the bluff in front of the chateau. Only about 205 ft. of wall is to be built at present, this portion being immediately in front of the casino. Later it will be extended in both directions to a total length of about 600 ft. The wall proper is 8 ft. high, 7¾ ft. wide at the footings and 2 ft. wide at the top. It is surmounted by an ornamental parapet wall about 2 ft. high, on the top of which will be placed growing plants in wooden boxes. The footings of the wall are about 5 ft. below mean tide and rest on chestnut and oak piles 15 to 30 ft. long, stagger-spaced on about 4-ft. centers, which were driven to refusal in the gravel. The wall is built in 32-ft. alternate sections with a concrete key and keyway at each joint. The part of the wall below flood tide level is built during periods of low tide. The manner of delivering the concrete to the wall will be referred to later.

Above the sea-wall on the edge of the bluff is the casino. This is a reinforced concrete structure about 135x36-ft., having a 1-story and basement central section which becomes at each end two stories and basement, by the addition of small pavilions, shown in the accompanying illustrations. The main floor is at El. 20.6, or about the same as the top of the bluff. In front of the casino, extending its whole length, at El. 20.1, is a concrete terrace 9 ft. wide, from each end of which stairs lead down to a 12-ft. terrace at El. 9.1, about 2 ft. below and just inside the top of the sea-wall parapet. In the rear of the casino is a low terrace garden, under which the basement is extended with a concrete column and slab construction. This portion of the basement, in which are kitchens and serving pantries, is connected with the hotel buildings by a reinforced concrete tunel, 8½ ft. wide and 10 ft. high. The basement directly under the casino building will be occupied by the cafe, billiard room and private dining rooms. The restaurant and other dining rooms will occupy the main floor, and on the roof of the central part of the building will be an open garden overlooked by private dining rooms in the two end pavilions.

The basement also extends under the upper terrace about 9 ft. beyond the front wall of the casino along its whole length. In front of the central section of the building this extension forms a long corridor, the floor of which is only 4½ in. above the sea-wall terrace, which is reached from the corridor through arch openings forming an arcade. The 1x4-ft. piers of the arcade are spaced 12½ ft., center to center, and support the front of the upper concrete terrace and its balustrade. They are without vertical reinforcement, but each arch is reinforced with two ½-in. round rods with bent ends and two similar rods are placed over each pier top.

In the casino space has been economized by building the wall and interior columns partly or wholly within the walls. The columns carrying the greatest weight are those on 12½-ft. centers along the front and rear sides of the cafe and restaurant. To these are attached the wall girders and the transverse girders which carry the main and the roof-garden floors. These columns are T-shaped, the stem of the T being



Cross Section of the Casino.

very short and enclosed in the wall. Their sectional dimensions in the basement and main stories are shown on an accompanying drawing. Each column is reinforced with four 1-in. round rods, one in each of the two inside corners, and the other two immediately in front of these near the outer surface. Hoops of ¼-in. round steel wire encircle the rods at 12-in. intervals.

The main floor and roof girders have a clear span of about 25 ft. and are 2 ft. wide and 18 in. deep, including the 7-in. floor or roof slabs, which are carried by the girders without intermediate support. Each girder is reinforced with one 1¼-in. and five 1½-in. rods placed near the lower surface. Each rod is 20 ft. long, including a 4-in. right-angle bed at each end. Three rods are tied into the column at one end of the girder and the other three rods are fixed in the column at the opposite end. The reinforcement near each end is therefore only half as much as that in the central three-quarters where the rods lap over. Each girder is also reinforced with four ¼-in. additional rods disposed in the upper half of the girder, as shown in an accompanying cross-section. These rods, however, serve more as a support for the stirrups and floor slab rods during construction than as reinforcement.

The wall girder below the roof slab forms the basis of an ornamental entablature, the upper part of the girder being built out roughly to form the corona of the cornice. This extension is reinforced with brackets made of ¼-in. rods and placed on 12-in. centers. These brackets and the forms for the girders are shown, ready for the placing of the concrete, in an accompanying picture, in which may also be seen the wooden strips lightly tacked to the inside of the forms to form a dovetail attachment for the cement bed moldings. Each dovetail is formed by three strips of wood, the center strip being triangular in section with its edge at the bottom of the dovetail and its greatest width flush with the surface. When the middle strip is taken out the other two can be removed readily without breaking the edges of the concrete dovetail. Between the bracket rods, in the position shown in the picture, were placed short pieces of tin speaking tube just long enough to extend through the corona. Through these tubes will be passed the wires used together with cement mortar in firmly attaching cement dentils. When the attachment is complete the wires will be wholly embedded in cement mortar to conceal them and protect them from corrosion.

The site of the hotel buildings is about 200 ft. in the rear of the casino. The main building will have on each side a wing, the three buildings being connected by a reinforced concrete covered passageway and all facing the bay. Each building will have a framework and floors of reinforced concrete and inner and outer walls, above the basement, of terra-cotta blocks finished with stucco. The east wing, now under construction, has two full stories and a basement and an attic story with dormer windows under the mansard roof. It is 145x50 ft. and contains about sixty guest rooms. In each of these stories there is a longitudinal central corridor 6 ft. 4 in. wide along each side of which are arranged the bathrooms and closets with their accompanying chambers, as shown in a partial floor plan, which also indicates the general spacing of the columns.

In the upper stories practically all the columns are enclosed with the walls, their sections being rectangular, square, L, or T-shaped or cruciform, depending on the walls intersecting at a particular column. All the basement interior columns are octagonal and each is reinforced with four ½-in. rods spirally wound with 3/16-in. wire on about a 4-in. pitch. Above the main floor the outer lines of interior columns become cruciform and those along the corridors become square. The latter are in the pipe ducts or closets and do not form unsightly corners in the rooms. Above the basement, hoops of ¼-in. steel on 12-in. centers are used instead of the spiral winding. The arrangement of the reinforcement in making the transition from the octagonal to the cruciform section is shown in an accompanying sketch. In designing the columns 500 lb. was taken as the maximum allowable working stress in the concrete.

The floor slabs are 4 in. thick and are attached to the wall girders and to longitudinal girders extending along the four lines of interior columns. In the chambers the slabs are reinforced by longitudinal and transverse ½-in. rods on 6-in. centers in each direction. The corridor floors are reinforced with ½-in. transverse rods

on 6-in. centers and every third rod extends through to the inside chamber walls to provide reinforcement for the floors of the bathrooms, hallways and closets. The interior floor girders are 5x14 in., not including the floor slab, and each is reinforced near its lower surface between columns with two 1-in. rods. Extending through each column and into the girders near the upper surface of the floor slab are two 1-in. rods about 7½ ft. long. Stirrups of ¼-in. round steel are used to tie the upper and lower rods together.

They are dumped by an automatic device, which trips the side-door catches, allowing the gravel to fall to a pile from which the supply for the casino is taken in wheelbarrows. The supply for the other buildings is dumped from the cars into chutes through which it flows into dump carts. This hoisting engine is also used on the pile driver for the sea-wall, a supply of gravel being accumulated in advance sufficient to serve the work while the engine is not available for hoisting. The costs of material and handling are thus reduced to a minimum.

engine through a friction clutch and drum. A similar equipment is used at the east hotel wing. The concrete for the sea wall is mixed in the Ransome mixer at the casino and delivered to wheelbarrows on the main floor. It is then wheeled out on the upper terrace and dumped through chutes into the wall forms. Beyond the ends of the casino a trestleway has been built at the same level as the upper terrace, on which the wheelbarrows are run out.

In erecting the two buildings now under construction the column forms in each story have been set up and filled before the girder and floor centering for the floor above was put in position. This has been done so that the girder reinforcing rods at the top of the columns would not impede the ready flow of concrete into the form. In the hotel the columns in the three upper stories have the same lengths from the floor surface to the bottom of the girders above. This makes the same column forms available for each floor. The column forms end at the bottom of the girders and in framing the latter special pieces are cut and used as needed. All the forms are built on the work in a fully equipped shop.

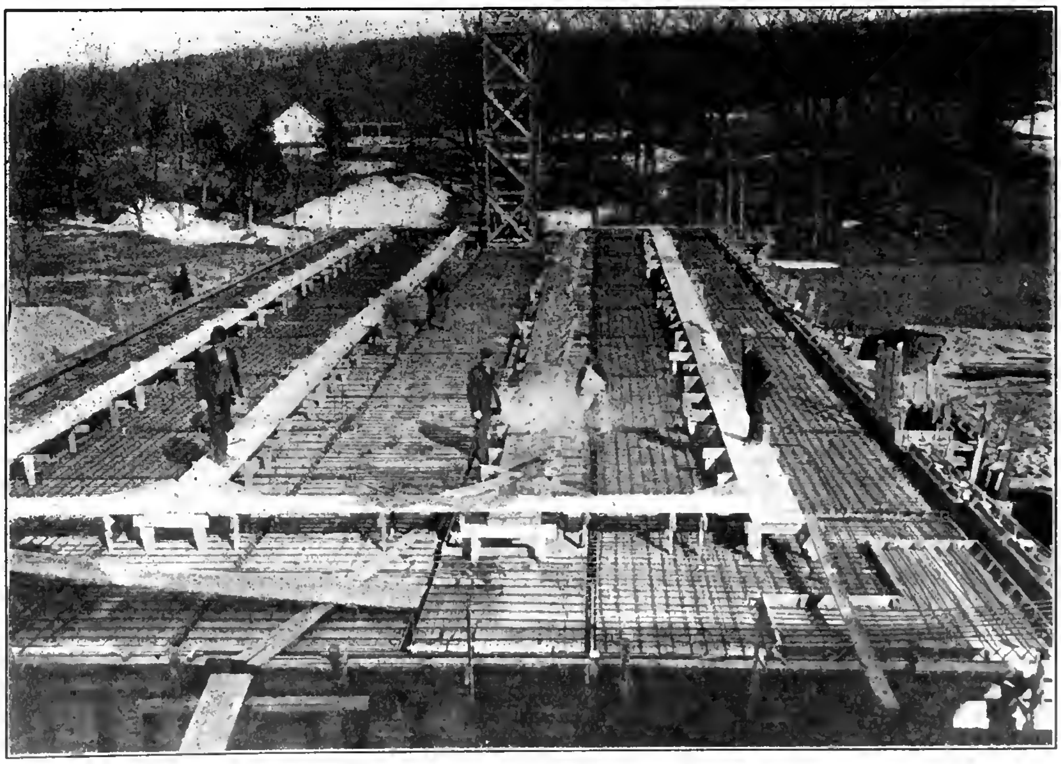
The reinforcement of the chamber floor slabs in the hotel wing consists of a double series of rods which were formed into mats of the proper size on a square wooden frame, the side pieces of which were notched to insure the proper spacing of the rods and facilitate the work. The intersections on all four sides were securely tied with wire and the mats put aside to be hoisted to the floor and placed where needed. The first floor of the hotel wing, just before the placing of concrete was begun, is shown in an accompanying illustration which also indicates the arrangement of the wheelbarrow runways and the position of the elevator.

Cornice Brackets in Wall Girder of the Casino.

The 8x21-in. wall girders at the sides and ends of the building form the basis for applied cement ornament of the general form shown in an accompanying cross-section. These girders are not designed primarily to carry the curtain walls, as the latter are built in solidly and their weight is transmitted to the concrete basement and foundation wall, but they act as floor girders, window lintels and building ties combined.

The garage as completed will be a 274x47-ft., 2-story reinforced concrete structure, but only one story is to be erected at present. Except for some small rooms at each end the entire floor area will be available for the storage of automobiles. There are two lines of 12x12-in. interior wall columns, placed 10½ ft. from the nearest sidewall and spaced on 17-ft. centers longitudinally. The 6-in. second floor slab is carried by transverse girders 12 in. wide and 24 in. deep, not including the floor slab. In designing this floor system it was assumed that the attachments at the ends of these girders and at their intersections with the interior columns were fixed, thus making the resisting moment of the wall and interior columns a factor in the support of the floor load. The arrangement of the reinforcing rods in these girders is shown in an accompanying sketch.

The concrete used in the structural work in all the buildings is made of Atlas Portland cement and unscreened beach gravel and is equivalent to about a 1:2:4: mixture. The cement is delivered in lighters at a dock about a mile and a half from the work and is hauled the remaining distance in wagons. The gravel is piled up on the beach in front of the casino with two-horse drag scrapers, when the tide is low, and is shoveled into two 1-yd. side-dump skip cars, which are hauled to the top of the bank on a double-track trestle incline by a Lidgerwood double-drum hoisting engine. At the top of the incline the cars are about 15 ft. above the ground.



First Floor of Hotel Ready for Concrete.

The concrete for the casino is prepared in a Ransome mixer placed in the basement near the center of the south side of the building with its hopper at the level of the main floor. It is driven by a New York Safety Steam Power Co. engine, supplied with steam by a vertical boiler some distance from the building. The mixer delivers into a dumping bucket elevator in the stair shaft which in turn delivers on each floor to a hopper from which wheelbarrows may be filled. The elevator is operated by the mixer

The cement ornament used on these buildings is formed in two ways. Balusters, hand-rails, columns, door-sills, dentils and similar pieces are cast in wooden molds made in the carpenter shop on the grounds. For this work a 1:3 mixture of Atlas Portland cement and beach sand is used, mixed about as dry as molding sand. It has been found that better results are secured if the mixture is allowed to take a slight initial set and is then retempered before being placed in the molds. This seems to prevent the

appearance of fine hair cracks and apparently in no way lessens the permanency of the work. The mixture is thoroughly rammed into the mold with ordinary wedge-shaped wooden molders' tampers. The casting is taken from the mold as soon as practicable and any broken corners or other imperfections are repaired with fresh mortar, carefully tamped into place and formed. In making the molds the carpenters work from full-size drawings provided by the architects.

Cornice and interior moldings of cement are formed with a screed in a manner similar to that generally used in forming plaster moldings. The rough concrete surface is first prepared by washing it thoroughly and dusting it while wet with a 1:1 mixture of very fine sand and cement, which is then rubbed in with an ordinary calcamine brush. A thin coat of a 1:3 mortar, mixed rather dry, is then worked on with a trowel. The ornament is then built up in ½-in. layers, a metal-faced screed, running on wooden guide strips being used to form the desired molding. Each layer of mortar is allowed to set 3 or 4 hr. before another is applied.

False floor girders, which have been liberally used to divide the restaurant and cafe ceilings into panels, are formed of cement mortar laid on expanded metal strips bent to shape over strap-iron brackets bolted to the ceiling with small wagon bolts, the heads of which are embedded in the ceiling concrete.

A rather interesting method was followed in the design and execution of this job in that the consulting engineer did most of his work through a draftsman in the office of the architects, and besides, secured for the owners a superintendent whose ability he could guarantee, who has had charge of all the execution. By this means large economies were secured in the design, jointly and simultaneously developed by the engineer and architect, along economic and artistic lines, respectively. In the same manner, economies in construction have been practiced by the engineer and owners working together so that the actual unit costs are said to be phenomenally low. If it had not been for the rigor of the past winter and the exposed site of the work, the progress would have been even better and the costs still lower. It may be noted that the methods herein followed are one solution of the difficulty usually encountered when reinforced concrete contractors are allowed to submit bids on their own designs. Even had the owners decided to erect the work by contract the same method of design would have been advantageous.

Messrs. Bustanoby Bros., proprietors of the Cafe des Beaux-Arts, New York City, are the builders and owners of the structures described. Messrs. Delano & Aldrich and Maurice Prevot are the architects, and Mr. E. P. Goodrich is the consulting engineer for the design and execution of the reinforced concrete work. All the details of the construction work have been under the supervision of Mr. Edward Mahl, superintendent.

An Important Correction should be made in the discussion of the Quebec bridge printed last week. The center post carries less than one-fourth of the entire shear of the cantilever and anchor arms, according to Mr. Theodore Cooper, instead of all of it, as stated.

Highway Work in Allegheny County, Pa.

Allegheny County, Pa., has now under construction 60 miles of macadam road, which when completed will bring the total of the county's hard roads up to 275 miles. The road work of the county since 1897 has been under the so-called Flinn Act, passed by the Pennsylvania legislature in 1895, which authorizes any county to take over from the townships such roads as it intends to improve, these roads then becoming county roads to be maintained thereafter without expense to the township.

The county has an area of 750 sq. miles of rough picturesque country, cut by deep valleys carrying streams to the three large rivers, the Allegheny, the Monongahela and the Ohio, which meet at Pittsburg, the geographical, as well as commercial center of the county. The topography has naturally made road construction quite costly, and at the same time has intensified the demand for road improvement. Heavy landslides are a common occurrence, and protection from streams has proved a costly item because of the great number of runs, most of which are torrents in time of high water.

The Road Department was organized in 1897 under the Act above referred to, and since that date has improved 215 miles of road. In addition to maintaining these roads it also maintains 24 miles of plank roads, which were purchased from corporations that had operated them on a toll basis. These will be maintained as they are until they are changed to macadamized roads. The earth roads still remain under the township authorities, the Road Department concerning itself entirely with hard roads. The total length of roads of all descriptions in the county is 1,766 miles.

The present development contemplates the expenditure of about $1,000,000 per year. The main roads radiating from Pittsburg are first improved, and when this work is completed connecting lines will be taken up, though where the latter are very important they are taken up at the same time as the other improvement. A county road tax and bond issue furnish the funds for the work.

The improved roads are built with a telford foundation and have a width of stone of 16 ft., and a width between slope lines of bank of 24 ft. The width of stone, 16 ft., allows of the passage of two vehicles abreast without crowding either one off the hard surface.

In improving an old road grades are revised, cutting the sharp hills and filling deep hollows. The sub-grade is rolled with a steam roller weighing not less than 10 tons, and all resulting depressions are filled, and the surface again rolled till it is even and compact. Shoulders are left on each side of the sub-grade and ample provision made for drainage through them. Where the existing soil is of such character that it must be removed, the surface is brought to the proper level with good material. Upon the sub-grade is laid a telford foundation of stones 8 in. deep, not exceeding 4 in. in width at the top and from 6 to 16 in. long. They are laid by hand with their broadest edges down, and longest side across the road. Not less than 10 per cent. of these stones may be under 7 in. in depth. The stones are laid to break joints, and are bound in place by inserting and driving down wherever possible stones of proper size and shape to wedge in solidly. All projecting points of the top surface are broken off with a hammer and driven into the spaces not already filled by the process of wedging. Wedging stones are driven until the foundation is to grade and 8 in. thick. The foundation is then rolled with a roller weighing not less than 10 tons, until the whole mass is thoroughly bedded into the earth subgrade, and the top is 4 in. below the finished grade at all points.

When the sub-grade is on shale instead of the telford foundation just described, a layer with a finished depth of 6 to 8 in. made with stone that will pass through a 3½-in. ring, and will not pass through a 2½-in. ring, is used. This layer is likewise compacted with a 10-ton or heavier roller. The stone used is that found convenient to the work, generally limestone or Ligonier stone.

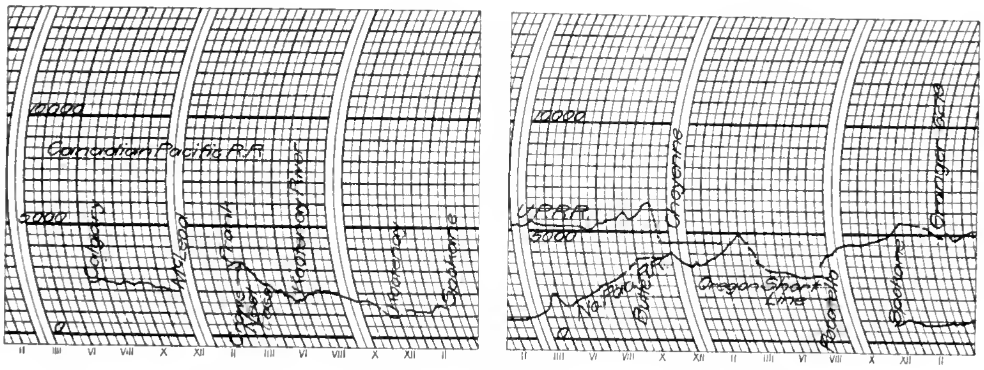
The surfacing consists of two layers of stone, with sometimes a finishing coat of crusher dust. The first surfacing layer is 2 in. thick when consolidated and is made of stones that will pass a 2½-in. ring, and not pass a 2-in. ring. After this has been rolled solid a second layer with a finished thickness of 2 in. is added. It consists of broken stone which will pass a 1½-in. ring, but will not pass a ¾-in. ring, to which may be added a proportionate amount of screenings, free from dust, that will pass a ¾-in. ring, and not a ¼-in. ring. This last course is thoroughly rolled until the surface is even and at the finished grade. When a binder course of crusher dust is used, it is thoroughly sprinkled and rolled until the mud flushes to the surface, and until the passage of the roller causes no wave in the surface. The surface of the berms between the broken stone and the gutters is finished with clay or good earth and then rolled.

In many places it is necessary to pave the gutters or open ditches, on either side of the road, and for this work a foundation of 3 in. of rammed gravel is used. Upon the gravel is placed a layer of bedding sand or gravel of sufficient depth to bring the gutter stones which will be rammed in to it to the proper grade. The paving stones are of roughly squared rubble, at least 8 in. in depth, set on edge, and the interstices between them are filled with sand.

At the same time the road is improved, fences on embankments, and watering troughs are constructed. The latter are placed at all springs and water courses.

The maintenance work on roads already improved is carried out systematically, the work being blocked out at the beginning of each year. The broken stone for resurfacing is bought by contract and hauled by contractors to the point of application on a tonnage basis. Six 10-ton rollers are owned by the department and used constantly in maintenance work.

The Road Department is under the direction of Mr. George T. Barnsley, chief road engineer of Allegheny County.



Cards from Recording Pocket Aneroid Barometer.

Letters to the Editor.

POCKET BAROMETER RECORDS.

SIR: You may be interested in the sheets inclosed, being the record of a pocket aneroid barometer. I have had this a little less than a year, and have traveled with it many thousands of miles, and across the United States, both east and west and north and south, and over the Rockies many times, and to the tops of some of our highest peaks. The inclosed sheets represent the record over a portion of the Canadian Pacific, of the Oregon Short Line and the Union Pacific railroads from Calgary in Alberta, via Spokane to Butte, Granger and Denver.

I find the instrument reliable within its limit of accuracy. The elevations on the present sheets should be increased by about 1,000 ft. You will see that they show a fairly accurate profile of the roads traversed. The horizontal distance is a function of the speed and consequently the profile is not to the same horizontal scale unless the speed is uniform. It serves, however, as an interesting record for reconnaissance.

The instrument consists of a small aneroid barometer with a pen something on the plan of the Richard recording instruments, the whole case being about 3½x4½ and 1¼ in. thick. The thing which makes it a success in railroad riding, walking and horseback riding, is the idea conceived by the maker of keeping the pen from the paper except at intervals of about two minutes. It then touches the paper for a short instant and is withdrawn, but without giving time for a long line.

I have carried the instrument on foot, on horseback, in my pocket and in all ways, without trouble in the record. Once in climbing a mountain, I slipped, fell down and rolled over, but without any effect upon the record. Should a jump take place at just the instant when the pen touches the paper then, of course, there would be a long line at right angles to the trace. When the descent or ascent is fast, the dots may not form a connecting line, as is shown in the passing of the hill near Cheyenne. This particular record included the crossing of the Rockies four different times. First at the Crow's Nest Pass on the Canadian Pacific, second, on the Northern Pacific some distance west of Butte, the third, on the Oregon Short Line east of Butte, and the fourth on the Union Pacific at Sherman Hill west of Cheyenne.

Yours very truly,

Fort Collins, Colo. L. G. CARPENTER.

CONCRETE SLAB FORMULAS.

SIR: In your issue of Aug. 3, page 131, you give prominence to a solution of the flat slab in reinforced concrete given by Prof. W. C. Unwin. It seems to me that the solution is one open to question. Prof. Unwin starts with the assertion that a flat square slab supported on all four sides fractures along a diagonal. Assuming that the bending moment is greatest along the diagonal of a rectangular slab a formula is derived for the magnitude of this bending moment, which is naturally a mathematical certainty, just as the bending moment along the diameter of a circular plate is a mathematical certainty. But the variation of intensity of this moment along the diagonal is entirely ignored, or rather the intensity is taken to be constant. There is just as much error in taking the intensity of this moment as uniform along the diagonal of a rectangle as there is in taking the intensity of the

bending moment along the diameter of a flat circular plate as uniform. It may be quite true that a flat slab, either square or rectangular, supported on four sides, will break on a diagonal line. This is proof of one thing, namely, that the greatest intensity of bending moment is at the center of the slab; for, as both diagonals are identically conditioned, either may be the one to fail, and their only common point is the center of the slab. It is not conceivable that the same intensity of bending moment extends clear to the corner of the slab. A crack once started in a diagonal direction would naturally extend into the corner and even over the support, merely on account of the brittleness of the material. This would be no evidence of a constant intensity of bending moment along the fracture. A crack once started in a brittle substance can be extended without the exertion of as much force as is required to start it.

On the same page of your issue the report quoted refers to flat plate theories as being applicable to reinforced concrete. These flat plate theories are worked out for steel plates, where the strength in both tension and compression is the same in all directions, and the extreme fibre stress at both top and bottom of the plate is found to be the same in all directions at the center. Furthermore, in Grashof's formula the true extreme fibre stress is not given, as in the case of beams, but it is throttled by a coefficient (Poisson's ratio). How can a fictitious extreme fiber stress in all directions be converted into actual stress in steel reinforcing rods in two directions? Advocates of Grashof's formula do not seem to have answered this question. They further do not make it clear why it should be necessary to pass through the labyrinth of the flat plate theory and through the loop of Poisson's ratio (and out again) in order to solve a flat plate in reinforced concrete, a material not at all contemplated in Grashof's formula.

Yours very truly, EDWARD GODFREY.
Monongahela Bank Building, Pittsburg.

COMPARISON OF VARIOUS PILES.

SIR: In designing the foundations of a building, the first and most important point to ascertain is the condition of the ground on the proposed site. It is not only necessary to learn the nature of the ground on the surface but the nature of the underlying strata must be determined. It often happens that while the upper ground may be firm and compact enough in itself to carry the required loads, yet the underlying strata are of such a nature, mud, quicksand, etc., that the application of any load would cause the upper stratum to settle seriously, thereby causing damage to the building. Or it may be that the upper ground is of no account at all for load carrying purposes, mud, swampy ground, etc., making it necessary to support the loads on some firmer stratum of earth found at some distance below the surface. In any such case, foundations are designed which are intended to transmit the loads of the building to firm and reliable ground, whatever distance that ground may be located below the surface of the earth. Sometimes it is found most expedient to use deep footings and heavy piers, going through the poor ground and resting on the good ground underneath. In other cases, principally from the standpoint of economy, piles, either of wood, iron or concrete, and of various sizes, are used for transmitting the loads through the poor earth to the firmer stratum underneath. These piles depend in a great measure for their support on the surrounding earth, and due to the friction between the sides of the piles and the earth, a great part of the load is taken up by the surrounding ground before the point is reached. It will be seen therefore that in using piles, a certain amount of dependence must be placed on the upper ground, inasmuch as it carries a certain portion of the load, the amount depending on the firmness of the ground.

Were it certain that the upper earth would always remain the same, the risk involved would be small, but there are certain points which make such a possibility uncertain. Very often piles are driven before any excavations are made, so that after the earth has been removed from around the tops of the piles for the capping, a certain amount of carrying capacity has been taken away from them. This, however, does not change the loads the piles have to carry. The lowering of the water level, due to drainage into nearby sewers or others reasons, will allow the tops of wood piles to rot, thereby rendering the proper transmission of the loads imperfect, sometimes causing serious settlement of, and consequent damage to, the building resting on the piles. Again, excavation near the building may destroy the supporting power of the surrounding earth, thereby causing the piles to settle, because part of the supporting surface is rendered useless.

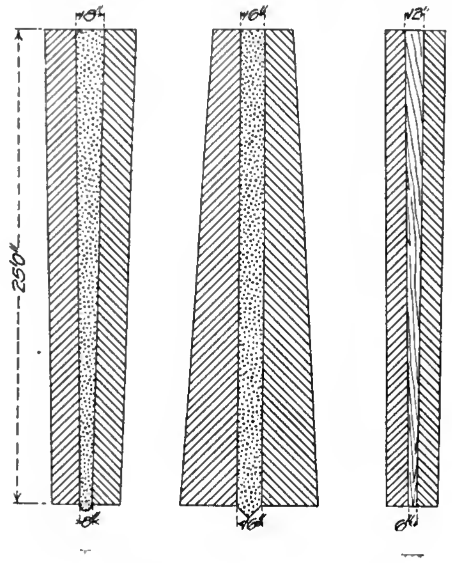


Fig. 1, Load Distribution by Friction.

All of these points must be considered in choosing the kind of foundation to be used for the building. The ideal pile would be one that transmitted the entire load to the firm and reliable ground, wherever that soil might be, placing no dependence on the poor ground through which it passes. There are no piles made which exactly fulfill these conditions, but it should be a matter of interest to everybody to find out which pile most nearly fulfills them.

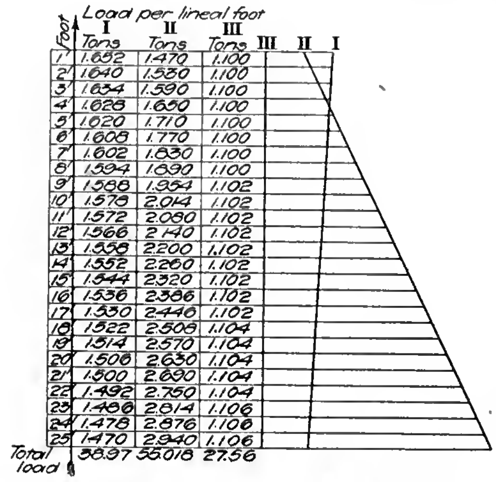
There are on the market, at present, practically only three styles of piles, the ordinary wooden pile, the tapered concrete pile, either molded before driving or made in place, and the cylindrical concrete pile.

For the purpose of comparing these piles let us assume ground conditions which will bring out the largest number of good points of each system, making the comparison as fair as possible to all concerned. Assume that the ground is of such a firm and compact nature that one square foot of pile surface at the butt of the pile will develop a carrying capacity of 0.35 ton, increasing uniformly to 0.7 ton per square foot of pile surface at the point of the pile. Assume each pile to have been driven 25 ft. into this ground. Also assume the ultimate friction of the concrete and wood against earth to be the same, and neglect the end bearing values of the piles. Then we have the superficial area for one lineal foot of pile at the butt and at the point for each pile to be as follows:

Pile	I.	II.	III.
Butt	4.71	4.2	3.14
Point	2.1	4.2	1.57

Multiplying these areas by the unit loads for the butts and points of the piles and scaling them off as shown in Fig. 1, and connecting the upper points with the lower points, diagrams are obtained which show not only the total loads carried due to superficial friction by the piles but also how the loads are transmitted to the surrounding earth. Fig. 2 shows this more in detail and also gives a table of loads carried by each lineal foot of pile as scaled from the diagram.

The diagram of pile I shows that a slightly greater load is transmitted to the surrounding ground at the butt of the pile than at the point. In other words, the very reason for the use of piles is defeated by placing over half the load on the poor upper earth. The diagram for pile III. shows that the loads are very uniformly distributed to the surrounding ground for the whole length of the pile, which is little better than pile I. The diagram for pile II., however, shows that small reliance has been placed on the carrying capacity of the upper earth, and that by far the greater part of the load is transmitted to the ground around the bottom of the pile. In other words, it shows that as the carrying capacity of the earth increased, the pile placed a



Foot	Load per lineal foot I Tons	II Tons	III Tons
1'	1.652	1.470	1.100
2'	1.640	1.530	1.100
3'	1.634	1.590	1.100
4'	1.628	1.650	1.100
5'	1.620	1.710	1.100
6'	1.608	1.770	1.100
7'	1.602	1.830	1.100
8'	1.594	1.890	1.100
9'	1.588	1.954	1.102
10'	1.578	2.014	1.102
11'	1.572	2.080	1.102
12'	1.566	2.140	1.102
13'	1.558	2.200	1.102
14'	1.552	2.260	1.102
15'	1.544	2.320	1.102
16'	1.536	2.386	1.102
17'	1.530	2.446	1.102
18'	1.522	2.508	1.104
19'	1.514	2.570	1.104
20'	1.506	2.630	1.104
21'	1.500	2.690	1.104
22'	1.492	2.750	1.104
23'	1.486	2.814	1.106
24'	1.478	2.876	1.106
25'	1.470	2.940	1.106
Total load	38.97	55.018	27.56

Fig. 2, Capacity of Piles per Foot.

greater load on it, thereby developing the power of the ground in a rational and logical manner. Pile I. places the greatest load where the earth is weakest and reduces the load as the soil becomes stronger.

Aside from this it will be noticed in summing up the loads carried by the various piles per lineal foot that pile III. carries the smallest load, pile I. next, and that pile II. will carry more than twice the load of pile III., and over half again as much as pile I. In all this discussion the end bearing of the piles has been neglected. To look at this point for a moment, it will be noticed that pile I. has an end bearing of 0.34 sq. ft., pile II. an end bearing of 1.4 sq. ft. and pile III. has an end bearing of 0.2 sq. ft., or, in other words, pile II. has an end bearing equal to four times that of pile I. and seven times that of pile III. Assuming in the soil discussed above that the end bearing will develop 5 tons per square foot, then pile I. will develop 1.75 tons, pile II. 7.0 tons, and pile III. 1.0 ton.

BOSTON, MASS. THOMAS MACKELLAR.

THE GALVESTON, TEX., CAUSEWAY which it is proposed to construct as a highway and railway structure from the mainland to the island on which the city stands will be nearly two miles long, according to present plans. About 8,000 ft. will be a causeway with a 50-ft. width for steam railways, 15 ft. for interurban railway, and 35 ft. for highway. The bridge is 2,000 ft. long and 63 ft. wide, consisting of a series of reinforced concrete arches, and a lift span of 100 ft. clear width.

LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico..........$3.00 a year
Canada ....$4.50 a year
Foreign subscription.....................$6.00 a year
25 shillings. 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGES OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,250 copies are printed. Total circulation for 1907 to date 493,500 copies, an average of 14,515 copies per week.

TABLE OF LEADING ARTICLES.

A Notable Power Transmission.

In these days it is unusual to find a power trasmission plant which includes startling features of novelty, and it is therefore interesting to note in the Kern River No. 1 plant of the Los Angeles Edison Co. engineering of an exceptionally advanced type. This plant was described in the last two issues of this journal. The Los Angeles region was the scene of the earliest work on this continent in modern power transmission and the engineers of the Coast have consistently kept on the firing line of progress ever since. The first plants of the Los Angeles Edison Co. were in the region of the original Redlands system and took their power from the streams in the southern canyons of the Sierras that sweep westward toward the Pacific. Most of the available powers here have now been developed and in seeking an increase of output the engineers cast their eyes northward. The present great plant is therefore on the Kern River, which is a tributary of the San Joaquin clear across the mountains and drawing its water from an entirely distinct watershed more heavily wooded and of somewhat different characteristics. The result will be that the fluctuations in the total supply of power will be decreased, and the system will be the more reliable. The great network in the northern part of the Golden State has somewhat of the same characteristics, the De Sabla power house, for instance, drawing its water from a slope quite different in its character from that feeding the Electra powerhouse, yet there is probably no case where there is quite such independence in the water supply as in the Los Angeles system.

Another striking characteristic of the Kern River plant is the very extensive and deliberate use of tunnels for the hydraulic works. This was partly suggested by the topography, but more probably by the extent of the works in length and capacity. Most of the California plants are fed by timber flumes, which follow the earlier practice of the ditch companies. Others with shorter distances to cover use steel pipe throughout. Here the main part of the conduit is in tunnels lined with concrete, and what is still more striking the pressure pipe above the powerhouse is itself a steel-lined concreted tunnel practically clear down to the penstocks. Here again, topography had something to do with the matter, but the innovation is a striking one nevertheless and it certainly simplifies the carrying of the large volume of water since the steel is backed by the concrete and does not have the serious difficulties that would have been involved in a plain steel pipe of the requisite dimensions. The tunnel construction is undeniably expensive in first cost, yet the upkeep should be low enough to compensate in large measure for the fixed charges and the chance of a breakdown is certainly greatly diminished. A system like that of the Edison Co. must be considered as a whole and while the other plants act as a partial relay this 20,000-kw. installation is so much the most important one for future work that it was certainly good policy to take no chances with the hydraulic works.

In the design of the power plant itself, perhaps the most striking feature is the size of the units. The impulse wheels are probably by far the most powerful single units ever produced and the generators are the largest ever coupled to impulse wheels, especially when overload capacity is taken into account. The generators themselves are for 50 cycles, the frequency of the original Redlands plant and of the later plants near it. Whether any lower frequency than this might be desirable at greater distances of transmission is an open question, but certainly there are no signs yet that even the long 60 cycle lines further north have been at all inconvenienced by the frequency. The voltage at present in the Kern River plant is 60,000, although the system is planned for the use of 75,000 volts later. In the climate of California there is no reason to hesitate in using it after the lines have been worked into good running condition. One of the interesting details in construction work to which attention should be called was the installation of a temporary hydro-electric plant to supply power for driving the tunnels and doing other preliminary work, and even more characteristic of Pacific Coast enterprise was the installation of an automobile trucking line for carrying cement and other material up to the works from the railroad. Automobiles have been used in construction work times enough, but this particular operation is beautifully characteristic of the way they do things on the Coast, where conservatism is not counted a virtue in and of itself, and where standards are held precious only so long as they remain useful. It would be well if every Eastern engineer had to do a turn of duty in the Rockies and westward just to get shaken out of some of the hidebound precedents that infest Eastern practice. The Kern River system is now only at the start; there is room for other plants when the need for more power arises, and certainly the Los Angeles Edison Co. is to be congratulated on the daring and effective work it has already accomplished.

Power-Plant Machine Shops.

The development of power plants of very large capacity within the last few years has created many new problems in design and operation. The question of maintenance of equipment with respect to continuous service is present in all commercial plants, but as the size of installations increases, the problem of local repairs assumes an importance which cannot be overlooked in any well-planned station. Repairs are frequent in small installations, but in a plant of from 10,000 to 20,000 kw. rating and upward, there is practically a continuous necessity for the pushing on of such work. The main generating units may not require the attention which is proportionally expended on smaller machines, but the auxiliaries and piping, valves, traps and other fittings in very large plants are employed on such a large scale that ample provision should be made for their maintenance, if possible, on the premises.

The power-plant machine shop is the natural outcome of the foregoing conditions, and it is interesting to note the way in which the small shop is coming into its proper place in the design of the larger plants. The comparatively new station of the Suburban Gas & Electric Company at Revere, Mass., illustrates this tendency in plants of moderate size, where the custom is to pump-drive the necessary machine tools by a small motor; and the Port Morris station of the New York Central R. R., with its individually operated set of machine tools located on a special section of the turbine room gallery, shows the importance of the local shop in the exacting service of a very large plant. Formerly a simple workbench equipped with a vise and such tools as the operating staff might personally own and be willing to keep at hand sufficed for the machine shop of a power station, and there is no doubt that some ingenious and handy repair jobs were executed in this way. The conditions are more exacting in these days, and it is a source of satisfaction that progressive designing engineers are appreciating the economy of well-lighted and decently equipped repair shops in the important stations. This kind of maintenance work has yet to be put on a firm basis, however, for until very recently the minor plant repairs have been handled by pretty much any one on the engine room staff. The cost of these repairs has seldom been figured, records of the shop work performed have been few, and the actual money value of a good shop inside the power house walls has been left very much to the imagination.

It should be clear enough by this time that a simple shop with a few tools driven by power is desirable and necessary to the best results in almost any plant, no matter how small it is. The

operating engineers usually possess considerable mechanical skill, and few stations are without the services of at least one man with special aptitude for putting together simple, home-made rigs and combinations of apparatus which will save the plant good money every month when installed. To encourage this kind of inventive ability is worth a great deal more than the low fixed charges on a lathe, drill, shaper and emery wheel with a small motor drive for the group. Even in very large plants there should be facilities for the working out of special ideas aiming toward securing lower fuel and water bills, reduced repairs and increased flexibility of operation. In the latter case, however, it is probable that the shop work will be so important that one or more machinists will be continuously on duty, and the exactions of taking care of generating units of very large cost may leave little time for the development of special rigs. Unless meritorious ideas can be tried out, there is a defeating of its own ends in part by the power plant shop, and it should always be realized that a certain amount of research along economical lines is quite as important as the mere routine grinding of valves, straightening of stems, adjusting packing, and assembly of pipe fittings which so often absorbs the shop tools' activity. Such a shop can do valuable work in the assembly of a new plant, and sometimes for months after it is started the shop will greatly facilitate the final adjustments of equipment. Direct connected tools with variable speed control are most advantageous in the face of their cost, in large stations, but even the small plant with group drive deserves better than hand facilities for the quicker and lighter repairs.

Engineering Office Libraries.

One of the most instructive recent papers for engineers is that by Mr. Lee, librarian of Stone & Webster, on the library department of that firm's organization. An abstract of it appears elsewhere in this issue, from which it will be seen that the department is considerably more than a library, for it really is an information bureau, answering questions not only by research in books and journals, but also by correspondence with those outside and inside the organization likely to know what is desired by the inquirer. It is a recent development and probably ten years hence will be strengthened along several lines which at present are but dimly recognized, but the department to-day is a concrete demonstration of the important part printed information plays in the actual business work of a large engineering organization. The day has gone by when a few school books will answer the requirements of such an office. The time lost in hunting for information or in working out problems that somebody has already solved represents a considerable financial loss, which it is the purpose of this library department to save.

It will be noticed that a large part of the library consists of documents, which is naturally the case with such a business as that of Stone & Webster. Apart from these papers, such documents might well include all the results of minor investigations and experiments made practically all the time in engineering offices of much size. Any item of engineering information, jotted down on a sheet of appropriate size, is just as suitable for preservation in a real working library as a three-volume treatise. Probably the lack of any system for filing such notes is the only reason they are not kept more often. Most engineers have attempted to preserve short notes in manuscript books, only to give up the practice when the trouble of writing them out and of finding them again has been discovered by experience. In consequence, the same man often has to hunt up information on a subject several times, just because it is not made permanently available when found the first time. Probably the time lost in searching for it once is trifling, but when that loss is multiplied several-fold, the total is worth considering. Moreover, in a large office, the chances are pretty fair that a good many people will repeatedly have occasion to refer to certain classes of information, so that a standing order might properly be posted requiring all information gathered in office time to be noted for filing in the library. Incidentally, it may be added, information likely to be generally useful and not of the nature of trade or professional secrets, might be sent to class journals, as is now the custom quite generally in mechanical engineering, although not in civil engineering branches.

It will be evident from a consideration of Mr. Lee's paper that the secret of usefulness of such a business library is its arrangement and indexing for immediate availability. It is this feature of the work that is most troublesome to the engineer and often proves hopeless to a trained librarian without engineering education. The engineer is likely to regard many of the minor details of library work as mere fussiness, and consequently his own system, which lacks them, is likely to break down as soon as it is given a good trial. The trained library assistant, who believes that all knowledge can be classified by the decimal system, is thrown into confusion by the discovery that there are more than ten equally important sub-divisions of some engineering subjects. A decimal classification can be worked out which will probably give satisfaction, when used by people trained in its system; the experience at the Mechanical Engineering Department of the University of Illinois is an indication of this. On the other hand, the importance of a geographical classification is very evident in a business office, as Mr. Lee points out in his paper. It is safe to say that a business man consulting the bound volumes of any journal for information regarding the details of a power plant in St. Louis will look in the index for the name of the city rather than under "power plant," yet indexing geographically is considered crude by most trained librarians. Before a good classification for an engineering office library is adopted, it is therefore desirable for the owners to determine just what they wish to index and for the librarian to cast off all prejudices and learn what questions he will be asked to answer. It may happen that the decimal classification will prove best, or the geographical, or one which is arranged by letters instead of numbers, so as to avoid the limitations of the decimal notation. Time spent in a thorough study of indexing before beginning the library arrangement is warranted by the vital importance of the subject. If the work is properly done and the library skilfully conducted in accordance with the system thus developed, the result will be to make readily available the information gathered by the office in its business and all the contents of class journals, trade catalogues and books. The command of such resources is worth a considerable sum in many offices.

The library managed in this manner is particularly useful in securing the best results from the valuable contents of class journals. The librarian examines each publication carefully as soon as it is received, and any information of immediate concern to the business of the office is brought to the attention of the man who is in charge of the subject. Even in offices which do not maintain a library, it is often customary to have somebody examine all such publications as they are received, for whatever information of immediate interest they may contain. Where a library organization is maintained, however, this examination is more complete, and articles likely to be of permanent value are indexed according to the library classification, thus making it unnecessary to refer in many cases to the indexes of the volumes themselves, which is a tedious and often unsuccessful method of search. Attention is particularly called to this point, because many offices are doubtless already spending a considerable part of the sum needed for pretty fair library work on an examination of journals and trade publications for temporary purposes only. Whether it is best to issue a regular bulletin of notes regarding the contents of class journals, as is done by Stone & Webster, must be decided by the special conditions of each case, but it is probably true that most companies conducting a technical business find it desirable to subscribe to enough copies of each important journal in their lines to provide a file in each branch office as well as at headquarters.

Reinforced Concrete Floor Plates or Slabs.

The problem of determining stresses in either rectangular or circular plates supported or fixed along their edges has always been a complicated matter in the theory of elasticity of solid bodies, and there has never yet been established a satisfactory simple theory of such plates. Nor have there yet been made enough tests of the bearing capacity of such plates, either to enable purely empirical formulas to be established or to determine empirical coefficients for the analytic formulas of the provisional theories thus far proposed. The whole subject was considered to be more of analytic interest than of practical importance until the extended application of reinforced concrete to the construction of floor plates or slabs has given to it a degree of real importance which it hitherto has not possessed.

The Engineering Record has commented upon this general topic in the past, but the many inquiries which have lately been made regarding the proper methods to be employed for the design of these plates, and the regulations for their construction which have been proposed by many bodies, including the French government, show that the subject needs much more consideration.

In the issue of this journal of Aug. 3 there will be found a number of formulas set forth in the appendices of the reports of the British Joint Committee on Reinforced Concrete. There is no attempt in that report to go into any such extended and refined analysis as that given by Clebsch, Bach and others who have treated the problem as belonging wholly to the theory of elasticity. Perhaps it is as well that some approximate or conventional theory should be employed. That procedure certainly contributes to simplicity and avoids the complication of the exact theory, which, after all, is based upon such nice conditions regarding the supported edges and their continuity, when continuous, that they are never realized. It is in the interests of the actual features of the case, therefore, that approximate or provisional and simple theories should be adopted, in which empirical quantities may be introduced. What is needed is some reasonable expression for carrying capacity which may be made accurate enough for all practical purposes by an empirical factor determined by tests upon full-sized plates loaded as in actual use. The principal formulas of this class are those of Rankine and Grashof, or some similar formulas, with the later additions of Bach's empirical theory, and such regulations as those of the French government.

The formulas of Rankine and Grashof for rectangular plates are chiefly based upon their assumed division into narrow strips parallel to the two sides of the rectangle, these strips being supposed to be so loaded as to make their center

deflections equal. Other formulas have also been based upon these fundamental assumptions, but developed into little different shape for the purpose of meeting the conditions otherwise ignored. These assumptions, like all of this conventional class, result in approximate formulas involving far too much error for unlimited use under any circumstances, but they yield forms which can frequently be effectively used in connection with tests of actual plates. In this manner factors or coefficients based upon such tests can be fitted to them so as to make them sufficiently accurate for purposes of design, within limits wide enough to give them much practical value.

The assumption that these strips of plate at right angles to each other must have equal center deflections is, of course, erroneous for all except those that are axial to the plate, and in the vicinity of the four sides of the plate the error is large. Again it is always assumed in this particular class of problems that the distribution of pressure along each edge of the plate is uniform, a condition never realized and sometimes very far from being realized. In the case of reinforced concrete plates, fortunately, this particular assumption probably does not involve material error. On the other hand, such plates are almost invariably continuous and the degree of fixedness around the edges is not only undeterminable, but it varies with the amount and position of loading. Under such circumstances, it is manifestly impossible to determine any accurate theory of treatment. The only possible procedure giving any promise of practical value is that already indicated, viz.: to test plates in as near actual conditions of use as possible, observing carefully their action with different loadings up to failure and then by aid of these tests to fit empirical quantities to the best form of approximate formula which can be devised.

The recent tests of Bach indicate that the greatest bending moments in square plates, and those nearly square, are found along the diagonals, and this probably holds for plates that are considerably oblong in shape, but not for long and narrow plates. In the central portion of the latter, at least, the line of maximum bending moment usually is parallel to the two longer sides.

The carrying capacity of plates, both rectangular and circular, needs a most careful and comprehensive analytical study, as well as an equally extended experimental investigation with their sides either continuous or simply supported. With the extensive use of reinforced concrete for floor construction, it has become of great practical importance to have available methods of design which can be depended upon to yield reasonably accurate results, especially for the heavy floor loads now required for both storage purposes and manufacturing machinery.

Notes and Comments.

Patching Reinforced Concrete is often done so quickly that the engineer in responsible charge of the work is unable to see just what conditions are hidden by the patches. It is well known, however, that sometimes these conditions are decidedly bad and indicate a lack of careful workmanship which should not be tolerated. Mr. H. M. Kennedy has recently made the suggestion that the building code of a city should prohibit such patching until the spots to be covered have been examined by a city inspector. Just how this rule would work in practice is somewhat doubtful, for the trouble in getting an inspector to pass on work is already serious in some cities and causes delays which reach a large total in a building operation of some magnitude. Mr. Kennedy states that in the work of his company a rule of this sort was put in force some years ago, according to which absolutely no patching is allowed to be done on concrete work immediately after it is stripped of its forms until it has been thoroughly examined and passed by the company's own inspectors. The result has been that every superintendent, foreman, and workman realizes that the work done under his supervision or by him is subjected to a minute scrutiny, and in consequence the character of the work has risen considerably above what it was before the rule was adopted.

The New Haven Electrification described last week is particularly interesting to railway civil engineers as departing from the third rail construction which has been in this country the accepted means of current supply when large units are used. Granted the use of high voltage, which is the condition of success in heavy railway work, the third rail becomes progressively less desirable as the voltage increases. At 11,000 volts, the pressure used for distribution on the New York, New Haven & Hartford, overhead construction is a necessity, and the engineers in charge very evidently made up their minds to take no chance in installing it. For high-speed work with an overhead trolley the catenary construction is also necessary. The section of road concerned contains a varying number of tracks and could not well be broken by pole lines, and the result was exceedingly solid, although costly, bridge construction. No electric traction system has ever been put in under more strenuous conditions than this, since the terminal requirements of direct-current operation demanded not only motors of very remarkable properties, but a complete duplicate collection and control system. It was wise policy to take no chances with the overhead equipment, making it mechanically as sound and perfect as possible regardless of cost.

Alternating Current Frequencies are now receiving the earnest attention of electrical engineers to whom they have the same significance that the battle of the gauges had to railway engineers a quarter of a century ago. At the present time 60 and 25 cycles are standard American frequencies, although others are in use in old plants. It is now seriously proposed to add another frequency to the list, 15 cycles per second, for the sake of the recently developed single-phase series-motor, for interurban and electrified steam railroads. The output of an alternating-current series motor is increased by lowering the frequency from 25 to 15 cycles per second, although the amount of increase is a matter of difference of opinion, those in favor of the change claiming 30 per cent. to 35 per cent., and those opposed claiming only about 15 per cent. The reduction in frequency would involve an increase in the size and weight of the generators at the power houses and of the transformers, both step-up and step-down. The question at hand is whether a certain percentage more motor power can be placed on a single-phase locomotive sufficient to pay for the inconvenience and expense of a change in frequency. The question is a serious one from the standpoint of the future, although not a serious one from the standpoint of the present. Railroads, more than any other engineering structures, must correspond, and be built to standards. If one large railroad should become electrified at a frequency of 15 cycles per second, it would probably necessitate the sequence of future roads on the same frequency. It would then probably be too late to retrace steps, or change the frequency.

Molecules and Electrons were the cause of a battle royal at the recent meeting of the British Association. So far as the molecule is concerned it would be difficult to mention any proximate doctrine that has been more important to theory and practice than the splendid speculation of Kekule, and yet in view of the work of Van t'Hoff and his successors no chemist would seriously defend the thesis that the carbon atoms in a molecule of benzol are literally arranged in the conventional hexagon. It is quite sufficient that they behave in many respects as if they were actually hooked together with valences. As with the molecule so with the atom. For more than a quarter-century past it has been perfectly well understood that the atom must be dynamically complex and the epoch-making work of Mendeleéf left little doubt in the mind of any serious thinker that the so-called elements are in some way structurally related. As to the electronic theory of matter, it works out very prettily up to a certain point, like other theories of matter and then gets into trouble. If one postulates subatomic particles endowed with any plausible set of properties, their interactions can be made to fit a large number of the more general properties of ponderable matter, as witness various speculations from the day of Æpinus up to date. We have had Maxwell's idlewheels and the vortex atom and a few others within recent years, and it does not help the matter much to call the fundamental unit chosen "electricity." Truth to tell, there is very little known experimentally about the electron and until more is found out about its dimensions and relations, its derived properties are of secondary interest. This much is clear, that a sufficient breach has been made in subatomic dynamics to justify an assault in force, which, whether it succeeds now or a century hence, can never wholly be driven back. Great experimenters are particularly needed just now and they are painfully scarce. There is a tendency toward rushing into print with work half completed and ill done that is perhaps in keeping with the spirit of the times, but which accords poorly with scientific conscientiousness.

The Power Development which the Chicago Sanitary District Trustees desire to carry out by extending the drainage canal through Joliet and erecting a plant at Brandon's Road seems likely to arouse a bitter struggle in the legislature before the bill authorizing the work is passed. According to a statement issued by a Joliet taxpayer, Mr. John H. Garnsey, the electrical power now generated at Joliet is developed at a dam owned by the State but leased to the Economy Light & Power Co., and if this dam is removed as proposed by the Sanitary Trustees and a new one built 2 miles below it, neither the city nor the State will be able to exercise any control over the power. The 35,000 to 40,000 h.p. which the Sanitary District Trustees expect to generate at the lower dam, will be used for the benefit of the Sanitary District and the people of Joliet will suffer thereby. In reply to this statement, President R. R. McCormick, of the Trustees, has given out a letter stating that the company purchased for less than $100,000 the marsh land at the proposed terminus of the canal extension and has fixed a price on it of $3,000,000 to the Sanitary District. It is the latter which will make the property valuable by constructing the canal extension and the Trustees do not believe they should be held up for the benefits their work creates. No promise to furnish 40,000 h.p. has ever been made, but on the contrary the Trustees have offered to furnish the city of Joliet with current at a price equivalent to $38 per street light per year, an offer which was not accepted, although the Economy Co. is paid $75 a year. It is evident from these extremely divergent statements that there is a good prospect of hearing some important debates on hydraulic power development at the next session of the Illinois legislature.

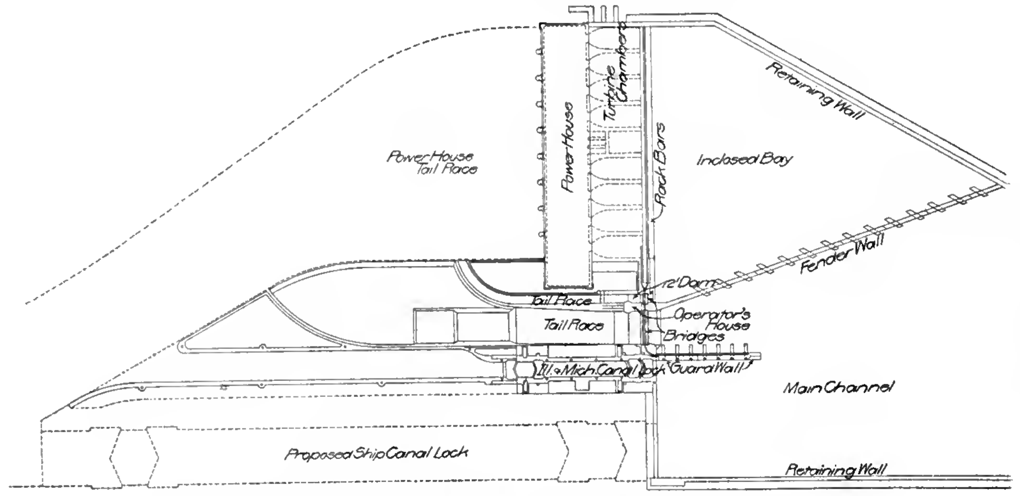
MOVABLE CREST DAMS AT THE WATER POWER DEVELOPMENT OF THE CHICAGO DRAINAGE CANAL.

Two movable crest dams, one 12 ft., and the other 48 ft. in length, are included in the water-power development of the Chicago Drainage Canal at Lockport, Ill. This power development will render available 33,000 h.-p. at the turbine shafts, based on a uniform flow of 600,000 cu. ft. per minute under the head of 36.5 ft. obtainable at the development, and on the guaranteed hydraulic efficiency of the turbines of 80 per cent. Under actual working conditions with an average flow at the rate of 600,000 cu. ft. per minute for the entire 24 hr. there will be available for peak loads 50,000 h.-p. or more, depending on the load factor. The works required to develop this power include an extension of the canal 10,700 ft. long, with a uniform channel width of 160 ft. and a nominal depth in this channel of 24 ft., the extension being partially in excavation and partially between concrete retaining walls and earth and rock embankments, a 69x380-ft. two-story power house and a tail race in earth and rock excavation, which is 6,800 ft. long, 160 ft. wide and affords a minimum depth of 22 ft. of water.

The canal extension is widened at its end at the power house to 522 ft., by a change in the direction of the right-hand retaining wall containing it. A forebay is thus provided for the power house, and space is obtained in a cross wall at the end of the head race and between the left-hand retaining wall of the latter and the off-shore corner of the power house for the two movable crest dams, a lock for the Illinois & Michigan canal and a lock for the canal of the proposed Chicago to the Mississippi River deep waterway. The power house has nine water turbine chambers on the upstream side which open directly into the forebay of the power house and are protected by trash racks, inclined slightly from the vertical. A heavy concrete fender wall, 525 ft. long, is built across the forebay from the right-hand retaining wall of the head race to the stream end of the power house, making an angle of about 80 deg. with the upstream side of the latter. This wall has fourteen arched openings in it, the tops of the openings being submerged at normal stages of water in the head race, and is provided to prevent vessels and large obstacles reaching the forebay. The 12-ft. movable crest dam is 45 ft. from the offshore upstream corner of the power house, in the cross wall at the end of the head race and inside of the downstream end of the fender wall. The 48-ft. movable crest dam is separated from the 12-ft. one by a concrete and iron structure, 12 ft. wide, which contains the operating apparatus for both dams; this dam is immediately in front of the downstream end of the fender wall. Beyond the larger dam and separated from it by a 24-ft. length of the cross wall at the end of the head race is a 20x220-ft. lock for the Illinois & Michigan canal. A heavy concrete guard wall, 150 ft. long, is extended upstream between the larger dam and the lock, at right angles to the cross wall of the head race, to prevent vessels being carried against the dam. Between the lock and the left-hand retaining wall of the head race is a 150-ft. length of the end wall of that race in which the end of a lock for the proposed ship canal can be built.

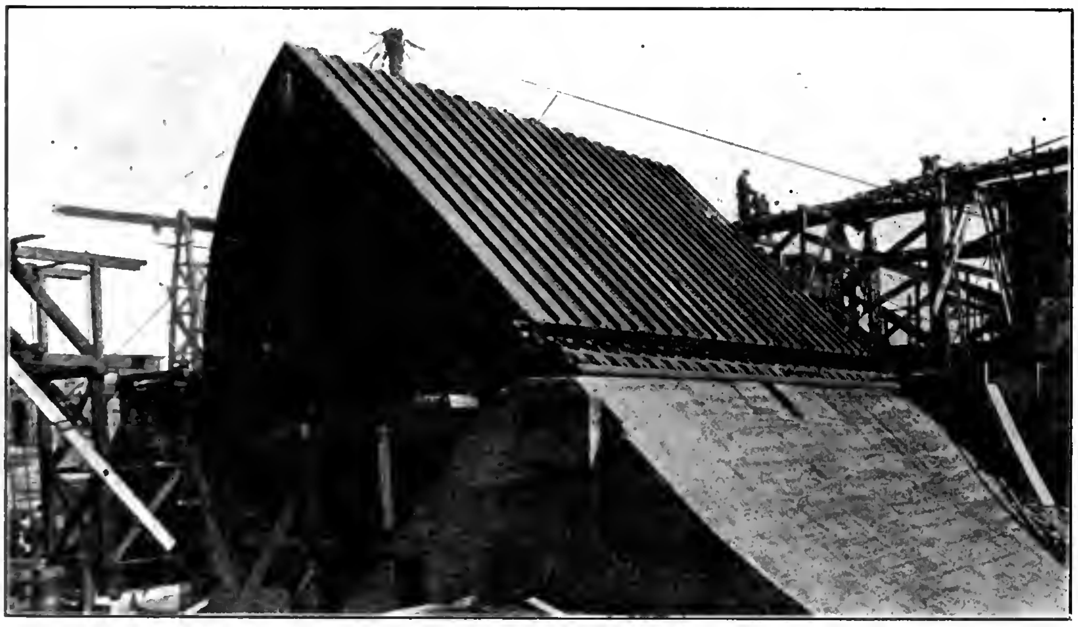
The two movable crest dams are provided to furnish a passage for all drift, such as ice, floating materials, waterlogged and submerged driftwood, and so forth, which cannot safely pass through the water turbines in the power house; and for controlling the rate of flow in the main drainage channel at times when only a portion of that flow is passing through the power house, and when otherwise necessary. Controlling works at one side of the end of the portion of the canal which is now in service are used at present for regulating the rate of flow in the Drainage Canal. These works are just above the upper end of the head race of the power development, the flow through them being discharged into the Des Plaines River. When the power development has been placed in service these works will be used only in an emergency. The two movable dams at the power house will then regulate the rate of flow, a vertical butterfly dam across the upper end of the head race being provided so the flow into the race may be shut off, if desired.

The 12-ft. dam is designed to provide means of passing all drift that finds its way under the fender wall into the enclosed bay above the power house. The trash racks over the openings into the turbine chambers of the power house are extended above a platform over those chambers. The upper end of the rack curves over a narrow-gauge track, which is laid on this platform and extends the length of the rack, so that small cars on the track will come partially under the curved ends of the latter. The trash which will



General Plan of Works at the Power Development Site.

collect on the rack may be pulled up over the end of the latter into the cars, which can then be run out on a bridge over the 12-ft. dam and dumped. The narrow-gauge track also extends across a bridge over the 48-ft. dam and out to the end of the guard wall of the canal lock. Machinery parts for the power house equipment may thus be delivered on vessels in the canal and then taken to the power house on this track.



Sector of 48-foot Dam, Blocked up during Construction.

The two movable crest dams are practically alike in details of construction and operation. Each movable crest is built of structural steel shapes and steel plates and is practically a 45-deg. sector of a cylinder with a 26-ft. radius. Each sector is hinged horizontally along the axis of the cylinder of which it would form a part, to the top of a back wall on which it is mounted on the downstream side. The radial deck plane and the curved upstream front of the sector are made watertight with steel plates, the deck being provided with steel angles for ice skids. The deck plane, the lower radial plane and the curved face are heavily reinforced by intermediate steel frames. When the crest formed by the intersection of the curved face and the radial deck plane is at the maximum operating height, the lower radial plane of the sector is horizontal. As the crest is lowered the sector rotates on its axis and moves into a space in the concrete base which is also approximately a sector of a cylinder, of about the same radius as that of the crest, the radial deck being horizontal when the crest is at its lowest position. The crests of both dams have a vertical range of 18 ft. from 2 ft. above to 16 ft. below Chicago datum, the water surface above the dams being 4 to 6 ft. below that level under normal conditions of flow.

The clearances and packing details between the ends of the movable sector and the faces of the concrete wall in which the sector is inserted, between the curved face of the sector and the top of the breast wall of the base and at the hinge on which the sector rotates are designed to confine the water in the chamber under the dam. Water is

admitted to and discharged from this chamber through controlling valves provided for the purpose. Air pipes under the radial deck of the dam are designed with details to maintain a free water surface in the chamber. The operation of the sector dam is similar to that of a bear-trap dam, the pressure due to the head of water under the sector balancing the weight of the latter and that of the stream flowing over it. This equality of moments holds for all positions of the crest, so that the sector being in equilibrium may be raised or lowered simply by raising or lowering the level of the water in the chamber under the dam. The height of this water level is controlled by a special balanced valve, called a weir tube, which is placed in a pit under an operating house between the two dams and is easily moved by a hand wheel in that house. Under the conditions of operation, the head of water required in the chamber will always be lower than the available head in the head race, the level in the latter ranging from 8 ft. below to 2 ft. or more above Chicago datum, in extreme cases.

A heavy cast-iron bed plate anchored to the top of the back wall of the concrete base carries the hinge on which the movable crest rotates. The anchorage for this bed plate consists of two rows of 2½-in. bolts. One row of these bolts is along the inner edge of the bed plate, the bolts being 2 ft. apart and extending vertically 16 ft. into the concrete base to anchor plates; the tops of the bolts in the other row are attached along the outer edge of the cast-iron bed plate, these bolts, which are 2 in. in diameter and 1 ft. apart, extending back at a 45-deg. angle to anchor plates 24 ft. from the face of the dam.

A cast-steel hinge chair is bolted to the heavy cast-iron bed plate on the back wall. This hinge chair is in 5-ft. 11 15/16-in. lengths, a clearance of 1/16 being provided between the lengths, a ¼-in. groove filled with cork packing preventing leakage. A 4-in. annealed steel journal is carried by the hinge chair and operate in a babbitted hinge box which is bolted to the movable sector. The hinge forms a water-tight joint between the concrete base and the movable sector. The upper and lower radial planes of the latter do not come quite to an intersection, but are connected by a tight diaphragm of steel plates to which the hinge box of the joint is attached. Two 1½-in. extra-strong galvanized-iron pipes are placed the length of the joint and have connections by which they may be supplied with live steam, so the joint may be kept free of ice in severe weather in case no water should be flowing over the dam.

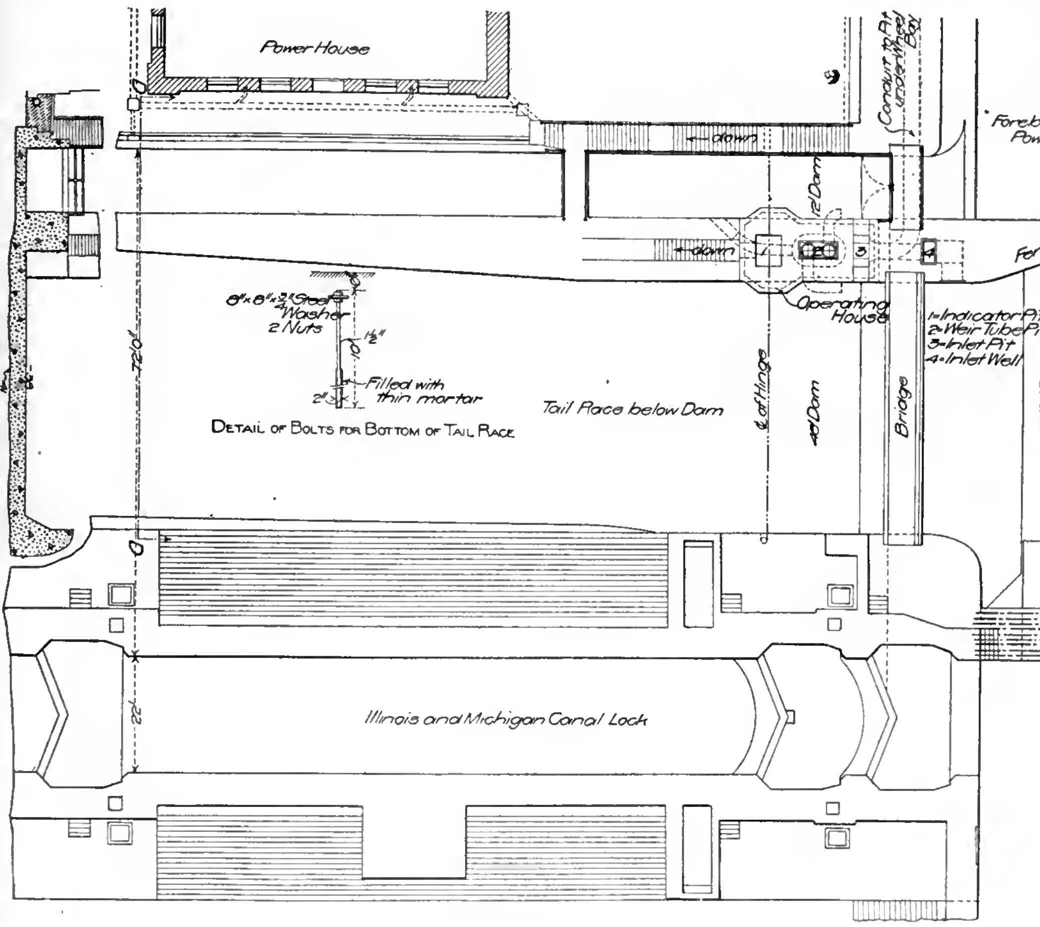
The face of the concrete walls at both ends of each dam are sheathed with steel plates riveted to Z-bars built into the concrete. These plates are normal to the hinge axis of the movable crest, and are ¼-in. from and parallel to the finished end of the latter at 60 deg. Fahr., so that the sector may rotate through its arc of 45 deg. and have ¼-in. clearance in all positions. In order to make these joints between the sector and the walls practically water-tight, a 1½-in. angle is placed loose over each joint the length of the deck plane of the sector. The tendency of the water flowing over the dam to enter the dam chamber through the joints at the end of the sector holds these angles in the joints. The angles are attached in such a manner as to prevent them from floating away or from being torn off by debris flowing over the crest. They are held against the side of the concrete wall by stiff steel springs. As under certain conditions the water in the dam chamber will tend to flow out of the latter, the joints at each end are also packed with brass on the inside along the part of their lengths where such outward flow might occur.

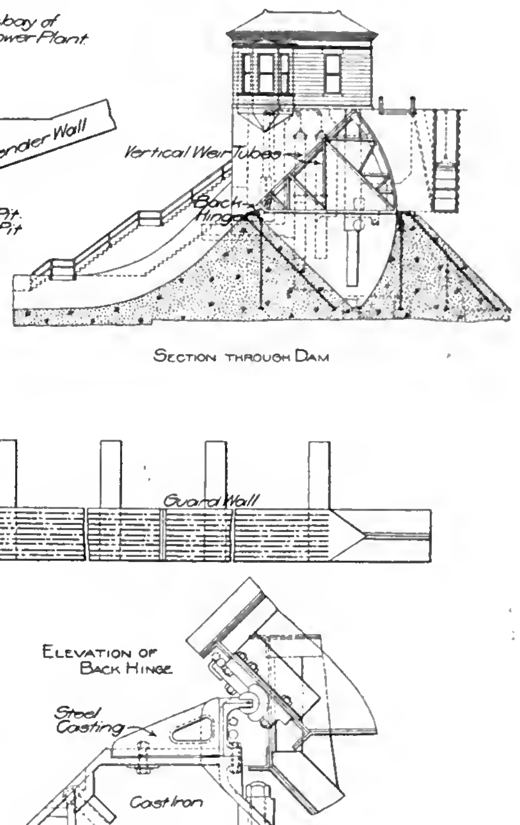
The joint between the curved face of the movable sector and the curved portion of the breast wall of the concrete base forming one side of the chamber under the sector is packed at the top of the breast wall in a manner which is designed to render it watertight. The plates which form the curved cylindrical face of the sector have planed edges and have the rivets which attach them to the frame of the sector countersunk. A steel angle, in 6-ft. lengths, is attached horizontally to a steel bed plate on top of the breast wall in such position that the full face of one of its legs bears against the curved face of the sector.

Three 1½-in. extra strong pipes to each panel of the sector connect the upper part of the chamber under the dam with the atmosphere and provide free air circulation above the water in the chamber. One of each three of these pipes permits a free flow of air or water into or out of the chamber, but the other two are provided with check valves which prevent an outward flow so the water will not be siphoned out of the chamber. Such water as may leak into the chamber will be carried away by the pipes, however, if the water level rises above the level of the openings of the latter.

When the dam sector is at its highest position, it can be blocked up by a series of props under the top of the plate on the breast wall which carries the packing angle that bears against the curved face of the sector. These props are notched cast-steel pawls which are spaced 12 ft. apart and are keyed to a 2 11/16-in. steel shaft so they can all be moved together. When the sector is resting on these props the water may be discharged from the chamber under the sector and the chamber entered for inspection, cleaning, and so forth.

The operation of both dams is controlled from a one-story concrete-block house, 12x26.5 ft. in plan, between the two dams. This house covers three pits in the concrete substructure on which it is built. These three pits are in a row, the axis of which is normal to the axis of the dams. The upstream one is called an inlet pit and is divided by two transverse walls into three wells; the middle well of this pit is connected through a conduit in the concrete wall between the two dams with the canal just above the 48-ft. dam. The port of this conduit is covered by a coarse trash rack mounted on a frame set flush with the vertical face of the wall. The water passes through a fine mesh rack in a wall between the





Arrangement of Movable Crest Dams.

end of the conduit and inlet pit before reaching the latter. The middle well of the inlet pit contains three valves; a pipe in the bottom of this well connects the two outside wells and is fitted with a gate valve, and the wall separating each outside well from the middle well is built with an opening, controlled by a sluice gate valve, through which the flow of canal water into each of the outside wells is controlled. All three of these valves are fitted with non-rising stems which terminate at the level of the floor over the pit and are operated by removable wheel keys. The inlet well, and through it the chambers under the dam, may be emptied through a conduit leading to the pit under the wheel bay in the power house.

Each of the two outside wells of the inlet pit communicates both at the top and bottom with the chamber under its corresponding movable dam. As the arrangement of the two wells is the same, a description of one will serve for both. The outer wall of the well is formed by the sheathing plates on the face of the wall at the end of the movable sector. Beneath the sheathing plate is an opening from the outside well of the inlet pit into the chamber under the dam, this opening being controlled by a sluice-gate valve with its valve rod passing up in that well. A rod on a lever which controls the shaft to which the props for supporting the dam are keyed also passes up in this well. A removable section or door opening into the inlet well is placed in the sheathing at the top of the well and provides means of entering the chamber under the dam when the latter is blocked up on the props in its highest position. In order to avoid accident to the operators or to the dam, this door is so designed that when it is in place it locks the rack bar which operates the dam props and the valve rod which operates the sluice gate at the bottom of the chamber.

A pit containing two vertical weir tubes is next to the inlet pit under the operating house. These weir tubes are made of 26-in. pipe and are swung from the top on chains passing over a pair of pulleys to counterweights. One of the tubes is connected with the chamber under one dam and the other with the chamber under the other dam, the water flowing out of these chambers over the circular weirs formed by the tops of the tubes. The height of the water level in these chambers can be regulated therefore by varying the height of these circular weirs, and the position of the crest of movable sector will thus be changed accordingly. This regulation of the height of water in the two chambers can be done separately or together, and is under perfect control at all times. An outlet conduit leads from the weir tube pit to the tail race of one of the dams.

The third pit under the operating house is at the downstream end of the substructure under the latter and next to the weight tube pit. This third pit has a window or door at the bottom on the tail race side and communicates with the chambers under both dams and with the outlet conduit from the weir tube pit. It contains a steel shaft and crank from each dam, harnessed in the operating room above to models of the dams which will indicate separately all the positions of each dam. Two pairs of 12-in. float gauge pipes, 12 ft. long, are also located in this pit and have connections which will indicate through floats attached to pointers, all stages of water above the dams and in the chambers under the latter. The pit is covered with a steel angle frame carrying a floor of hinged cast-iron plates. The weir tube counterweights and gears for operating the two weir tubes by means of floor stands in the operating room are placed under this floor. A bay window is placed at both ends of the floor over the indicator pit, in the sides of the operating house. The indicating gauges for one dam, the wheel for operating the gear of one weir tube, the model showing the position of the one dam, and so forth, will all be placed close to one of these windows and the similar apparatus for the other dam close to the other window so that they will be in easy sight and reach of the operator as he stands in the window. The operator may thus observe the movement of the crest of the dam as the regulating devices are manipulated, without leaving those devices.

The bridge over each dam opening in the end wall of the race is placed so a needle dam of timbers may be placed across the opening and the flow of water over the dam cut off as a final resource in case of an accident to the dams, or to a butterfly dam across the head race at the junction of the latter with the main canal. These bridges are of the through plate-girder type, their bottoms also being plate girders in order to bring both side girders into play when the upper ends of the timbers of the needle dam are placed against the girder on the upstream side. The lower end of the needle dam timbers will rest against a cast-iron plate in a shoulder on the upstream side of the base of the dam.

The downstream faces of the back wall of both dams is designed to suit the various conditions of flow. The 12-ft. dam has a tail race, 12 ft. in width, which connects with the tail race of the power house. The 48-ft. dam also has a tail race, 575 ft. long, connecting it with the tail race of the power house. Under certain operating conditions 40,000 h.-p. in water will pass over the 48-ft. dam, and will have to be dissipated between the latter and the tail race of the power house. Experience with the bear trap dam at the controlling works on the main canal has demonstrated that careful preparations must be made to gradually reduce the velocity of the water flowing over such a dam. The tail race of the 48-ft. dam is designed specially to break the force of the water flowing over the dam, without violent disturbance at any point. In the first 110 ft. of the race the width is gradually increased to 54 ft., the bottom dropping away from the dam on a slight grade. The bottom in this length is lined with a concrete floor anchored by bolts to the solid rock on which all of the structures of the power development are built. At the end of this 110-ft. length the bottom drops 11 ft. in 10 ft. forming a 55x75-ft. pool; beyond this is a second pool, 55x60 ft. in plan, which has 3 ft. less water in it than the first. A channel still 3 ft. more shallow than the second pool extends from the latter to a weir over which the water is discharged into the power house tail race. This weir has a total length of 275 ft., the tail race widening out to form a pool of that width just above it. A length of 48 ft. of the weir at one end has its crest 2 ft. above the bottom of the large pool at the lower end of the race; the crest of the balance of the weir is 5 ft. above the bottom of that pool. One side of the tail race is built on a curve so the principal flow over the dam will follow along it and pass over the low portion of the weir.

The power development of the Drainage Canal is being carried on under the direction of Mr. Isham Randolph. Mr. E. L. Cooley designed and detailed both of the movable dams.

Fender and Guard Walls at Movable Crest Dams from the Upstream Side.

SEWAGE DISPOSAL AT NORWICH, ENGLAND, will be conducted in an unusual manner, according to the London "Times," which states that Mr. A. E. Collins is the engineer of the works. The sewage will be forced by centrifugal pumps against a head of 117 ft. through a 33-in. reinforced concrete conduit about 2½ miles long to one or both of two vertical pipes and discharge over bell mouths into one or more of four detritus pits. The latter will have sharply sloping bottoms, and will be provided with sludge outlet valves leading to Shone pneumatic ejectors, by means of which the detritus can be delivered through rising mains to the higher levels of the farm. The arrangement of these pits is such as to enable nearly the whole of their cleansing to be done without stopping the flow of sewage through them. After leaving the detritus chambers the sewage flows over measuring weirs into the common supply channel of four hydrolytic tanks. The sewage leaves these tanks under a "skimming wall," and passes into further hydrolytic chambers provided with what are known as hydrolyzing cells. These cells are constructed with a large number of nearly vertical slate divisions, the object being to present as extensive a surface as possible. The solids in solution deposit upon these surfaces in the form of a feathery sludge which, on reaching a certain thickness, mostly falls to the bottom. It is removed from the tanks at intervals without interfering with their working, and flows to the Shone ejectors. The effluent will be used for irrigation of farming lands.

Retaining the Sides of a Large Excavation.

The new six-story steel-frame wholesale meat market building for Swift & Co., at 153rd St. and Brook Ave., New York, with its vaults under the 20-ft. sidewalk on two sides, occupies a 65x135-ft. area which has been excavated to a depth of about 21 ft. through 10 ft. of loose fill above a deep stratum of fine sand and quicksand, with abundance of ground water at a distance of about 12 ft. below the surface. The site was originally the bed of a considerable stream, which has not yet wholly disappeared, making it necessary to deal not only with ordinary ground water, but with a considerable subterranean flow. This condition, together with the treacherous and irregular character of the soil, made the excavation difficult and necessitated careful provision for the exclusion of as much water as possible from the pit and for the safe support of the earth on the outside. The sheeting was therefore designed not only to resist a heavy earth pressure, but to act also as a core wall or dam to intercept the flow of underground water. The soil was so wet and soft that the bottom of the pit offered very little resistance to vertical or horizontal pressure and would not afford a reaction for ordinary spur braces, so that a special system was designed to resist the external pressure on the sheeting.

A row of pits about 6 ft. square was sheeted down to a depth of 20 ft. at equidistant points on a line parallel with a long side of the excavation and about 20 ft. from it. A double line about 70 ft. long of 12x12-in. horizontal timbers, laid close side by side and breaking joints, was supported on the cribs at one end of the lot just above the bottom of the main excavation, which at this time had been carried, by preliminary open work, to a depth of about 12 ft. below the original surface. A narrow trench about 4 ft. deep was dug just beyond the line of excavation on each of the long sides of the lot, from end to end, and in each of them was laid a continuous line of 12x12-in. rangers. Transverse 10x12-in. timbers about 20 ft. long and 12 ft. apart were laid in inclined position on one side of the intermediate horizontal girder and their ends were abutted ad wedged against its vertical face and that of the outside ranger timber. Similar 12x12 in. inclined struts 45 ft. long were laid in the same planes on the opposite side of the intermediate girder and wedged against the corresponding ranger. The long struts were made in two pieces, spliced with butt joints and with a scab, and all of them were connected at both ends to the horizontal timbers by top and bottom scab pieces. Shallow trenches were dug to receive them where necessary and care was taken to locate them so as to clear the steel columns and piers in the frame-work of the building.

Sheeting and Bracing the Excavation for the Swift & Co. Building.

On one side of the lot where the excavation reached a maximum of 21½ ft. depth, 3x10-in. tongue and groove sheeting 24 ft. long was started on the outside of the ranger, and on the opposite side, where the excavation had a maximum depth of 14 ft., 2x10-in. tongue and groove piles 14 ft. long were started simultaneously with them. As the piles were driven, excavation was carried on, care being taken to keep the bottom of the pit generally 2 or 3 ft. above the lower ends of the piles, thus reducing the tendency of the quicksand in the bottom to rise. After the excavation was deep enough to develop considerable external pressure on the sheeting and bring the inclined braces to a solid bearing against the intermediate girders, one end of the latter was braced against the transverse ranger laid across the lot on the line of excavation and the opposite end near the center of the lot was temporarily secured by rakers, with their lower ends bearing against distributing timbers like grillages or dead men buried in the soil. Sheet piles were driven across the outside face of the end ranger and the excavation carried on inside of them; the external pressure they received was largely transmitted to the intermediate horizontal girder, where part of it was absorbd by the end raker and the remainder was absorbed by friction with the struts or was directly transferred to the side sheeting by a pair of special struts in the planes of the regular transverse struts, which were inclined about 80 deg. from the direction of the main girder so that their vertex pointed toward the line of transverse sheeting. The ends of these struts were scabbed to the center and side rangers like the regular transverse struts, and as any displacement in the center ranger tended to force them into a transverse line, they acted like a toggle, setting themselves tighter and tighter as the pressure increased and transferring it to the side rangers. By this device the pressure against the end sheeting was successfully resisted until the lines of rangers, the transverse bracing, and the side sheeting had been placed the full length of the lot and the intermediate ranger was made to abut against the transverse ranger at the opposite end, thus transmitting the pressures from one end to the other and dispensing with the need of the inclined rakers.

As the excavation progressed a second system of rangers was set against the sheeting about 6 ft. below the first and was braced through the intermediate ranger in the same way. Undue deflection in the transverse struts and in the intermediate ranger was prevented by the use of cribbing and vertical shores wherever necessary, which were changed to correspond with the increasing depth.

View Showing Excavation Carried to Greater Depth.

The sheet piles were driven by a No. 4 Inger-

soll-Sergeant steam drill with the rotating device removed and the drill replaced by a square steel bar. A flat steel bar was bent to form a rectangular frame and bolted to the drill enclosing the lower end. A rectangular hole through the flat end of this frame engaged a corresponding projection formed by a steel anvil block riveted to the upper side of a driving cap. The cap was simply a piece of a thick steel bar bent to a U-shape and fitted snugly on the top of the sheet pile. A pair of handles were bolted to opposite sides of the drill so that it was easily kept engaged with the driving cap while striking it rapid blows that forced the pile down about 1 in. per minute when the point was 4 or 5 ft. below the surface. An expenditure of $15 transformed the machine from a rock drill to a hammer which did very satisfactory service on this work and has been adopted by the contractors for similar work in other places. It is thought, however, that the efficiency of the hammer would be promoted by increasing its weight 50 or 100 lb., as may perhaps be done by adding castings to the framework. As it required 4 men to carry the hammer comfortably, it proved too heavy to hold, unaided, while in operation and was therefore suspended by a rope from overhead supports.

At first a pair of shear legs about 15 ft. high were set up on the edge of the excavation and served as towers for an old 5/8-in. derrick guy which was utilized for a sort of improvised cableway. The cable was rove through a snatch block, which, being reversed, served as a trolley for carrying the hammer over the sheet piles. While driving the sheet piles on the sides of the excavation, vertical posts were in some cases substituted for the shear legs to carry the cable-way, and in other cases the cable-way was replaced by a horizontal 2x12-in. plank 16 ft. long set edgeways at a clear height of about 12 ft. above the tops of the piles. This plank was supported at each end by a vertical post, seated on the top of the pile and having side pieces nailed to it to form jaws engaging the tops of the piles, so they could easily be slipped along from pile to pile. They were knee-braced by inclined struts spiked to the verticals and to the transverse horizontal struts.

The steam hammer was not in this case provided with a rolling support, but was merely suspended from a sling passed around the horizontal beam. In all cases the hammer was raised and lowered by a four-part hand tackle and required a vertical clearance of about 9 ft. for effective operation. The hammer was operated by two men on top guiding it with the handles and a third man below to adjust the pile cap.

The sheeting and bracing was accomplished in 5 weeks by an average force of 18 men. All of the excavation was done with pick and shovel, and the spoil was removed in wagons driven out of the pit on an incline at one end. After the sheeting was driven the water in the excavation was kept down by two Pulsometers.

The H. Wales Lines Co., of Meriden, Conn., is the general contractor, and the work above described was executed by Messrs. Miller, Daybill & Co., under the personal direction of Mr. F. Daybill, and Mr. H. L. Muchmore, superintendent.

THE COLORADO RIVER CONTROL work undertaken by the Southern Pacific Co. to divert the flow of the river from the Salton Sink was completed last month, and official announcement has been made that affairs are again in the hands of the California Development Co., which will have control pending an agreement between the governments of the United States and Mexico and the corporations involved. The Southern Pacific Co. has, it is stated, expended $1,500,000 in the work of closing the breaks in the bank which caused all the damage.

The Construction of the New York Central Office Building, New York.

An important feature of the terminal improvement for the New York Central & Hudson R. R. R. Co., now under construction in New York is the great office building occupying two complete blocks on Lexington Ave., between 43rd and 45th Streets. This building when completed will be about 275 ft. wide, 452 ft. long and about 280 ft. or 20 stories high above the curb, with one complete story and part of another extending to a maximum depth of 35 ft. below the curb. It will have three interior 62x130 ft. light wells extending from the roof to the second main floor 36 ft. above the curb which coincides with the first office floor. Below the street level the building will be used for train service, and the first story, which is very high and sub-divided for part of its area by a mezzanine floor, will be used for a branch post-office. The upper part of the building will be devoted entirely to office purposes.

The building is of steel cage fire-proof construction with cut stone exterior walls, backed with brickwork and with cinder concrete floors, roof and ceilings, and fire-proofing around all steel members. In a general way the building is symmetrical in plan around the longitudinal and transverse center lines. It will contain in all about 35,000 tons of structural steel and the estimated cost is approximately $9,000,000, exclusive of the value of the site. At present only the north end of the building, up to the sixth office floor, is under contract and this portion of it, which contains about 7,500 tons of structural steel, will be completed and the offices of the company transferred to it before construction is commenced on the corresponding lower part of the south end of the building, which is somewhat larger than the north end and will extend across 43rd street, containing two of the three light courts. The permanent floor of the sixth story will be built with the first section to serve as a temporary roof for the fifth office story and the thirteen upper office stories will be added at a future time not yet determined. The steel frame-work of the part now being erected is proportioned for the stresses produced by the full-height building and all of the structural details are designed for the requirements of the 20-story structure. A general description of the building and details of the structural steel work of fthe lower portion were published in The Engineering Record of Feb. 24, March 17 and April 7, 1906, and reference to them will show clearly many of the interesting features of the steel work alluded to in this article.

The general contract for the lower part of the building was awarded to the John Peirce Co., and in January, 1906, work was commenced on the first part of the building, 220 ft. long at the north end, reaching from 44th to 45th street. The ground had already been cleared and the excavation made to the required depth of about 20 ft. below the curb by the contractor for the yard improvements, who had also built at this point a massive concrete retaining wall adjacent to Lexington avenue. The general excavation for the building was carried everywhere into the solid rock, for the column foundations. In the entire building there are about 180 main columns and a large number of short sub-columns, many of which carry extremely heavy loads and are seated on single-tier I-beam grillages proportioned for a maximum pressure of 36 tons per square foot on the surface of the rock. In a few instances where cast-iron pedestals and short concrete piers were adopted the latter were reinforced and loaded with the same unit pressure which gives a very liberal margin over the maximum of 50 tons per square foot allowed by the Building Department.

All grillages are made with three to nine 24-in. 100-lb. I-beams, connected with three lines of tie-bolts and gas pipe separators. After the beams for each grillage were assembled together they were suspended by vertical bolts from pairs of transverse girders supported on blocking and very carefully adjusted with their panel lower flanges at the exact height required for the top flanges of the grillage beam. The suspender bolts were screwed up tightly, bringing the grillage beams into close contact with the supporting girders, while grout was filled in from the surface of the rock to about 1-in. above the bottom flanges, and the spaces between the beam webs were filled with well-rammed concrete, which was allowed to set thoroughly before the supporting girders and suspension rods were removed.

Timber cribbing was built up from the bottom of the excavation to about 18 ft. above curb level and on it were erected two wooden travelers each consisting of a horizontal platform with two stiff-leg derricks braced together at the forward corners. The derricks had wooden masts about 35 ft. high and steel booms about 60 ft. long, with a capacity of 15 tons each. The 20x30-ft. platforms were mounted on double-flange wheels running on rails spiked to 12x12-in. longitudinal stringers. These travelers unloaded the columns and girders from trucks in the street and assembled them in the structure. After erecting the first panels of columns and girders, the traveler truck was transferred to the floor-beams and thereafter the travelers moved on the completed portion of the frame-work and the use of cribbing was dispensed with.

Great energy was displayed in erecting the first two tiers of steel work as rapidly as possible so that the street floor could be built and the story below it used for the suburban passenger traffic which was put in service there in December, 1906. As it was necessary to complete entirely each tier of beams as fast as the traveler was advanced, there was considerable danger of interruption to the work through possible delay in receiving some of the beams or girders and therefore above the postoffice floor the travelers were largely superseded by four guyed derricks with 60-ft. booms arranged so as to command the entire area of the building and the adjacent street, making it possible to unload and erect materials without rehandling. These derricks were lifted up every second tier and were operated by Lidgerwood hoisting engines with separate boilers, two of which were located on the street floor and two on the third floor to avoid obstructing the trains in the basement story.

The special design of the building involved extremely heavy column loads and long span girders and resulted in the production of very massive members to be handled by the travelers and derricks. Among these were the bottom sections, over 50 ft. long, of columns with loads of over 3,190,000 lb., each which were made with special sections tapering from 24x24-in. at the top to 24x58-in. at the bottom. One section, the heaviest piece in the building, weighed nearly 32 tons; others weighed about 1,000 lb. per lineal foot and, although nearly as heavy as many of the girders, were handled by the single derrick booms.

In order to clear the railroad tracks, the basement columns were spaced 44 ft. apart on centers, a distance which, being unnecessary in the upper stories, was there diminished by intermediate columns carried on heavy girders and trusses of 44-ft. span.

Immediately over the track the floor was carried by 72-in. plate girders 44 ft. long and the

heavy outer wall, self-supporting up to the main cornice, 80 ft. high, was carried on pairs of 84-in. girders 44-ft. long, that weighed about 18 tons each. In the postoffice floor there are 48x22-in. box girders 44 ft. long and lattice girders over 7 ft. deep, and between the third and fourth office floors there is a series of heavy triangular transverse trusses 12½ ft. deep which support the fifteen upper stories. The members of these trusses were shipped separately, assembled in position, and field-riveted there. All other columns and girders with maximum weights of over 30 tons each were completed, shop-riveted and erected as single units. The rivets in the field connections were driven by an ordinary force of six gangs of men, each operating a Chicago pneumatic hammer driven by compressed air received from the mains supplying the plant installed by the contractor for the excavation and other work in the terminal yard adjacent. The erection of the steel work was commenced by laying the grillages in July, 1906, and was substantially finished in March, 1907, with an average force of about 100 men.

The first floor, at street level, was laid as soon as possible after the erection of the steel work had been carried above it, so as to afford a protection for the train service below. It was of the standard cinder concrete type proportioned for a live load of 365 lb. per square foot. To afford additional protection from possible falling objects all of the cinder floor in the Post Office department was covered with single 3-in. plank except in the city department, where it was doubled 3-in. planks. The floor of the pipe gallery below was protected by about 20,000 square feet of water-proofing. Besides this a temporary false roof of galvanized iron was built under a portion of the second floor, and special pains were taken in waterproofing and draining under the two concrete-mixing platforms.

All floors are of the Roebling flat-arch reinforced type and are independent of the ceiling construction, which will be of the suspended type. Beams, columns, girders and truss members are fire-proofed with cinder concrete 2-in. thick, reinforced with and laid on light steel-shapes, secured with standard clamps and hooks to the members, except the beam soffits, which are protected by ½-in. of cement mortar on metal lath. Wooden forms were built around the truss members, conforming closely to their cross-section, and the fire-proofing concrete was rammed within them to enclose all parts of the truss. About 11,000 yd. of 1:2:5 Atlas Portland cement concrete was required for the 432,000 sq. ft. of floor and roof surface and for fire-proofing the steel work. All concrete was mixed in two Foote machines made at Nunda, N. Y., each of them driven by a 10-h.p. General Electric motor. These machines were fitted with automatic screw feeds delivering without other measurements any required proportions of the materials to the mixing hopper where they were thoroughly incorporated together by a spiral mixer which carried them through the open trough and discharged them into a wheelbarrow below. Each machine had a capacity of about 175 yd. in 8 hr.

On account of the necessity of preserving the lower part of the building unobsructed for the train service, it was impossible to store sand, cement, cinders, brick and other material there, as is usually customary in such buildings, and the materials were unloaded and hoisted to the second floor, where they were stored and then rehandled as required. Concrete materials were elevated by a link belt conveyor to a small hopper in the top of the concrete tower whence they were automatically delivered by gravity to the automatic screw feed Separate General Electric motors were provided at each concrete machine to drive the elevators and a small crusher designed by the Roebling Construction Co. installed there to break up any large lumps of slag to a maximum size of 1 in. The concrete was discharged from the machine into wheelbarrows which were lifted in pairs by two platform elevators designed by the Roebling Construction Co., and built by the Lidgerwood Mfg. Co. Four other platform elevators were installed at equidistant points in the building to handle other materials. Two of them were made by the Lidgerwood Mfg. Co., one by the Maine Electric Co., and one, operated by steam, was made by the American Hoist & Derrick Co.

Interior Court of Grand Central Office Building Showing Scaffold.

The cut stone in the exterior walls includes about 62,000 ft. of Indiana limestone and 15,000 cu. ft. of granite from the quarries of the Stony Creek Granite Co., Conn. This stone was partly stored on the ground and partly on the sidewalk bridge alongside the building, and was handled entirely by four boom derricks seated on the roof and operated by Lidgerwood steam engines. The heaviest pieces weigh about 7 tons each and were carefully anchored to and generally supported directly from the steel framework. All of the window frames are made of cast-iron or bronze and were very carefully set before the stone work was built around them, the joints being afterward calked with oakum and putty. Almost as soon as the masonry work was commenced it was interrupted by a strike, which delayed it for nine months, so that effective operations on it were not begun until May 15, since when about 60,000 cu. ft. have been laid and the work is now rapidly progressing.

The cut stone is laid from the inside of the building but the brick face walls of the interior courts are built from outside scaffolds; part of these are of ordinary construction, supported on cantilever beams, but forty of them are patent scaffolds made by the Wm. Murray Co., New York. Each of the latter is about 5 ft. wide and 9 ft. long, with longitudinal floor boards laid on transverse pairs of 2x1½-in. angles, back to back, with vertical connection irons between their web. These connections project above the top flanges and receive small cast-iron drums fitted with worm-gears operated by detachable cranks.

Each scaffold has four drums and each drum has 100 ft. of ½-in. wire rope made fast at the upper end to 8-in. horizontal cantilever I-beams about 20 ft. long, projecting over the edge of the roof and anchored to it at their inner end. Stirrups enclosing the outer ends of the I-beams take bearing on their top flanges and have horizontal bolts through their projecting lower ends to receive the loops at the upper ends of the suspension rope. These platforms can be rapidly and evenly lifted by the brick layers so as to keep them always at the level most convenient for effective work. They have been found very convenient and efficient on this work and on other jobs where they have been used by the same contractor. About 250,000 pressed brick are required for the court walls and are backed up with ordinary red brick, 1,800,000 of which are required for that portion of the building now under contract. In the sixth story a buzz saw and an emery wheel driven by a 5-h.p. General Electric motor were installed and at each end of the building a broad temporary staircase with hand rails was built for the use of the workmen and was believed to have effected a considerable economy in saving time.

The average total force of about 350 men employed by the general contractor is under the direction of Mr. E. F. Dodson, superintendent. The steel work was fabricated and erected by the McClintic-Marshall Co. The work is designed and constructed under Mr. W. F. Wilgus, Vice-president of the New York Central & Hudson River R. R. Co., by Messrs. Reed & Stem and Messrs. Warren & Wetmore, associated architects. Mr. Chas. A. Reed, Executive, and Mr. H. G. Balcom in charge of steel work and structural designs.

The Value of Land taken for water works purposes, according to the Massachusetts Supreme Judicial Court in Sargent v. Town of Merrimac, 81 N. E. Rep. 970, is made up of the value of the land, apart from its special adaptability for water supply purposes, plus such sum as a purchaser would add to that value on the chance that the land might be some day used as a water supply.

The Asphalt Pavement on the Thames Embankment.

One of the most interesting pieces of pavement laid of late is the sheet asphalt work done on the Thames embankment at London. For a number of years an attempt was made to keep the roadway on this street in a satisfactory condition with macadam. It was believed that this would make the carriageway more agreeable, owing to freedom from noise, but the macadam has been a failure mainly on account of lack of durability and somewhat owing to dust. The street is one of the highest class in London and it was felt that the best type of pavement was warranted for it. Sheet asphalt was not regarded with particular favor in London, but the excellent results attained with it elsewhere finally led the authorities to award a contract to the Trinidad Lake Asphalt Paving Co., Ltd., for the work.

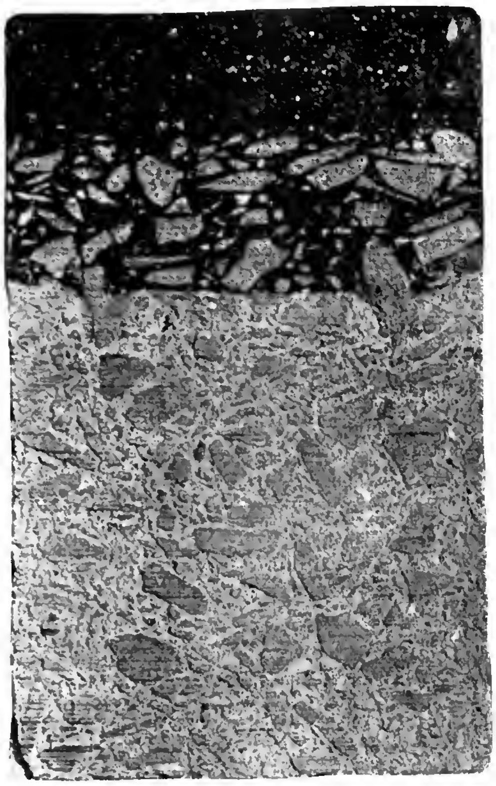
The macadam of the Thames embankment is of great depth, and it was accordingly decided that the best pavement to try would be one with about 3 in. of a very close binder, laid on top of the old macadam, and then a wearing surface suited for the character of the traffic. The old surface was accordingly graded down to a depth of 9 in. by means of a scarifier attached to a road roller in the manner shown in an accompanying illustration. The material loosened in this way [illegible] the harrows and when the full depth [illegible] had been taken off the surface was very carefully brought to grade. Owing to the compacting of the material under long traffic the portion remaining was in a hard, dense condition.

The most interesting feature of the work was the very thick course of close binder. This course is different from the open binder course used on many asphalt pavements in America, which has generally not been dense or strong enough, owing to voids and the use of unsuitable stone to carry a heavy traffic, and has been a source of weakness in consequence. The improved binder which is being introduced where the local authorities can be persuaded to pay for it consists of the same grade of stone as the old binder, but with the voids completely filled with the fine mixture used for the surface coat. With a mixture of such composition, well cemented with a bituminous cement, a perfectly stable course is obtained between the foundation and the surface, which is capable of sustaining the latter under any travel to which it may be subjected, without the slightest vibration.

The surface mixture was placed on the binder and rolled down in the customary way in this country, as shown in one of the accompanying illustrations. The pavement now has been exposed to wear for about a year, and its appearance and the class of traffic to which it is subjected are well shown in one of the illustrations.

In a paper by Mr. Clifford Richardson which was printed in this journal on June 1, attention was called by the author to what he considered the best type of sheet asphalt pavement for use on the streets having continuous heavy travel. The accompanying illustration gives a cross section of such a piece of pavement. Mr. Richardson considers that for such service a Portland cement concrete base at least 6 in. thick is necessary, and an even thicker foundation if the sub-soil is not of the firmest character. Under ordinary circumstances 6 in. of foundation is believed to be enough if it is constructed with a high-grade Portland cement and good hard stone, for which good gravel may be substituted in many instances. It is believed that every effort should also be made to provide proper drainage of the base.

Upon such a base Mr. Richardson advises the use of 2 in. of close binder, like that used in the Thames embankment pavement, and shown in the accompanying cross section. The stone for this binder should be hard enough to carry the travel without crushing. On this binder should be laid a wearing surface of standard grading made with a cement consisting of a mixture of suitable bitumens skillfully combined and handled. This surface should be 1 1-2 in. thick, and a thicker



Pavement for Heavy Travel.

Method of Loosening Old Macadam.

Close Binder Ready for Surface Mixture.

Placing Surface Mixture on Binder.

The Thames Embankment Pavement.

surface is unnecessary, if the work is done carefully and the materials are suitable, because the rigid character of the support makes it unnecessary for the top to be anything but a true wearing course. If an open binder course and poor foundations have been laid, than a wearing coat 2 in. thick is necessary.

The Pumping Plant at Milton-Royal.

The water pumping plant at Milton-Royal, England, is rather interesting on account of the use of two 20-h.p. Diesel engines for operating the triplex pumps which raise water from a pair of wells to a reservoir, the total height overcome being about 177 ft. Although the engineers are not normally required to do so, they will start the pumps against the full head of the reservoir readily. An automatic device has been provided for stopping the engines when the reservoir is full. Adirect-acting balanced float regulator is fixed in the reservoir at the head of the delivery main. The float is placed in a separate cast-iron chamber which has only a small opening into the reservoir to ensure perfectly steady motion of the float. When pumping is in progress, and the water in the reservoir has run to within an inch of its top-water level, the regulator commences to close, and gradually increases the pressure in the delivery main until the relief-valve in the pumping station opens automatically. Underneath the discharge-pipe of the relief-valve a copper bucket is suspended at the opposite end of a counter-balanced lever. When the bucket fills, it raises the counterbalance and in so doing closes the oil-cocks upon the pipes supplying fuel to the engines, which stop in about one minute. The water in the bucket then runs out at a small hole, and the bucket returns to its original position for the next automatic stop. The float regulator is set with a minimum opening sufficient to create a maximum back-pressure of about 50 ft. in the rising main when both engines are running, if the bucket is forcibly prevented from falling. The apparatus prevents the water from being run to waste at the reservoir unknown to the attendant, and allows him to be absent from the pumping-station for short intervals. The present practice is to run a set of engines and pumps every day until it stops automatically; one set being used one day, the other the next. This practice allows careful daily inspection of the machinery at rest, and of any repairs that may require but a short time.

Atlantic City Sewer Construction.

The sewer system at Atlantic City, N. J., was installed by a private company to serve a population which varies from about 40,000 in winter to over 400,000 in summer and at present has about 9,000 buildings connected, among which are many hotels, some of them of large size. As the surface of the ground is very flat and its elevation varies from 0 to 6 ft. above high-tide level, the grades of the sewers are necessarily kept very low and very careful design and accurate construction are necessary to secure a gravity flow, which, in some cases, is combined with pumping to the outlet. As the growth of the city is constant and rapid, corresponding extensions and improvements of the sewage system are continually in progress, which have varied in cost from $50,000 to $100,000 annually for several years.

The work under construction this season includes 4,600 ft. of intercepting mains receivlng the gravity flow of one district and a pump well 20 ft. deep and 25 ft. in interior diameter into which they discharge. This well is intended merely to connect the gravity and pumping systems, and is not designed to provide storage, as the sewage is pumped by centrifugal pumps to the outfall through a 16-in. and a 24-in. cast-iron pipe about 2 miles long. The well is located in very fine sand containing large quantities of ground water up to a level about 4 ft. below the surface. Its site was first enclosed by a circular cofferdam 33 ft. in diameter made with 12-in. 35-lb. United States sheet piles about 26 ft. long. Ninety of these, handled by a center boom derrick, were driven in three days with a single hydraulic jet, sometimes assisted slightly by a steam hammer.

Excavation inside the cofferdam was made by hand, the sand being shoveled out over the tops of the piles until the pit was about 8 ft. deep, after which a portion of it was shoveled on to platforms and thence reshoveled over the tops of the piles in order to continue the work while waiting for the installation of a Carson-Lidgerwood cableway of 300-ft. span, which is also to be used for the excavation of the sewer trench. The interior of the cofferdam is braced by successive tiers of horizontal rangers from 5 ft. apart at the top to 3 ft. at the bottom. These rangers are made of 10x10-in. timber, in lengths of about 6 ft., with their ends cut radial so as to fit together and make accurate polygonal rings exerting balanced reactions and forming horizontal arches in equilibrium, which resist the external pressure without any transverse or radial bracing, thus leaving the entire area of the cofferdam unobstructed. At each joint the rangers are securely spliced together between top and bottom steel plates 1/4 in. thick and about 24 in. long, secured to both timbers with vertical 3/4-in. bolts. As the sheet piles were driven several feet below the bottom of the excavation they form a sort of core wall which intercepts the flow of the ground water and enables the excavation to be kept dry by a single 3 1/2-in. pulsometer working in a sump which also drains a short length of the trench excavated for the connecting sewer mains.

After the excavation is completed, about 200 piles 12 ft. long will be driven in its bottom and cut off below grade. They are arranged about 25 in. apart in concentric circles 25 in. apart and are capped with circumferential 3x10-in. timbers on which is laid a continuous tight floor covered with 2 ft. of 1:3:5: concrete made with Atlas Portland cement and 1 1/2-in. broken trap rock. A six-ply felt and tar waterproofing is built into the concrete 3 in. above the bottom and extends continuously through the vertical cylindrical walls of the well to the surface of the ground. The upper portion of the concrete floor is reinforced by horizontal and transverse rods 1/2 in. square from 4 in. apart at the center to 8 3/4 in. apart at the circumference. The walls are made of unreinforced concrete 28 in. thick at the foot and support the pump room floor 10 ft. above the center of the bottom. The floor is made with a continuous 6-in. slab of concrete reinforced by two layers of expanded metal and supported in the center by a single 12x24-in. transverse girder with four 1-in. square reinforcement rods in its lower flange. A concrete roof similar to the floor construction will be supported on the tops of the walls.

The pump well has two inlets, one 36 in. in diameter connecting it to the old well, and the other 66 in. in diameter connected with a reinforced-concrete pipe 66 in. in diameter inside, which is 600 ft. long and intersects at the opposite end the similar 4,000-ft. line of new 54 in. intercepting sewer. All of the pipe is cast in steel molds near the site in sections 3 ft. long with male and female ends. The 66-in. pipe is 6 1/2 in. thick and is reinforced with seven 3/4x3/16-in. longitudinal bars and three 2x1/8-in. hoops, interlocking with them. Each hoop is cut so that the middle portion of the steel can be sprung out, forming loops engaging the

Driving Wooden Sheeting with Hydraulic Jet.

Driving Steel Cofferdam Sheeting with Jet.

longitudinal bars. The ends of the longitudinal bars project beyond the ends of the concrete sections and are bent back 180 degrees to form hooks overlapping each other and securely locked together by circumferential bars threaded through them after adjacent sections of the pipe are assembled together.

The pipe is cast vertically in molds, each with an annular cast-iron bottom ring forming the female joints and receiving the inside and outside walls of the mold. Each wall is made with four segmental cylindrical pieces of ⅛-in. steel connected together with top and bottom latches. The inner wall is secured at the bottom by an adjustable spider made with two horizontal ¾-in. pipe arms intersecting each other at right angles and terminating at their outer extremities with cross heads, each of them carrying two horizontal set screws for adjustment. The top of the wall is stiffened by an inside welded steel ring. The outer wall is braced in position by small separators engaging the inner wall, and the longitudinal reinforcement bars are set vertically with their lower ends engaged in sockets in the annular base plates and their upper ends fixed by the separating pieces.

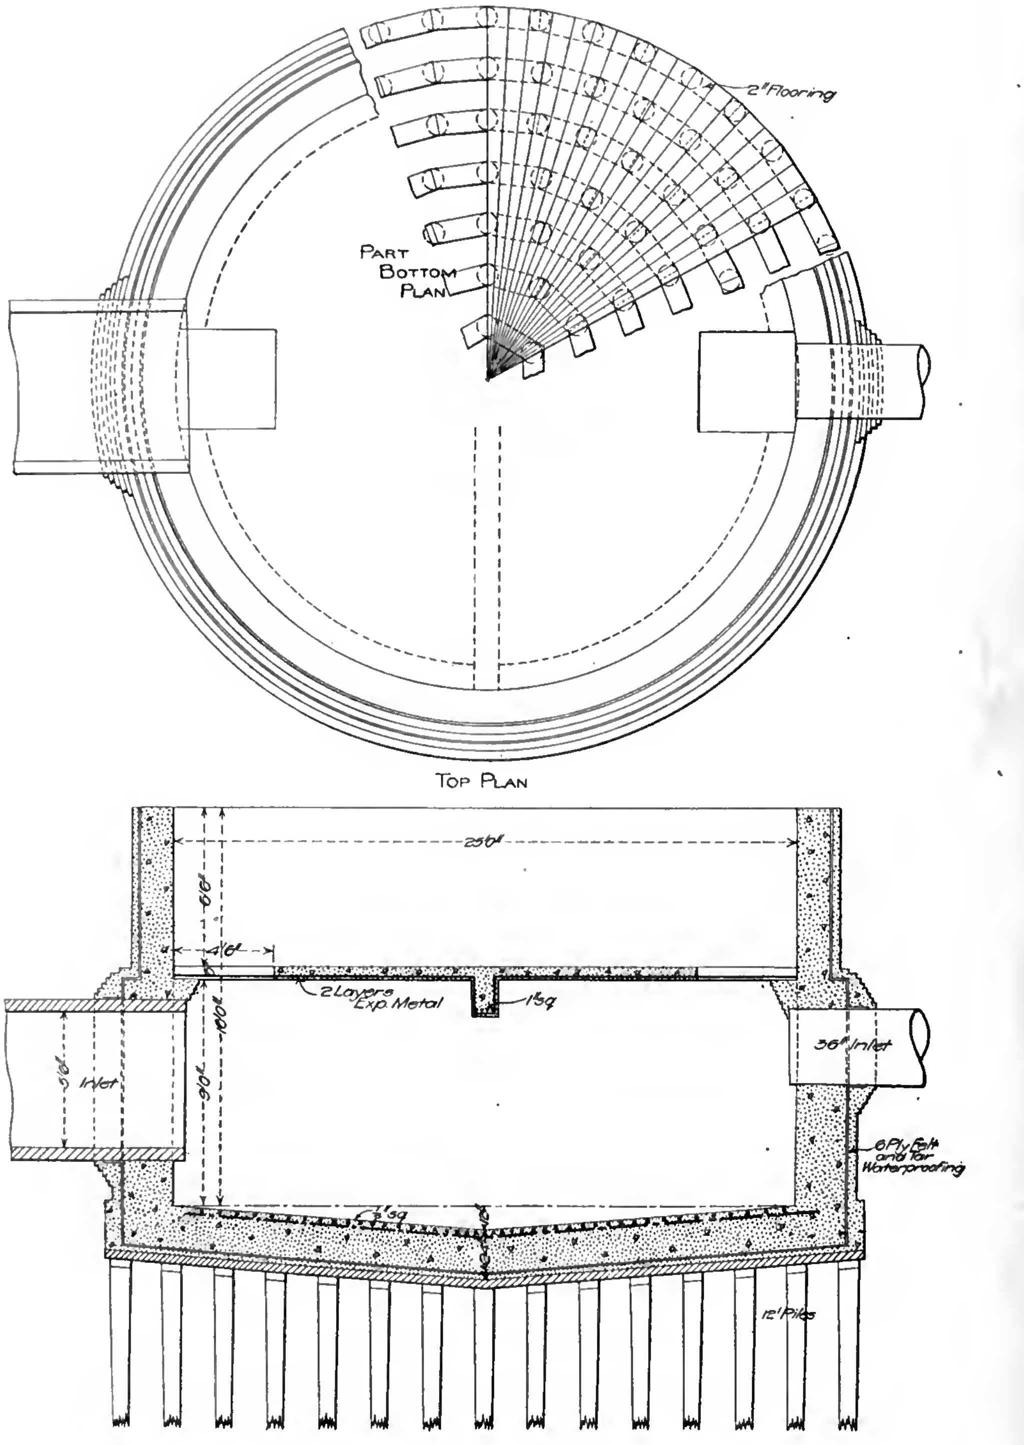
Small quantities of very dry concrete are placed in the mold and rammed until the water flushes well on top. When the mold is about one-third filled, the first ring is slipped down, engaging the longitudinal bars, more concrete is added and rammed, the second ring is inserted and finally the concrete is filled in to the top of the mold. All portions of it are thoroughly rammed with steel rammers weighing about 12 lb. and curved to fit the circumference of the pipe and nearly close the annular space between the walls. These rammers are about 12 in. long and their ends are slotted to engage closely the longitudinal bars and insure ramming both sides of them. After the mold is filled a special cast-iron top ring is set on it and filled with concrete to form the male end of the joint. As soon as this is well rammed the ring is removed and the pipe section left standing until the next morning when the mold is stripped from it and used for other sections. Each 3-ft. section of 66-in. pipe weighs about 4,000 lb. and contains 1 1/7 cu. yd. of concrete made with Lehigh cement and ¼ in. clean gravel. In this case the concrete is hand mixed and is made in proportions of 1:2:4, but when machine-mixed proportions of 1:2½:5 are found satisfactory. Ten complete molds were provided, and with them 10 sections of pipe daily are made with a gang of 12 men and superintendent.

The pipes were rolled along the trench and lowered to position by derricks and the stresses thus occasioned were considered to test them sufficiently, although they were subjected to very rigid surface inspection. One section of pipe only a few days old was struck by a heavy truck and the only injury it sustained was chipping off a few cubic inches of concrete on one edge, which can be easily patched, while the truck itself was seriously damaged. When the pipe sections are laid in the trench, their male and female ends are properly engaged, circular strips are threaded between the overlapping hooks of the longitudinal reinforcement bars at the joints, the inside of the joint is pointed with 1:1 cement mortar, the exterior is covered with a galvanized iron strip bolted in place over a canvas gasket, and the joint is filled with grout poured on the top of the pipe. This develops sufficient pressure to produce leaks if any weak places exist and these are immediately noted by the inspectors and corrected while the joint is being made so that it eventually makes a smooth, tight, strong connection between the successive lengths of pipes.

The trench for the 66-in. pipe is 9 ft. wide and 14 ft. deep, and is sheeted with 2x12-in. planks driven with a water jet at about 65 lb. pressure delivered through a 2½-in. pipe and a 1-in. nozzle. The edges of the planks are rabbeted 2½ in. to make a ship plank lap joint, which gives good satisfaction in this soil, composed of fine sand or quicksand. The trench is excavated to a depth of about 2 ft., and in it are assembled the 8x8-in. rangers or waling pieces and cross braces framed together with splice plates and blocked up to the level of the surface of the ground. The piles are rapidly driven outside them with the hydraulic jet, aided by occasional raps with a sledge hammer, and rapidly penetrate their full length of 18 ft., after which the excavation is completed and successive lines of rangers are framed in as the pit is finished. After the completion of the trench the pipe handled by the cableway is laid and jointed at the rate of about 22 sections per day by about 5 men.

Sections of similar pipe 42 in. diameter inside and 4½ in. thick were jointed together and placed on supports 8 ft. 3 in. apart on centers and tested by bending loads of 16,500 lb. uniformly distributed, which did not produce observable deflection. A deflection of ¼ in. was produced by a load of 17,500 lb., the first crack appeared with a load of 21,700 lb., and the pipes finally collapsed with a load of 28,320 lb. Three sections of 36-in. pipe jointed together were subjected to hydraulic pressure of 40 lb. per square inch which did not cause destruction but developed a longitudinal crack in one pipe.

The Atlantic Construction & Supply Co., Mr. J. H. Decker, chief engineer, is the designer and contractor for the work here described. The reinforced pipe is made by the Reinforced Concrete Pipe Co., Jackson, Mich., Mr. G. E. Johnston, superintendent.



Concrete Pump Well.

The Recovery of Brass in San Francisco has been carried on by interesting methods during the past few months on the site where the brass foundry of W. T. Garrett & Co. stood before the fire of April, 1906. At the time of the fire three stories of the building were filled with finished brass goods and the metal, melted by the heat, ran into the basement. Some of it has been recovered in large masses, some by screening the earth and debris, and some by hydraulic sluicing over riffles.

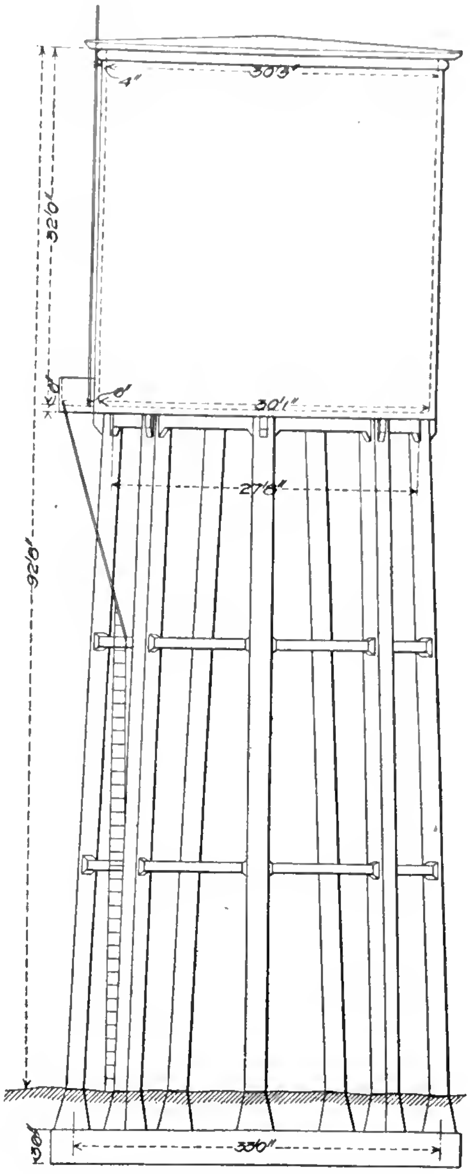
A Reinforced Concrete Water Tower at Anaheim.

In reconstructing the water works for the city of Anaheim, in southern California, the problem of a structure for an elevated water supply was one that had to be solved, the immediately surrounding country being very level with no natural reservoir site available. The population supplied is about 3,500 and it was necessary to have a storage capacity of 175,000 gal. with a minimum head of about 60 ft. Bids were called for upon specifications for an elevated hemispherical-bottom steel tank on steel towers and for a tank and tower of monolithic reinforced concrete construction. The specificatons for the concrete tanks required that bidders must be able to show successful examples of reinforced concrete construction either of tanks or stacks, or structures of a similar nature.

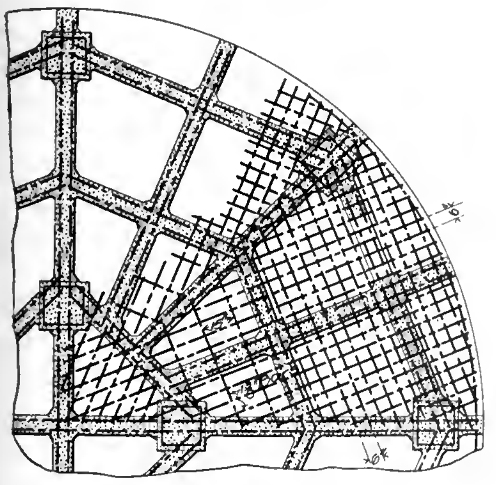
The bids for steel tanks and towers ranged from $9,200 to $12,500, while for the reinforced concrete tank and towers two bids were received, one for $10,400, which was accepted, and the other much higher. The greater durability, reduced cost of maintenance and better appearance led the city trustees to accept the reinforced concrete structure.

The specifications under which the contract was let required the contractor to furnish his own detail drawings and to give a complete description of his method of construction, but allowed considerable latitude in the kind of reinforcement and even in the plans for the structure, subject, of course, to the approval of the city. In the plans and specifications as prepared by the contractor, the design submitted by the city is closely followed, although the contractor elected to reduce the amount of concrete in some parts of the structure, to increase its richness and also to make some other slight changes.

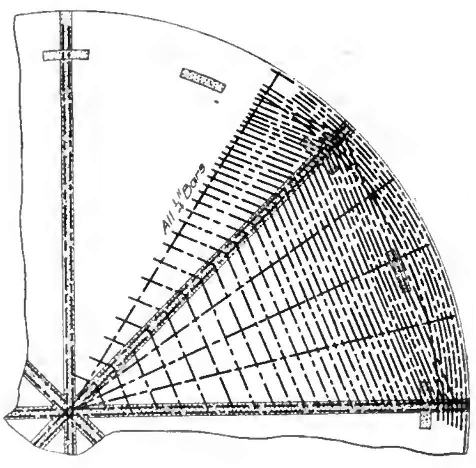
The tank is approximately 30 ft. 3 in. in diameter and has a clear interior depth of 32 ft. It rests on twelve reinforced concrete columns, each 22 in. square and 60 ft. 2 in. long, eight of them being placed equidistantly on the circumference



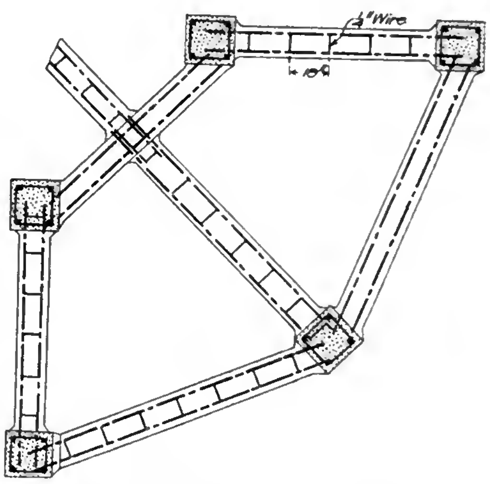
Reinforced Concrete Water Tower.



Floor and Girders at Bottom of Tank.



Roof Reinforcment.



Horizontal Strut Reinforcement.

of a 33-ft. circle and the other four on the circumference of a 4-ft. 4-in. circle. The columns are braced by two series of horizontal struts at the third points of the length of the columns, but no diagonal bracing in vertical planes is used. The batter of the columns and the manner in which they are built into the foundation slab and the tank floor are intended to provide for the lack of diagonal bracing. The horizontal struts evidently contribute in the rigidity of the tower by dividing the columns in effect into three compression members.

The soil at Anaheim is an alluvial deposit underlaid with strata of sand to a depth of 50 ft. and in periods of great rains these strata are said to resemble quicksand. This led to the adoption of a very conservative foundation bearing pressure. Holes sunk near the location showed that the first stratum of sand was about 8 ft. below the surface. The excavation is carried down 6 ft., and in case sand should be encountered at that depth it is to be removed for 18 in. and replaced with soil or clay.

The reinforcement consists throughout of twisted square steel bars tied together where necessary with ¼-in. round iron. The steel is to have an elastic limit of about 40,000 lb. per square inch before twisting and about 60,000 lb. after twisting, and an ultimate strength of 80,000 lb. Extra care is required in placing the steel in its proper position and especially to prevent any movement of the reinforcement while concrete is being placed. All joints between adjacent continuous rods in tension are to be lapped 12 in. and bound together by wrapping with soft steel wire.

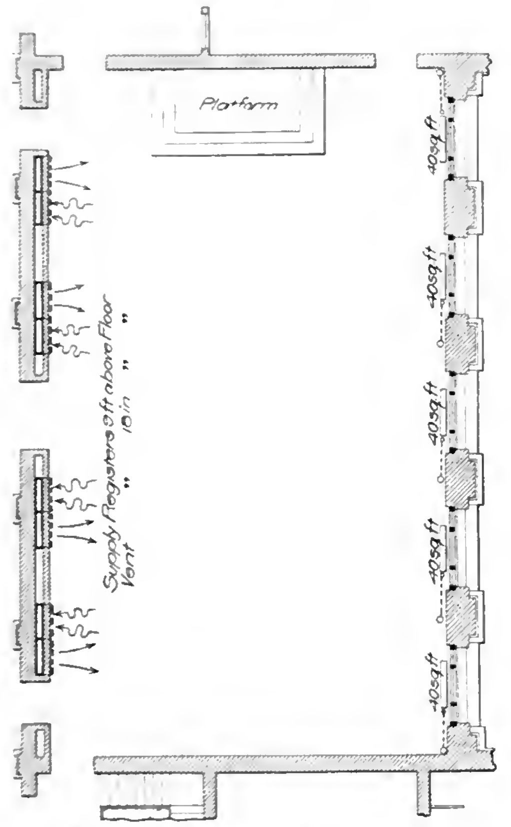
The foundation consists of a reinforced concrete slab 36 in. thick and 37 ft. square, extending out beyond the limits of the tower and tank on all sides. It is made of 1:3:4½ concrete, the crushed rock or gravel varying in size from ¼ to 3 in. in largest dimension, and is reinforced by twisted steel bars placed 2 in. from the underside of the slab. The bottom bars are of ⅞-in. material, 16 in. on centers and at right angles to them are placed the distribution bars of ¾-in. material, 12 in. on centers. On top of this foundation slab are built the pyramidal pedestals of the columns which are anchored to the slab by means of the twisted steel bars running through them and imbedded in the concrete of the foundation. The columns are reinforced with four ¾-in. twisted bars, one in each corner, tied together with ¼-in. iron wire. When the tank is empty the assumed wind pressure is sufficient to cause tension in the columns and the vertical reinforcing in the latter is therefore designed to resist both compression and tension. The ends of adjacent rods are kept in line by being placed in a socket about 12 in. long, and in order to resist tension are joined by a splicing bar of twisted square steel about 48 in. long, firmly bound to them with soft steel wire. The columns and girders are made of 1:2½:2½ concrete, using the run of the crusher under ¾ in. for the stone.

The struts have a cross-section 14x16 in. and are reinforced with four twisted bars either ½-in. or ⅝-in. material, one being placed in each corner and tied together, as explained for the columns. By far the most complicated part of the reinforcement consists in the beams and girders supporting the floor of the tank. Most of these beams and girders are 8 in. wide, varying in depth from 12 to 16 in. The placing of the reinforcement in them does not differ from the standard methods except that the stirrups of ¼-in. wires are used quite plentifully. The floor of the tank is 6 in. thick, reinforced with ⅜-in. bars placed with varying centers according to the span, the greater part of them being placed in a right angled grid on 6-in. centers both ways.

The sides of the tank vary in thickness from 6 in. at the bottom to 4 in. at the top and, like the floor, are made of 1:2:2 concrete, the stone being the run of the crusher under ½ in. In case the rock should vary to such an extent as to give a more dense concrete if mixed in some other proportion the amount of sand and rock will be varied accordingly. The reinforcement of the sides consist of ¼-in. twisted steel bars placed vertically on 24-in. centers around the circumference of the tank, running from the floor to the roof, across which laid horizontally and continuously around the tank as a hoop are ¾-in.

twisted steel bars with centers varying from 3½ to 12 in. For the lower half of the height of the tank these hoop bars are ¾-in. steel, for the next 5 ft. of ⅝-in. steel, and for the remainder of the height of ½-in. steel. The spacing of the ¾-in. bars varies from 3½ to 7 in., of the ⅝-in. bars from 5 to 7 in., and of the ½-in. bars from 5 to 12 in., the smaller spacing, of course, being used in the lower part of the section containing a given size bar.

The roof is a flat cone having a rise of only 12 in., and is carried by 8 radial reinforced concrete girders, varying in depth from 9 to 15 in. The roof is 2 in. thick reinforced with ¼-in. twisted steel rods laid both radially and perpendicular to the radii, the latter bars reaching between the girders which support the roof. The spacing of the bars laid crosswise of the radial ones varies from 3 in. near the edge of the tank, where the span between the girders is longest, to 12 in. near the center, where the span is very short. A steel ladder allows access from the ground to the tank.



Systems in Board of Works Meeting Room.

The water-proofing of the tank is considered the most particular part of the work. Every effort will be made to prevent lack of continuity in the walls due to cessation of work from day to day. The inside of the tank is to receive a water-proofing coat, ½ in. thick, composed of 1:1 cement grout. Of the cement used 96 per cent. must pass a 100 mesh screen and 82 per cent. a 200 mesh screen. The contractors will also use some astringent to aid the water-proofing. The specifications require the contractor to keep the tank filled with water for ten days before acceptance, during which time it must not develop any structural weakness nor any objectionable leakage.

The structure was designed by Mr. F. R. Schanck, of Messrs. Clem A. Copeland & F. R. Schanck, consulting engineers, Los Angeles, who have designed and have charge of the rebuilding of the municipal lighting plant and the water works of the city of Anaheim, of which Mr. A. L. Lewis is superintendent. The contractor is Mr. Carl Leonardt, Los Angeles, Cal., the plans being those of Mr. T. F. Osborn, engineer for the contractor.

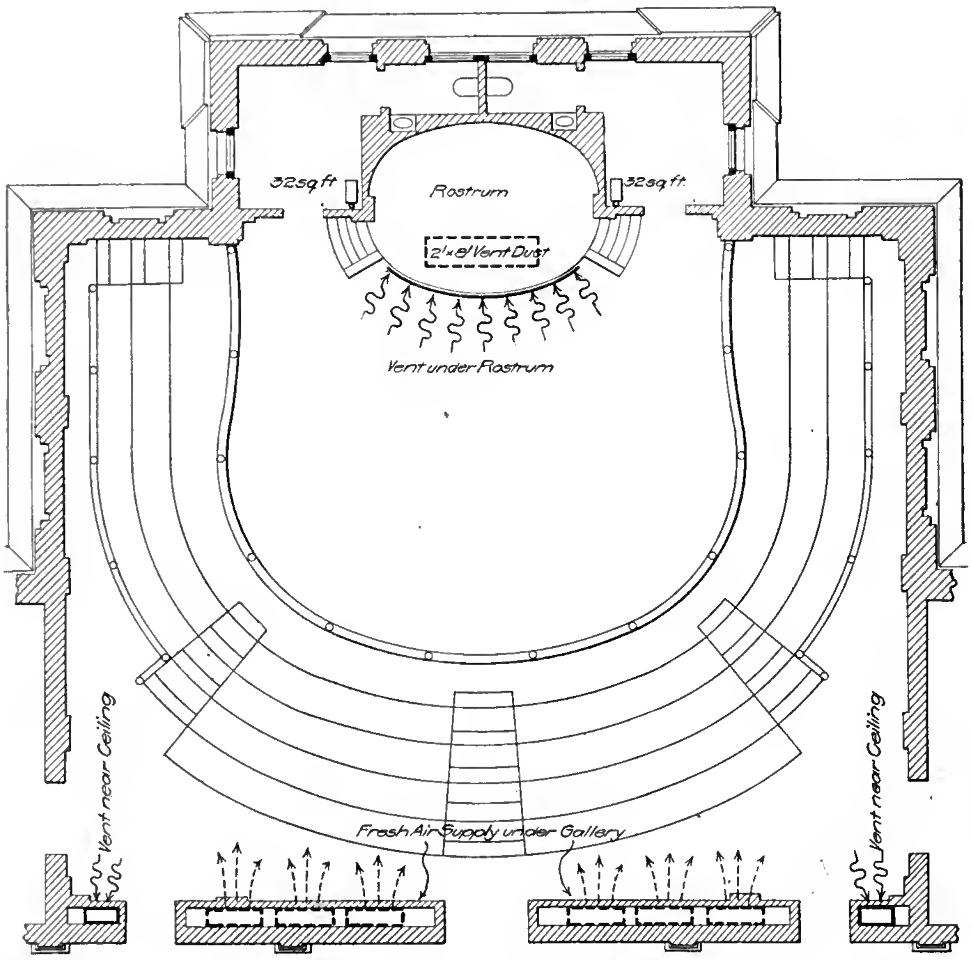
Mechanical Plant of the New City Hall, at Newark, N. J.—Part II.

Heating System.—The heating system of the new City Hall is a combination of direct radiation and hot blast operated with the exhaust from the steam-using machinery of the power plant, with make-up of live steam supplied automatically when the exhaust steam supply is insufficient. The radiation is in general connected on the single pipe system, with the exception of the indirect radiation which is supplied on the two-pipe system. The heating in a large part of the building is independent of ventilation, but in a number of the larger rooms used by many people the direct radiation is supplemented by indirect heating. The radiation throughout is operated with gravity return, but is in all parts of the building under automatic thermostatic control. An interesting feature of this installation is the use of an air line with novel exhaust, which connects the air valves on all radiators into a header in the sub-basement that extends across to the boiler house and up to an outlet inside of the chimney near the top, the purpose of the latter connection being to remove all air and vapor from the radiators freely by induced draft.

The radiation is distributed in the usual arrangement under window sills for counteracting window glass exposure, the heating surfaces of the units being proportioned on the thermal unit basis of heat loss from the building. The arrangement is such that there is a radiator unit under every window in all rooms to be heated, except in certain small rooms and store rooms which are not occupied. Even in rooms which are fitted for fresh air supply with indirect heating, the usual window-sill radiator arrangement is maintained, and in a number of the larger offices, radiators are installed on the inner walls to provide for additional heating or to counteract possible cool drafts from the corridors. In the Common Council chamber which has no side window lighting but dome sky-lighting only, there are no radiators installed, indirect heating being depended upon entirely. The interior court spaces within the corridors, which are similarly lighted by sky-lights, are heated in general by radiator units distributed at the basement corridor level, while the sky-light glass exposure is counteracted by hot blast delivery from the indirect heating system, which is directed upward toward the sky-light so as to diffuse with and counteract the cool descending currents of air. In the rear wing of the basement, however, there are two court-rooms which, although having side window lighting, are heated entirely by the indirect system, there being no radiators installed in the rooms.

The radiation installed is of the cast-iron construction throughout the entire building, including the tempering coils and reheaters of the ventilating systems, that for direct radiation being for the greater part of the Classic form in both the single and double column patterns and in heights of 31 and 38 in., according to the window-sill clearances. The reheater coils are of the Losee pattern and are installed in the duct connections of the fresh air supply system in the sub-basement as will be referred to in connection with the ventilating equipment. The latter radiators are under the direct control of the thermostats which control the direct radiation for the corresponding rooms supplied and are thus essentially a part of the heating system. The amounts of heating surface installed in the various sections of the building are given in the accompanying table.

Steam is supplied to the direct radiation from the sub-basement by 64 riser lines, which range in size from 1½ to 4 in. and supply from 1 to 8 radiator units each. Forty-three of these rise direct to the top floor of the building, 5 to the 3d floor, 6 to the 2d floor and the remainder to radiation on the 1st floor, all of the lines decreasing in size as the radiator branches are taken



Ventilation of the Council Chamber, Newark City Hall.

off. All of the lines are anchored on the second floor level, each anchorage consisting of a short

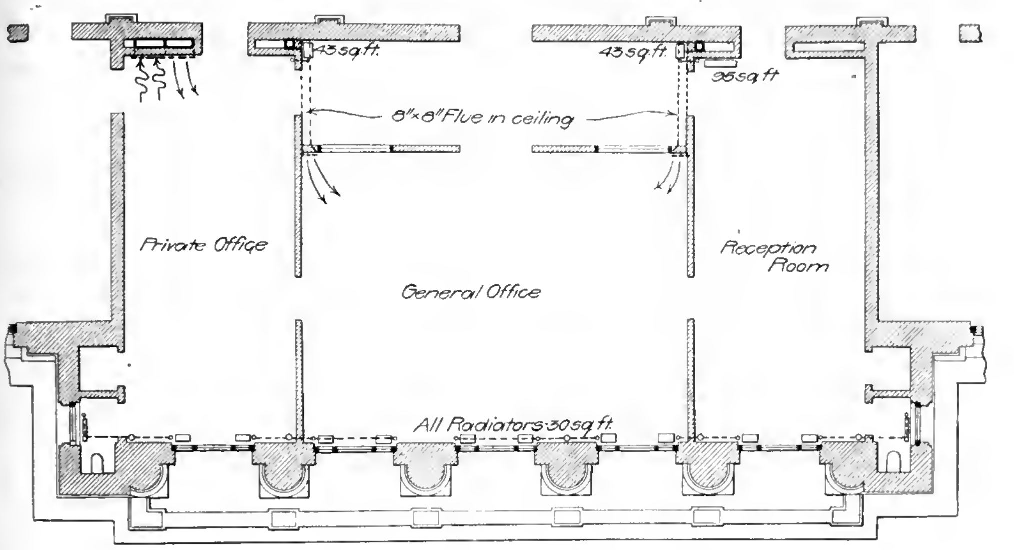
nipple connected into the pipe between two couplings, a strap anchor being clamped onto the nipple to prevent the pipe from settling. All branches to the radiators as well as also the air line connections are imbedded in the floor construction with due allowance made for expansion both upward and downward from the 2d floor anchorage point. All risers are fitted with cut-off valves just below the sub-basement ceiling, below which connections are made to branches of the heat distributing mains. Each of the risers is dripped at its base into the condensation return system which has mains and branches paralleling those for the low pressure steam distribution to all parts of the sub-basement; the drip connections are all large in size, having carrying capacities equal to approximately one-half that of the risers, and the drainage is all by gravity. The system of air lines through which air and vapor is drawn from the air valves on all radiators, corresponds exactly to that for steam supply to the radiation, the risers and branches to radiators duplicating exactly those for steam supply with the exception of size, the arrangement and proportion being approximately the same.

The heating supply system originates in the exhaust steam header in the power plant division of the sub-basement as referred to in the article in the previous issue. This header is a 16-in. exhaust line which connects through a grease extractor first to a 10-in. atmospheric exhaust outlet that leads to the boiler house exhaust head and thence through a gate valve to the heat distributing mains. Beyond the gate valve there is a live steam make-up supply connection through which live steam is added to the heating system when the exhaust from the steam using machinery is insufficient; the latter consists of a 6x8-in. Foster reducing valve which is capable of reducing the pressure from 90 lb. to 1 lb. and this is fitted with a 4-in. bypass for hand operation if necessary. The heating system header is a 12-in. steam line with four branches to the four corner sections of the building, those to the front corners being 8-in. and those to the rear are 10-in. lines. From the end of the heating main, an additional 4-in. line is extended to the fresh air supply fan room in the rear corner of the sub-basement to supply the tempering coils. Branch lines from these mains extend to all parts of the sub-basement to supply risers, decreasing in size as supply connections are taken off and they are graded with the flow of steam, condensation being drained out through the drip connections at the bases of all risers supplied.

The condensation return system parallels that for low pressure steam distribution in the sub-basement in general; the drainage connections at the bases of the risers and also those from the tempering and reheater coils of the fresh air supply system, delivering into a series of mains which conduct the condensation to a tank depressed in a pit in the westerly portion of the sub-basement. These mains are like the steam mains, arranged in four divisions, which extend to the four corners of the sub-basement to connect with the various apparatus and risers. The condensation receiving tank is a 3x8-ft. steel cylindrical tank which is located in the pit so that it is entirely below the sub-basement floor level, and the condensation gathering mains deliver into this in two groups, each through a 6-in. connection with return seal.



Heating and Ventilation of the Mayor's Office.

The condensation tank pit is about 3 ft. deep and 13x16 ft. in size in order to accommodate the return pumps on a level below that of the tank and thus facilitate the handling of the hot returns. These pumps are 7½x4½x10-in. Worthington duplex pumps which return the condensation, under control of a Kieley pump governor on the condensation return tank, to the boiler house for use in the boilers, as referred to in the preceding article upon the power plant of the City Hall. On account of the low level of this condensation tank, the condensation drains freely from the radiation both direct and indirect, and is delivered to the boiler house for boiler feeding as rapidly as it accumulates. The return of condensation is also facilitated by air line systems, which consists of a piping system with ⅜-in. connections to the air valves of all radiation, all of which connect into a 3-in. vapor header in the sub-basement that extends to the boiler house and up to an outlet within the sack near the top to effect an induce draft; the very srong draft of the stack induces a strong exhaust to these vapor lines and is found to be very effective in removing air and vapor from the heating system mains. All of the piping in connection with the heating system, both for low pressure steam supply and return, is covered with H. W. Johns fire felt applied to a thickness of 1½ in. and enclosed in canvas jacketing.

Ventilation.—While the City Hall building is situated on a spacious grounds and has ample corridor spaces within, which are the conditions most favorable for natural ventilation of a building, artificial ventilation has been provided for in a number of the public and more extensively occupied portions. These include the Common Council chamber, the Board of Works meeting room, the court-rooms in the basement, the Mayor's office and some of the large and much frequented offices. In certain of these, notably the Common Council chamber and the court-rooms, the fresh air supply system is depended upon solely for heating, while in the remaining portions fitted for mechanical ventilation, the indirect heating is supplemented by radiators which are so placed as to counteract window glass exposure, and accomplish partial heating if the indirect systems be shut down. Ample changes of air are provided for in all of the ventilated portions to provide for maximum conditions of occupancy so that, with the profuse ventilation that has been provided in the corridors and interior court area, a very satisfactory and effective ventilation of the entire interior of the building is secured. The equipment also includes two independent exhaust systems for the groups of toilet rooms in either end of the building and air filters of the cheese cloth type for the fresh air supply. An unusual feature of the installation is the use of a Corliss engine drive for the operation of both the fresh-air supply and exhaust fans.

The ventilation is applied to the building in general on the downward system, the fresh air being delivered to the rooms supplied near the ceiling line, while the foul air is exhausted through registers near the floor line. An exception to this is to be noted, however, in the case of the fresh air supply to the interior court areas which rise from the basement through the center of the building to large size double sky-lights at the roof line; in this case the hot blast is delivered to these spaces through registers located 10 ft. above the first floor level, the purpose being principally to deliver heated air centrally under the sky-lighting which will diffuse with the cool descending currents from the glass surface and prevent cold drafts. The mechanical ventilation is confined entirely to the basement and first and second stories and the greater part of it is applied to the more important offices on the first floor. On this latter floor, which has a clear head-room from floor to ceiling of 19 ft., the counting room of the Water Board, the Tax Commissioner's business office and the Tax Receiver's counting room are large important offices in which profuse ventilation was required. On the second floor there is the meeting room of the Board of Works, the Mayor's office and the meeting room of the Police Board, all large rooms, to be ventilated, while in the basement there are two police court rooms, the business office of the Street Department, and the general office of the Alms Department of the City, which are extensively occupied and require ample ventilation. Ventilation arrangements in the Common Council chamber was carefully designed to produce the best results without bringing the system into evidence and the design follows closely the methods which are usual in theater and public hall ventilating installations. In addition to this ventilation is provided in the sub-basement for both the engine room and a jail room of the Police Department.

The proportions of fresh air supply and exhaust selected for the various offices ventilated were taken with reference to average conditions of occupancy, while in the Common Council chambers, the court-rooms and the various meeting rooms, ample ventilation is provided for maximum conditions of occupancy, fully 30 cu. ft. per minute being supplied for every person accommodated in the room or hall. In addition to the capacity of ventilation provided in these rooms for crowded

conditions, the distribution of both supply and exhaust registers were carefully arranged to produce most effective results in clearing the air in all parts of the room. The registers and duct work are designed throughout for low velocities of flow, those for fresh air supply being operated with delivery velocities of about 2,000 ft. per minute in the basement duct lines which is reduced in the rising flues and connections to about 1,000 ft., and through the delivery registers to about 500 ft. per minute. The ducts and connections of the exhaust ventilation system are similarly proportioned, except that slightly lower velocities of flow are provided for. The details of the duct system connections and outlet registers for both fresh air supply and exhaust ventilation from all rooms in the building are presented in an accompanying table from which the general proportions of the system may be observed.

The ventilating systems, both fresh air supply and exhaust, are operated by fans located in the sub-basement. Owing to the extent of the service, two blower units are used in either case instead of one large unit, and each two units are located in spacious fan rooms that serve as intake chambers, the delivery being made direct from the fan outlets to the duct work or tunnel connections as the case may be. The fans are all three-quarter-housed steel plate fans, built by the B. F. Sturtevant Co., and have 12 vane wheels, 8 ft. in diameter, which are 60 in. in width for the fresh air supply fans and 48 in. wide for the exhaust fans. They are all operated at 225 r.p.m., at which the supply fans have each a capacity of 62,250 cu. ft. per minute or a total capacity of 12,500 cu. ft. per minute for the fresh-air supply division, while the exhaust fans at this speed handle 50,000 cu. ft. per minute each, removing together 100,000 cu. ft. from the building per minute. A unique feature of the fan installation is the method of drive, which consists of a 100 h.-p. Corliss steam engine with belted jack shaft driving connections. This engine is, as stated in the preceding article, located in the westerly portion of the sub-basement from which it is belted to a 98-ft. jack shaft extending along the rear wall in the direction of the fan rooms. This shaft is operated at 150 r.p.m., and the fans are driven by single belt drives, the wheel shafts being coupled in tandem. The engine is a Watts-Campbell simple Corliss engine with 16x30-in. cylinder and operates normally at 75 r.p.m., at which speed it develops 75 h.-p. It has a 10-ft. fly-wheel which is belted direct to the jack shaft and is fitted with a safety governor which will automatically stop the engine should the speed be increased more than 10 per cent. above normal.

The fresh air supply fans are located in a fan room 22x44 ft. in size in the easterly rear corner of the sub-basement to which the fresh air is drawn in through a group of cheese-cloth air filters and a set of tempering coils: the room itself thence serves as an intake chamber, from which the fans draw directly while delivery is made through duct connections to the distributing duct lines outside. The air filter consists of a series of 8 cheese cloth frames, 7 ft. in width by 11 ft. high, which present a total area of filtering medium of about 600 sq. ft., with which, at the maximum delivery of the fresh air supply fans of 12,500 cu. ft. per minute, a low filtering velocity of about 20 ft. per minute is obtained. The screens consist of wooden frames upon which the cheese cloth medium is stretched over wire netting for stiffening and backing purposes and they are mounted in an angle iron frame work, with provisions for removing when necessary for cleaning.

The air supply is heated in winter weather before being delivered to the building by a tempering coil in the fan intake and reheater coils in the duct delivery connections to the various rooms, by means of which arrangement the temperature of the air delivered to the various rooms may be accurately controlled. The tempering heater consist of a row of 10 special cast-iron radiators each containing 150 sq. ft. of radiating surface which are mounted in a row on a 12-in. brick wall, 5 ft. in height between the fans and the air filter. The upper portion of the rooms surrounding the radiators is shut off by a galvanized iron partition while in the brick supporting wall are three 36x60-in. dampers for the purpose of by-passing the tempering coil when desired, thus reducing the temperature to which the air supply is tempered in the intake.

The reheating coils are installed in the fresh air supply ducts to each of the rooms ventilated, for individual heating of the air thus supplied according to the requirements of each room. They are installed in the sizes indicated in the accompanying table of duct sizes and each reheater is thermostatically controlled from the room served. With this arrangement the most effective application of the indirect heating is secured as each delivery is thus independently adjusted to the heating requirements and is shut off whenever the direct radiators in the room can maintain the desired temperature. The Johnson system of temperature regulation is installed, there being thermostats in each of the rooms ventilated which, in addition to that controlling the direct radiation, controls all of the indirect heating of that room. The tempering coil is under the control of a thermostat in the supply fan room to regulate the amount of tempering of the incoming air.

The exhaust ventilating fans are located in an 18x20-ft. room in the central portion of the sub-basement space into which the exhaust gathering ducts from all parts of the building are led, this room serving as an exhaust chamber for the fans. The gathering duct connections consist, as will be noticed from the sub-basement plan of the City Hall in the preceding article, of two 6x66-in. ducts, a 34x108-in. duct and a 42x72-in. duct. The fans have intake direct from this chamber and deliver to the atmosphere through the piping tunnel which extends underground to the boiler house building at the rear of the main building. This tunnel is, as stated in the preceding article, 8 ft. square, and connects at the boiler house end, into a large brick flue rising to a point about 40 ft. above the sidewalk, where it has a hooded outlet. This flue is 6x15-ft. in area and has a full sized damper near the top which is controlled from below by ropes to permit of shutting off the outlet in case it is desired to shut down the system in cold weather. The ventilating flues are all without automatic dampers or control with the exception of those from the Council chamber which have automatic dampers under the control of thermostats in the chamber which causes them to open when the temperature increases above a predetermined point and closed when the temperature lowers.

The public toilet rooms of the building are ventilated by independent exhaust systems in order to prevent the possibility of communication of odors through the duct work to other parts of the building. These toilets are located in the two rear corners of each floor from the basement to the fourth floor, there being two on each floor, about 11x17 ft. in size, or 10 in all, and for their ventilation, two 2½x5 ft. vent shafts were built in the wall construction adjoining these rooms, from the sub-basement to the roof in either corner. They are connected with the toilet rooms by 6x6-in. vent register openings at the ceiling line for exhaust and also serve an important purpose in accommodating the soil pipes and other pipe lines of the plumbing system in open construction. These vent shafts are each connected in the attic to motor-driven cone exhaust fans, which operate continuously, independent of the other ventilation systems, and discharge through copper vent hoods through the roof. The fans are 36-in. 16-blade full-cone cased fans which are direct-connected to 3 h.-p. Sprague motors and operate at 650 r.p.m. Owing to the use of alternating current for operation of the lighting service in the building, these motors are operated on an independent supply of 500-volt direct-current, for which a special service connection is made by the local lighting company, and suitable switches are installed for control of the motors from the sub-basement. The private toilet rooms in other parts of the building have outside windows and are not fitted for mechanical ventilation.

The mechanical plant of the City Hall was designed for the architects by James M. Seymour, Jr., consulting engineer, Newark, N. J. The architects of the building were John H. and Wilson C. Ely, of Newark, N. J., and Mowbray & Uffinger, New York. The commissioners for the new City Hall were Andrew Kirkpatrick, Gottfried Krueger and James E. Howell.

THE ELECTRIC PUMPING PLANT of the Scunthorpe, England, water works consists of two units which force a supply through 2 miles of 9-in. main against a maximum head of 240 ft. The supply is drawn from an infiltration gallery. One pumping unit consists of a horizontal triplex pump, belt-driven from a 50-h.p. alternating current motor. The second unit consists of a three-stage Worthington turbine pump, driven by a similar motor through a flexible coupling. Three-phase 25-cycle, 2,200-volt current is supplied from a station 4¾ miles distant through an underground transmission line. The inaccessibility of the pumping station for carting fuel and supplies made the adoption of electrical power essential. The use of gas, oil and steam was fully considered, but the peculiar nature of the undertaking was decidedly in favor of electricity.

Some Notes on Oriental Water-Works.

A paper read before the American Water-Works Association by George A. Johnson, principal assistant engineer with Hering & Fuller, New York.

During the writer's recent trip around the world it was his privilege to make a somewhat extended study of numerous Oriental water-works. It would be out of place in a paper of this character to go much into detail or to attempt a complete description of all the works visited. In this article, therefore, will be given as briefly as possible the more salient features of Japanese water-works, and of the works at Shanghai, China, Singapore, Straits Settlements and Bethmangala and Calcutta, India, observing the general lines followed by the writer in his illustrated lecture on this subject delivered last June at the Toronto Convention of this Association.

Some of the data used in this paper have been taken from an article by the writer which appeared in The Engineering Record, May 11, 1907. For their great kindness in aiding the writer in his endeavor to obtain information upon the works described, hearty acknowledgments are due to Dr. Y. Nakajima of Tokyo; Mr. S. Inoue and Dr. S. Tanabe of Kyoto; Mr. Z. Mita of Yokohama; Mr. K. Funabiki; Mr. H. Ono, Mr. K. Inouye and Mr. Y. Tsujimura of Osaka, Japan; Mr. McLeod and Mr. Mollison of Shanghai, China; Mr. Pierce of Singapore and Mr. Bell of Penang, Straits Settlements;; Mr. Fogarth of Bethmanagala and Mr. McCabe and Mr. Peirce of Calcutta, India.

Water Works of Japan.—There have been public water supplies of a kind in Japan since the year 1600 when Iyeyasu, founder of the Tokugawa dynasty of Shoguns, inaugurated the first public water supply at Tokyo. These original works were remodelled and improved some 65 years later, and were improved and extended many times during the next two centuries. It was not until 1892, however, that the present modern and efficient works were put under construction, and it was 1898 before they were completed.

To Yokohama belongs the credit for having installed the first modern system of water works in Japan, begun in 1885. For the data from which the following digest of modern water works practice in Japan has been prepared the writer is indebted to his friend, Mr. S. Inoue, Chief Engineer of Kyoto Municipality, Japan, and a member of this Association. In 1889 the construction of the Nagasaki water works was begun. Osaka commenced her works in 1892, Hiroshima in 1896, Kobe in 1897, Hakodate in 1898, Shimonoseki and Okayama in 1900 and Akita in 1903. In all, therefore, there are ten cities in Japan provided with public water supplies, nine of which are filtered before delivery to the consumers, the Hakodate supply being unfiltered. In addition to these ten cities there are Kamiura, Sawarazawa and Iizuka, towns with populations of 2,165, 1,396 and 1,240, respectively, which have public supplies, that of one, Kamiura, being filtered.

The total population of the thirteen cities and towns which have public water supplies is in round numbers about 4,100,000, and of this number roughly 4,000,000 are supplied with filtered water. In general terms about one-third of all service lines are metered, and there is a fire hydrant provided to about every 50 houses. The average daily water consumption is about 25 gallons per capita. The total capital cost of all existing Japanese waterworks systems to date is in round numbers $11,500,000, or $2.80 per capita.

Tokyo Water Works.—The original design of these works called for a capacity of 45,000,000 gal. per day, or sufficient to serve a population of 1,500,000. Construction work was begun in 1892 and the works were first put into commission in 1898. In 1904 the population of Tokyo was 1,870,628.

The intake is located on the Tama River at Hamura, and from there to the present works the water flows by gravity through about 30 miles of open and closed canal. On reaching the works at Yodobashi the water passes through sedimentation basins, three in number, each 720 x 360 x 19.5 ft. deep, having a total capacity of 67,300,000 gal. These basins may be worked intermittently or continuously and when operating as continuous flow basins the period of sedimentation is equal to about 36 hours, and the velocity of flow through them to about 0.067 in. per second.

From the sedimentation reservoirs the clarified water flows through regulated outlets onto slow sand filters, of which there are eighteen one acre units. The sand layers are 30 in. in depth and are supported by 24-in. of graded underdraining material. The filters are operated at a rate of 2,933,000 gal. per acre daily, corresponding to a total gross capacity for the 18 filters of 52,794,000 gal. daily.

The filters require scraping about seven times a year on an average. At such times the dirty sand is removed from the beds, dumped into cement lined troughs, water applied and the sand agitated by coolies with rakes until clean.

There are three filtered water basins, all covered, located at Yodobashi, Hongo and Shiba respectively. The capacity of each basin is 7,500,000 gal., corrresponding to a total storage capacity of about 12 hours.

Two thirds of the supply is delivered by gravity to the low level districts. The remaining one-third is pumped at the Yodobashi station to the high level district in Yotsuya, Akasaka, Azabu, Shiba, Kojima, Ushigome, Koishikawa, Hongo and Kanda wards. The pumping station at Yodobashi contains four 300-h. p. pumping units each of a capacity of 7,500,000 gal. per day when working against a head of from 80 to 100 ft. There are twelve Lancashire boilers and two sets of Green economizers.

The charges for water vary, according to the use to which it is put, from 6 to 10 cents per 1,000 gal. The water is of excellent quality, clear, soft and without noticeable color.

At the present time there are 85,539 services and 5,177 fire hydrants. The metered services number 20,514.

The water consumption ranges from 11 to 23 and averages 17 gal. per capita daily. The total cost of works to date is $4,250,000.

Osaka Water Works.—The Osaka water works were put under construction in 1892, and originally designed to serve a population of 600,000. They were later extended to serve a population of 800,000. The population of Osaka in 1904 was 1,026,767.

The supply is derived from the Yodo River frrom whence it is raised by three centrifugal pumps to a series of four settling basins against a total head of about 30 ft. After 36 hours sedimentation the water is applied to slow sand filters and then pumped by seven triple expansion pumping engines of the Worthington type to the distributing reservoir at Osaka Castle against a total head of about 130 ft. The capacity of this storage reservoir is 3,750,000 gal.

The raw river water has a turbidity ranging from 10 to 350 parts per million. There will be about 20 days in the average year when the turbidity of the raw water will be over 100 parts per million, and about 50 days when it will be over 50 parts. The alkaliniity averages about 20 parts per million, and the numbers of bacteria range from 40 to 30,000 and average about 2,000 per cubic centimeter.

The settling reservoirs, four in number, are each 330 x 360 x 12 ft, effective depth. Their combined effective capacity is 42,600,000 gal. The sediment in these basins is flushed out once annually, when between 3 and 4 in., or about 5,200 cu. yd. are removed. The cost of labor for flushing out this material is 2 cents per cubic yard.

The cost of the basin completed in 1903, the effective capacity of which is about 10,000,000 gal., was $83,370, exclusive of the cost of land which costs at present $2.00 per tsubo, or $2,420 per acre.

The filters are of the slow sand type, eleven in number, ten of which are 151 x 182 ft. and one 182 x 350 ft. The total filtering area is therefore 7.77 acres. The tanks are of concrete and brick and the filter finished in 1903, 182 x 7.5 ft. deep cost $40,700 or $27,840 per acre exclusive of the filtering material which cost about $3,000 per acre additional.

The filters are operated in an up to date manner, although the rate of filtration is not automatically controlled and fluctuates with the pumpage. The average actual rate of filtration is 2,900,000 gal. per acre daily. The net rate is equal to about 2,600,000 gal. per acre daily.

Each filter requires scraping about twice a month on an average, and at such times about one-third inch of material is removed. No attempt is made to recover by washing the sand thus removed and it is used for fill. A gang of coolies is kept busily engaged at the river bank practically all of the time screening sand which is hand dredged from the bed of the Yodo River opposite the water works, brought to the shore in boats and there sun dried and pan screened.

The water rates vary from 10 to 60 cents and average about 20 cents per 1,000 gal. The filtered water is of excellent quality, has an alkalinity of about 20 parts per million, and during the year 1905 contained the average number of 25 bacteria per cubic centimeter.

There are at present 48,513 services of which 9,369 are metered. There are 3,000 fire hydrants. The total cost of the system to date is $1,653,020.

Yokohoma Water-Works.—The Yokohama water works were put under construction about 22 years ago when the first pipe lines were laid from the Sagami River. The new intake is located on the Doshi River near the foot of Fujiyama, and from there to the site of the filteration works on Nogiyama, a distance of some 30 miles, the water flows by gravity.

The works were originally designed to serve a population of 70,000 and have since been extended to serve 300,000 people. In 1904 the population of Yokohama was 331,597.

The raw water of the Doshi River is normally clear and noticeably free from color and turbidity except at times following heavy rains. The alkalinity of the water is about 27 parts per million.

On reaching the filtration works the four supply mains discharge into two receiving wells of masonry construction and from them is distributed to slow sand filters. These wells are small and permit of comparatively no storage. Suitable regulating devices are provided to maintain a constant water level in the wells and on the filters.

The three slow sand filters built some 21 years ago have recently been supplemented by three more filters. The beds are arranged in two batteries, one of four and one of two filters. The former are each 120 x 70 ft., and the latter are each 120 x 80 ft., corresponding to a total filtering area of 1.212 acres. The tanks are built of masonry and brick. The sand layer is 2.5 ft. thick supported on a layer of graded under-

draining material 18 inches in depth. The sand is of medium size, rather dark in color, and of good stable quality. It costs about $2.75 per cubic yard in the filters.

The filters are operated at the somewhat high rate of 6,530,000 gal. per acre daily, and require scraping about once a month. Sand washing procedures are similar to those employed at the Tokyo water works.

There are two baffled clear water basins, both covered and having a total capacity of 3,192,000 gal., corresponding to a storage of practically 12 hours supply.

The filtered water is high grade, clear, soft and colorless, and stands in enviable repute among the citizens of Yokohama. The works are well built and well operated. There are at present 2,745 metered and 7,679 unmetered services. There are 1,236 fire hydrants, or one to every 50 houses. The consumption ranges from 19 to 29 and averages 24 gal. per capita daily. The total cost of the system to date is $1,548,140.

Kobe Water Works.—The Kobe water works were put under construction in 1897 and consist of impounding reservoirs in the hills immediately back of the city, slow sand filters and small distributing reservoirs. The system is a gravity one throughout.

The impounding reservoirs, two in number, have a total capacity of 483,000,000 gal. corresponding to a storage of 140 days supply at the average rate of consumption of 3,480,000 gal. daily. The catchment area for the most part consists of the steep slopes of the hills back of the city and two small brooks serve as the main feeders. The watershed is but sparsely populated owing to its mountainous character.

The raw water, owing to the lengthy period of storage allowed, is never excessively muddy when applied to the filters. It is soft and free from noticeable amounts of color.

The filters are eleven in number, and have a total area of 3.04 acres. Prior to its application to the filters the water passes through a small settling reservoir of a capacity of 1,000,000 gal. The distributing basins are 5 in number and have a total capacity of 260,000 gal.

There are at the present time 11,581 services in the city, 2,576 of which are metered. There are 1,173 fire hydrants. The works were designed to serve a population of 250,000. In 1904 the population of Kobe was 295,276.

The water consumption ranges from 20 to 40 and averages 30 gal. per capita daily. The total cost of the system to date is $1,468,640.

Nagasaki Water Works.—These works were put under construction in 1889, and consist of impounding reservoirs, slow sand filters and distributing reservoirs. It is a gravity system throughout.

The original works were designed to serve a population of 60,000, but have since been extended to serve 182,000. In 1904 the population of Nagasaki was 159,041.

The impounding reservoirs are three in number and have a total storage capacity at a daily average consumption of 1,680,000 gal. or 293 days supply, or 493,000,000 gal. The supply is drawn frrom small mountain streams.

From the storage reservoirs the water flows to the slow sand filters, nine in number and having a total area of 2.36 acres. From the filters the water flows to four clear water basins, having a total capacity of 2,930,000 gal., from which it is distributed by gravity to the city.

At the present time there are 5,001 services in the city, 953 of which are metered. There are 492 fire hydrants.

The total cost of the system to date is $788,080.

Hiroshima Works.—Construction work was begun in 1896. Population in 1904 was 127,117. The works were designed to serve a population of 120,000. The source of water supply is the Ota River. There are two settling basins with a total capacity of 1,200,000 gal. The slow sand filters four in number, have a total area of 1.75 acres. The clear water basins, two in number, have a total capacity of 950,000 gal. Water consumption ranges from 15 to 40 and averages 28 gal. per capaita. There are at present 6693 services in the city, 1610 of which are metered. There are 709 fire hydrants. The total cost of the system to date is $465,560.

Shimonoseki Works.—Construction work was begun in 1900. Population in 1904 was 46,905. The works were designed to serve a population of 60,000. The supply is derived from small mountain streams. The impounding reservoir has a capacity of 286,000,000 gal. There are three slow sand filters with a total area of 0.87 acre. There are two clear water basins with a total capacity of 270,000 gal. Distribution is by gravity. Total cost of the works to date is $449,080.

Okayama Works.—Construction work was begun in 1900. Population in 1904 was 81,324. The works were designed to serve a population of 80,000. The source of supply is the Asahi River. There are two settling basins with a total capacity of 3,090,000 gal. There are four slow sand filters, with a total area of 1.31 acres. There are two clear water basins with a total capacity of 810,000 gal. The total cost of the syystem to date is $401,900.

Akita Works.—Construction work was begun in 1903. The population in 1904 was 33,695. The works were designed to serve a population of 40,000. The source of supply is drawn from the Asahi River, a branch of the Omono River The settling basin has a capacity of 100,000 gal. There are two slow sand filters with a total area of 0.66 acre. The capacity of the clear water basin is 750,000 gal. The total cost of the system to date is $235,150.

Hakodate Works.—Construction work was begnu in 1898. Population in 1904 was 88,071. The works were originally designed to serve a population of 60,000, but have since been extended to serve a population of 150,000. The supply is drawn from Aka River. The storage reservoir has a capacity of 1,530,000 gal. The water is not filtered. There are two distributing reservoirs the total capacity of which is 1,920,000 gal. The daily water consumption ranges from 22 to 35 and averages 26 gal. per capita. There are at present 2,509 services in the city, 729 of which are metered. There are 410 fire hydrants. The total cost of the works to date is $229,310.

Sawarazawa Works.—Construction work was begun in 1898. Population in 1904, was 1,396. The works were designed to serve a population of 1,229. The supply is drawn from small mountain streams. The impounding reservoir has a capacity of 300,000 gal. The water is distributed by gravity direct from this reservoirs to the consumers. The total cost of the works to date is $5,060.

Iizuka Works.—Construction work was begun in 1898. Population in 1904 was 1,240. The works were designed to serve a population of 1,085. The supply is drawn from mountain streams. The impounding reservoir, from which the water is distributed direct by gravity to the consumers, has a capacity of 200,000 gal. The total cost of the works to date is $4,090.

Kamiura Works.—Construction work was begun in 1900. Population in 1904 was 2,165. The works were designed to serve a population of 2,500. The source of water supply is the Ushimaki River. The water is applied direct to a small sand filter (area .017 acre). The clear water basin has a capacity of 22,000 gal. The total cost of the works to date is $3,410.

Water Works of Shanghai.—Shanghai is located on the east coast of China, south of the Yellow Sea and near the mouth of the Yang-tse-Kiang. It has a population of about 600,000. The water works were built with the particular object in view of supplying the foreign population of that city with pure water. The total number of people tributary to these works at present is in round numbers 45,000, of which 12,000 are of English and American birth and the remainder Chinese.

The water supply is drawn from the Hwang-ho River, the waters of which are normally very turbid, as is the case with all rivers emptying into the Yellow Sea. In fact it is the excessive muddiness of such waters as those of the Yang-tse-Kiang and Hwang-ho that gives the name to the Yellow Sea, the waters of which are colored a deep yellow for more than a hundred miles from the mainland of China.

The raw water is raised from the river by two centrifugal pumps of local make and discharged through two 20-inch pipes into the settling basins. These basins are four in number and provide a period of sedimentation of about 25 hours.

From the settling basins the water is applied to slow sand filters of which there are twelve. The areas of these beds range from 1/6 to 1/3 acre. Considerable fine clay remains in suspension even after a preliminary sedimentation of 25 hours, and the filters require scraping at intervals of one month or less.

Passing the filters the water flows to a clear water reservoir having a capacity of 6,000,000 gal., and is pumped therefrom through one 25-in. and two 20-in. mains to the consumers. The daily pumpage ranges from 5,000,000 to 7,000,000 gal.

The construction work in this plant is high grade, and the filters are very efficient notwithstanding the fact that they are somewhat overworked at times.

Singapore Water Works.—Singapore is located on the Island of Singapore at the southern extremity of the Malay Peninsula. The island is about 250 square miles in extent and is separated from the mainland by the narrow Straits of Tebrau. The population of the city is estimated at 200,000.

The water supply is derived from small jungle streams which drain about 28 square miles. The storage reservoir is located on Thomson Road a short distance outside the city and has a capacity of about 1,000,000,000 gal. The raw water is not particularly turbid, but is always highly colored. Much of the time the water has a strong fishy odor and to the taste is often highly objectionable.

The raw water flows from the storage reservoir by gravity to the outskirts of the city where the filtration works are located. The filters are of the slow sand type, eight in number, with a total filtering area of 2 acres. Operation is intermittent; that is, the beds are allowed to rest empty about 12 hours in every one to two weeks, the length of the operating period varying according to the season. By this procedure it is understood that a considerable degree of success has been achieved in removing the objectionable tastes and odors from the water, although at the time of the writer's visit, July, 1905, the filtered water had a pronounced "fishy" odor. The actual rate of filtration is said to be about 1,050,000 gal. per acre in 24 hours, corresponding to a daily yield of about 2,100,000 gal. for the eight filters. The average daily consumption is said to be about 5,000,000 gal. daily.

Water Works at Bethmangala, India.—These

works were constructed in 1903-4 for the purpose of supplying the Kolar Gold Fields with pure water. The gold fields are located in the State of Mysore, in southern India, and about 60 miles from Bangalore. The water works are located just outside the village of Bethmangala and about 7 miles from the gold fields. Up to the time of installing the present works the water supplied to the laborers at the mines was not only of extremely poor quality, but very scarce, a small given amount being allowed each laborer daily. These laborers are chiefly natives, but there are also, it is understood, some 800 English miners among the 20,000 workers at the mines.

The water supply is derived from the Palar River upon which the large storage reservoir at Bethmangala, together with many similar reservoirs used chiefly for irrigation purposes, is located. The capacity of this reservoir is 1,737,612,000 gal., sufficient at a daily consumption of 2,400,000 gal. for 724 days supply. The rainfall at Bethmangala averages only about 17 in. annually and the raw water is deeply colored, and at times high in suspended matter. (A number of the details which follow have been taken from an article by the designer of these works, Mr. E. B. Weston, and published in The Engineering Record, Dec. 17, 1904, acknowledgment of which is hereby made.)

As to the filtration and distributing system, the raw water enters a masonry inlet chamber located in the Bethmangala reservoir and thence flows by gravity to a suction well adjacent to the filter building from which it is raised by two lift pumps to the coagulating basin. The coagulant (sulphate of alumina) feed enters the raw water pipe leading from the low lift pumps to the coagulating basin. After four hours continuous coagulation and subsidence the water passes over outlet weirs into the supply pipe leading to filters of the American type. Passing the filters it is discharged through Weston automatic controllers into a flume and thence into the clear water basin, being raised thence by high lift pumps through a 16-in. main to the Kolar gold field against a total head of about 500 ft.

The coagulating basin, located just outside the filter building, is uncovered, is constructed of granite masonry and lined inside with brick laid in "surki" mortar. The floor of the basin is of concrete. The basin is divided into two sections by a partition wall and has a capacity of about 400,000 gal.

The filters, four in number, are of the Jewell gravity type, circular in plan and built of granite masonry. Over the manifold collecting system is placed a thin layer of gravel surmounted by 3.5 ft. of fine sand. Each filter has a rated capacity of 620,000 gal., corresponding to a total capacity for the four filters of 2,480,000 gal. per 24 hours. The rate of filtration is automatically controlled by means of Weston effluent controllers.

The clear water basin is located about 30 ft. from the filter building, is below ground level and covered. The basin is built of granite masonry and the roof of masonry.

There are two low lift pumping outfits with a total capacity of 5,280,000 gal. per 24 hours, and three high lift outfits of the Worthington type of a total capacity of 3,600,000 gal. per 24 hours. There is also a centrifugal pump for washing the filters having a capacity of 2,000 gal. per minute. The last named is belt-driven by a Pelton wheel operated with water from the 16-in. high pressure main. Steam to drive the high and low lift pumps is supplied by two Babcock & Wilcox boilers, each of 225 h.-p. with Green economizers.

There is a stand tank at Champion Reefs Mine in the gold fields, built of brick laid in cement mortar. All the filtered water is pumped to this tank from which lead branch lines to similar tanks located at the different mines, and to the service reservoir at Robertsonpet, a town about a mile distant.

The works were designed by Mr. Edmund B. Weston and built by the Jewell Export Filter Co., for whom Mr. R. W. Lawton acted as superintendent of construction. The amount of money appropriated for this work was $324,000.

Since the works were completed periodic analyses of the raw water and filtered water have been made by the official bacteriologist of the Mysore Government. The average results of the test made during the period Sept. 8-11, 1906, the last results available to the writer at this time, showed 4,350 bacteria per cubic centimeter in the raw water and 13 in the filtered water. Cholera, which prior to the installation of these works was very prevalent, has been practially absent among the employees of the mines since the works were put into operation. The filter plant itself is a model of neatness, and is operated in the most intelligent, painstaking and efficient manner.

Calcutta Water Works.—Calcutta is located in the province of Bengal, on the right bank of the Hugli River and about 45 miles inland from the Bay of Bengal. The present population is estimated at 1,100,000.

The Hugli River, from which Calcutta derives its water supply, is the most western branch of the Ganges. The drainage area of the Hugli is about 25,000 square miles, although in addition to the run-off of this watershed considerable excess flow from the Ganges enters the Hugli during July, August and September, when the flood season is at its height, through the Bhagirathi, Jellinghi and Matabanga Rivers which connect the Ganges and the Hugli above Palta.

The waters of the Hugli River are normally very muddy, and at times, especially in the rainy season, excessively so. A better idea of the effect on the muddiness of the water produced by the heavy rains which occur in the rainy season may be had from the statement that while the average rainfall in this vicinity amounts to only about 60 in. annually, as much as 40 in. has fallen in a single week, and in 1900 the rainfall on two successive days was 14.5 and 10.8 in.

The river water at the intake at Palta is subject to tidal influences; in fact the rise of the tides is felt 75 miles above this point. During the dry season, namely, February to June, the water is quite brackish for a part of practially every day, necessitating a cessation in pumping for substantially one-half of the time.

The original works were put under construction in 1867, greatly enlarged in 1888, and now consist of two pumping stations where the water is raised from the river, settling reservoirs, slow sand filters, and gravity conduits to a reservoir on the outskirts of the city. Auxiliary pumps here force the water through mains direct to the consumers in the northern part of the city, the remainder being discharged into three reservoirs, two situated in the town and one in the suburbs, from each of which it is pumped to the remainder of the consumers.

The original settling basins, construction of which was begun in 1867, are six in number, and are built of masonry. Four are provided with semi-concentric silt-catching pits and two are plain. The original basins are each 500x250 ft., and range in depth from 7 to 9 ft. The total capacity of these six basins is 21,000,000 gal.

The "new" settling basins, finished about 15 years ago, are merely earth excavations, puddling being practically dispensed with. Notwithstanding the fact that these basins are excavated in a sandy clay the leakage amounts to practically nothing. Two of these basins are each 2,500 x 350 x 9 ft. deep. The remaining two basins are each 2,500 x 250 x 9 ft. deep. The total capacity of the four basins is therefore 84,000,000 gal., making a total capacity for the six original and four new basins of 105,000,000 gal. These basins are worked on the fill and draw plan and the period of sedimentation is therefore variable.

As the water enters the settling basins it is treated for approximately three months in the year, namely, during the rainy season of July, August and September, with aluminoferric. The chemical is applied in the proportion of about 2 grains per gallon, although the method of application precludes accurate measurement. A bag of chemical is suspended directly over the inlet, and is dissolved by the inflowing water. The aluminoferric costs about $20.50 per ton delivered at the works.

The original filters are twelve in number, each 100 x 200 ft., corresponding to a total filtering area of about 5.51 acres. The filtering material consists of 30 in. of fine river sand supported on 4 in. of course sand and 12 in. of graded gravel, respectively. The effluent collectors consist of small cross drains covered with tiles. These drains lead the effluent to main collectors laid along the center of the beds and these main drains deliver the effluent into collecting wells from which it flows directly into the conduits leading to the auxiliary pumping station on the outskirts of the city.

The new filters are twenty-four in number, each 200 x 100 ft., corresponding to a total area of 11.02 acres. In construction these filters are in general the same as in the case of the original filters, with the exception that the effluent collectors consist of two courses of dry bricks laid sufficiently far apart to provide suitable waterways. The total filtering area of the thirty-six filters is 16.53 acres.

The average daily wastes consumption is estimated at 27,000,000 gal. daily (25 gal. per capita) and the actual rate of filtration at about 2,825,000 gal. per acre in 24 hours.

There are three effluent collecting wells in the plant, with a total capacity of about 42,000 gal., and from these wells the filtered water flows through two conduits to the outskirts of the city. The conduits are 4 and 3.5 ft. in diameter, respectively, and 12.5 miles long.

It is the custom at present to supply filtered water, to the entire city, under about 30 pounds pressure at the various distributing stations during the day hours, excepting the hours 10 a. m. to 3 p. m. during which hours water is supplied under low pressure only to the more thickly populated sections of the city.

Filtered water is not used for street sprinkling, sewer flushing or fire extinguishing purposes, a complete separate unfiltered water system, being in use for this purpose, the water being pumped direct from the river into the raw water mains.

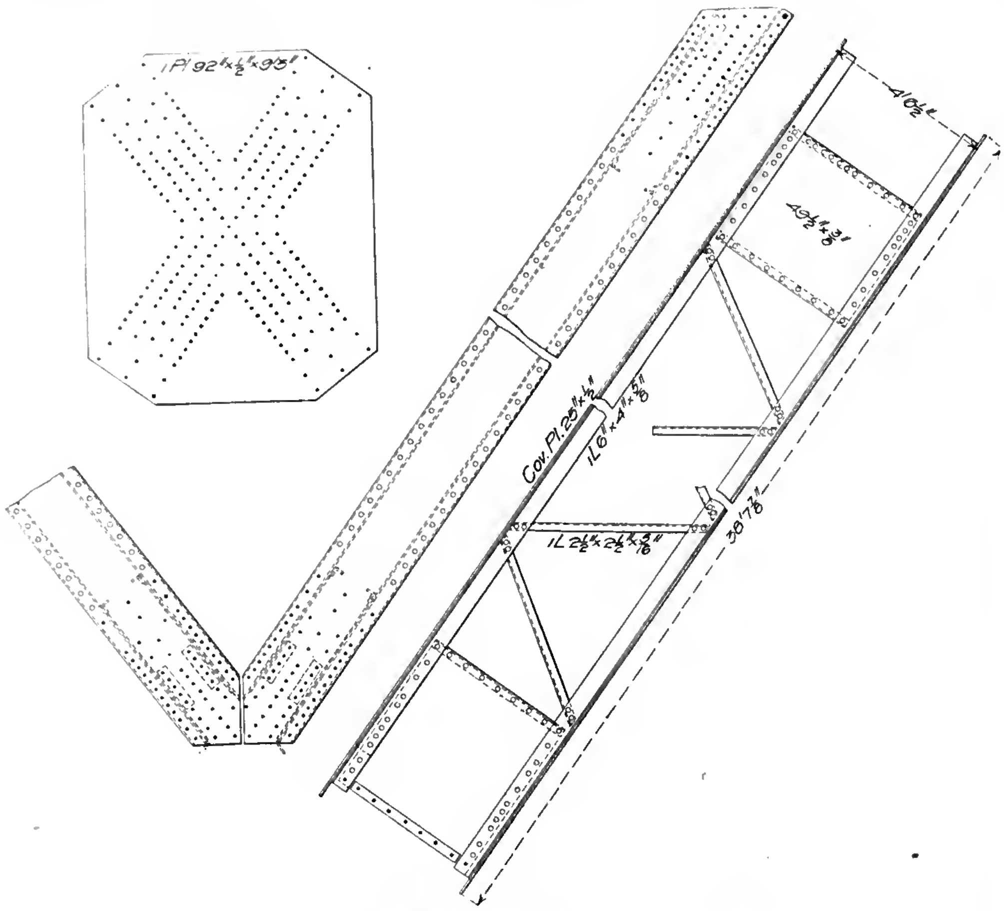
Tunnel Linings in Rock far below the surface are often considered exposed to extremely heavy pressures, which do not come into play immediately on excavation. According to Dr. Karl Brandau, such evidences of general pressure were never experienced during the construction of the Simplon tunnel. Where the superincumbent mass was greatest, the lightest type of masonry lining was almost universally employed, and has never shown the least sign of damage. Wherever merely local and unimportant pressures were observed, they were invariably due to decomposed rock of small internal cohesion. He therefore believed that no considerable difficulties arise from the pressure of the superimposed rock in the construction of a tunnel, even at depths of more than 6,800 ft., in good compact stone, though great difficulties are experienced in plastic material of considerable thickness.

The Quebec Bridge Superstructure Details.—Part IX.

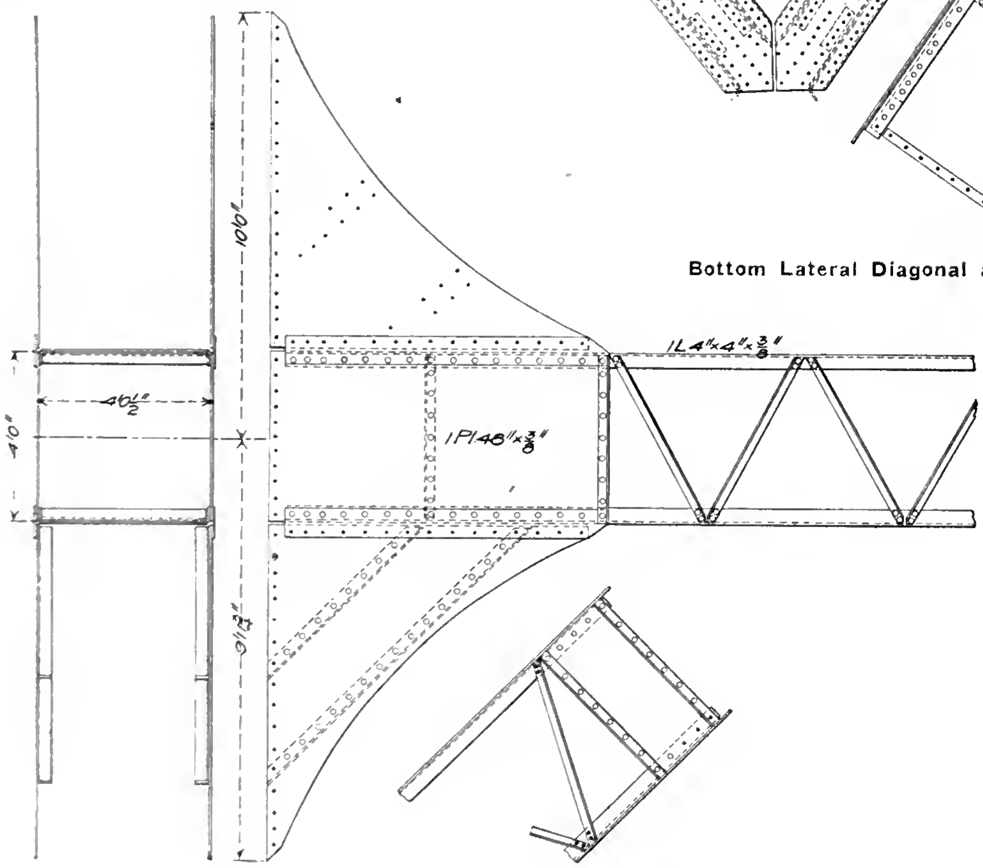
Transverse Bracing.—It is assumed that the bridge is exposed to a horizontal wind pressure of 25 lb. per sq. ft. on double the exposed surface of one truss and on one side elevation of the floor, one-half of the amount being static and the other half a live load. To provide for the stresses thus developed there are three lateral systems in the floor plane and in the planes of the top and bottom chords respectively, besides transverse bracing in the planes of all vertical posts. Horizontal shear is transmitted through special connections from the center suspended span to the ends of the cantilever arms and thence to the center posts where it is transmitted through the main transverse bent to the river pier. Wind stresses in the anchor arm spans are transmitted to the river piers and to the anchorage piers, reaching the latter directly from the floor system and the bottom chord and indirectly through the inclined end post and the vertical portal bents from the top chord system. The transmission of these stresses from the superstructure to the anchorage pier is effected by the very novel and ingenious connection illustrated in The Engineering Record of December 29, 1906.

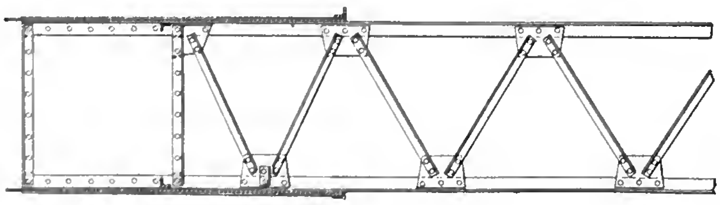
The top chords are connected by transverse struts at panel points and between them there are X-braces with I-shaped cross section having a uniform depth of 3 ft., and all of them made with two pairs of 6x3½x7-16-in. angles riveted together back to back and latticed. One of the struts is made continuous and the other is cut to clear it at the intersection where they are spliced together with top and bottom flange cover plates and vertical web-connection angles. The lattice bars are made with zig-zag angles having at each end two rivets in small gusset plates riveted between the vertical legs of flange angles. Their top and bottom flanges are field riveted between end connection plates at the ends of the transverse struts.

The top lateral transverse struts, like the diagonal members, are uniform throughout the anchor spans and have rectangular cross sections about 4 ft. deep and 4 ft. wide made with four 4x4x⅜-in. angles with their flanges turned inward and latticed on all sides by zig-zag 2¼x1½x5-16-in. angles with two rivets through the ends of each. Horizontal top flange plates project beyond each end of the struts and are field riveted to the top of the vertical post. The bottom flanges of the struts are also connected to the vertical posts at both ends by pairs of ⅜-in. gusset plate knee-braces 7½ ft. long which also serve as jaws to receive the field riveted connections of the X-brace diagonals. Horizontal and vertical batten plates are riveted to the four angles at both ends of the truss making a complete closed rectangular section there and stiffening it for the web plate connections with the diagonal struts.



Bottom Lateral Diagonal and Connection of Intersection.





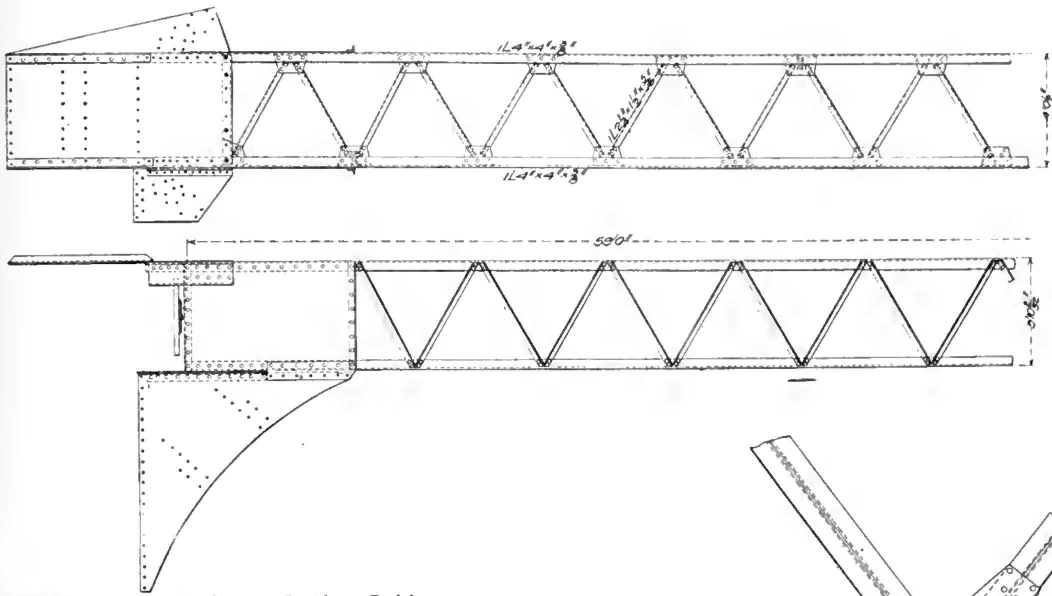
Intermediate Transverse Strut.

The bottom lateral system consists of transverse struts at panel points and intermediate X-bracing with diagonal struts having rectangular cross section 4½ ft. deep and 25 in. wide, made with four 6x4-in. flange angles riveted to 25x½-in. top and bottom cover plates and united by vertical latticing of 2x3-in. zig-zag angle bars. Both struts are cut to clear with mitred joints at the intersection where they are spliced by field riveted 92x½-in. flange cover plates 9 ft. 3 in. long and by vertical web connection angles on the side plates. The ends of the struts are field riveted between horizontal connection plates projecting from the lower chord flanges. The lower chord transverse struts are similar to the X-bracing.

All vertical posts are connected by top and bottom and intermediate transverse struts, the panels between which, excepting that which includes the space immediately above the railroad track, are X-braced with diagonal struts having rectangular cross sections made with four angles latticed like those of the transverse struts. At intersections they are cut to clear and spliced like the lower lateral diagonals and at the ends their flanges are field riveted between wide gusset plates on the ends of the transverse struts. At the end of the anchor arm the roadway is at the same level as the lower chord and has room for no transverse bracing below it. As the depth of the truss increases there are either one or two panels of transverse bracing below the roadway and the diagonal members have I-shaped cross sections made with angles back to back latticed. The transverse struts above the roadway have

very deep end cover plates field riveted to the flanges of the vertical posts with their edges curved to give a more pleasing outline. The projections of the plates below the horizontal struts serve as knee-braces and are stiffened by angle bracing frames like short trusses riveted between the inner faces of the plates and forming diagonals between the struts and the posts. In the deepest portions of the trusses special diagonals are provided in the panels just below the floor and their members virtually form portions of the trussed floor beams, as described in the last issue of The Engineering Record.

Mr. E. A. Hoare is the chief engineer of the structure and Mr. Theodore Cooper is consulting engineer. The contractor for the fabrication and erection of the steel work is the Phœnix Bridge Co.



Upper Transverse Strut. Quebec Bridge.

HEAVY EXCAVATION IN RED GRANITE has been carried on along the line of the Grand Trunk Pacific Ry. at a cost of 19.4 cents per cubic yard for drilling and blasting, by methods recently described in detail by M. G. P. McFarlane in the "Engineering and Mining Journal." In the smaller cuts, hand drills with 1-in. steel were used on holes to a depth of 30 ft. The holes were started with two hammers to the drill, and when down about 5 ft., the drill turner also took a hammer, for the rapid blows jumped the steel enough to bore a fairly round hole. Steam drills were generally used in the large cuts, a 3-in. machine drilling to 25 ft., and a 3¼ or 3½-in. machine to 30 and 35 ft. The cheaper grades of steel were used almost exclusively, as they were found to wear about as well as the high grade brands. Mr. McFarlane found it desirable to drill two holes 10 ft. on each side of the center line of the cuts and burdened not to exceed 15 ft. The advantage of this was that very little drilling was necessary to square up the bottom of the cut. Where the cut exceeded 30 ft., he found it best to take it out in two benches. After drilling, a chamber was formed at the bottom of the hole by springing with dynamite enough times to make a place to hold the blasting charge. The latter was figured at 60 lb. of black powder or 40 lb. of dynamite for each 100 cu. yd. of the shot. The advantage of machine drilling was evident in the springing necessary to make the chamber, for heavy springing causes the rock to shift at times and the larger holes drilled by machines permitted considerable shifting before the hole was finally closed off. The slips and floors caused by springing put a practicable limit to the size of the blast, which was reached with 30-ft. holes burdened 15 ft., and throwing out 400 to 800 tons of muck.

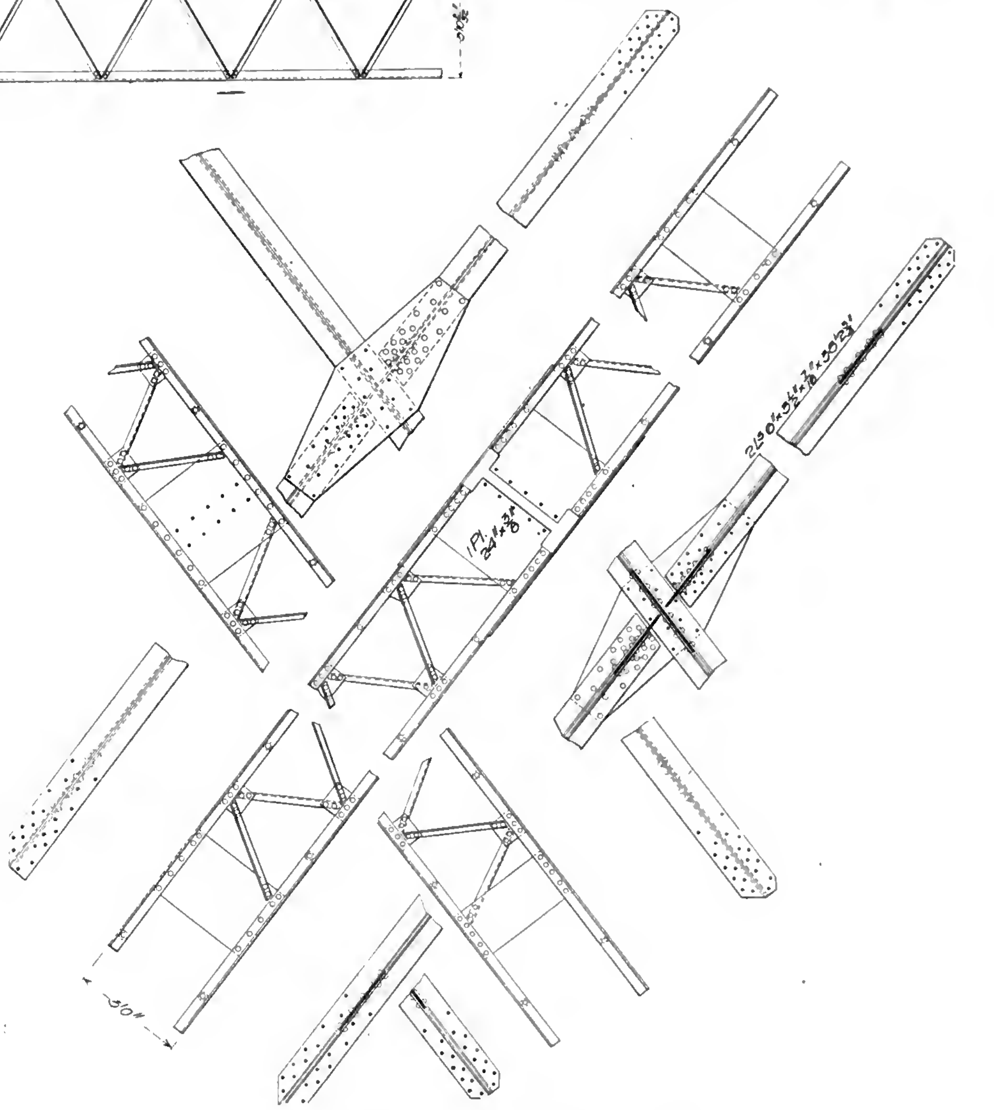
The Library System of Stone & Webster.

At the Asheville meeting of the American Library Association, a paper of unusual interest to engineers was read by Mr. G. W. Lee, on the library system of Stone & Webster, of Boston. This firm with its Engineering Corporation and their departmental offices, has the general control, including operation, engineering and financing, of some thirty public service corporations in various parts of the country, from Maine to Texas, from Puget Sound to Porto Rico, with also one in Cape Breton. Besides these, which have to do with gas and electric lighting, electric railway and power transmission, are three other industrial enterprises which would add electrochemical and textile manufacturing interests to the list. The library is at the service of them all, though particularly for the use of the headquarters in Boston.

Questions.—It is impracticable to give anything like a complete list of the questions and requests that come for immediate attention or for extended research, but a selection serves to indicate the scope of information which the library endeavors to have ready access to. The following are fair samples of what one would expect to find on the record of demands: (1) Underground conduit systems, more particularly the cost. (2) Periodical references on the grounding of the secondary. (3) Write-ups on power plants of Kansas City and Minneapolis. (4) Central station economies by Goldsborough and Fansler at the Niagara meeting of the A. I. E. E., July, 1903. (5) References on getting shocked through electric conductivity of fire streams. (6) The use of peat gas. (7) Vacuum system vs. direct steam heating. The answers to these particular questions were, for the most part, found through the indexes to the technical journals; though requests for works on railway construction, for methods of estimating population, for a book on boilers and stokers, and for information on the measurement of water flow were answered in other ways.

Questions of names and addresses frequently come up and, still more than the preceding, call for experience, besides familiarity with a number of reference books. They are such as might arise in almost any office, viz: (1) Name of Secretary of State of Texas. (2) Vice-President of Milwaukee, St. Paul & Sault Ste. Marie R. R. (3) Initials of Mr. Blackman, president of Rollins College. (4) How to spell the name of an automobile resembling "Michelon." (5) Is Charles S. Sperry's title "Captain Sperry?" Almanacs, newspaper directories, Who's Who, the advertising pages of trade journals, etc., are obviously possible sources of information for some of the above questions.

The group of questions concerning spelling, rhetoric, etc., like the one immediately preceding, includes the sort of questions people in general are likely to want answered, while savoring also of the personal use of the Library. The following are typical: (1) Is s always added for possessive singular after an apostrophe when a



Top Lateral Diagonals, Quebec Bridge.

word ends in s, i. e., is Davis' as correct as Davis's? (2) Authority for spelling to-day and to-morrow without a hyphen. (3) Authority for the spelling Phenix, Ala. (4) Is basket-ball one word or two words? (5) The abbreviation for mid-night. There has been many a failure to find rule or authority for much that one would expect to be settled by our ordinary dictionaries, encyclopedias or rhetorics. Particularly disappointing is it not to find cut-and-dried rules for addressing persons in public office.

Less obviously, to the uninitiated, the following list seems to bear upon the interests of street railway and lighting companies, viz: (1) Wealth of the United States and of the World. (2) Cost of living in Mass. for a number of years back, also an average for the whole United States. (3) Weights of different kinds of vegetables per bushel. (4) Altitudes of various cities. (5) Average temperatures of various U. S. cities. (6) Data on Key West. (7) Lumber shipments from Florida ports in 1904. (8) Is Savannah the greatest naval stores port in the world? It is such questions as these that stimulate one to preach a crusade for inter-library, inter-state, inter-national reference work, a clearing-house system for all human demands. But the people who ask these statistical questions are hardly interested in such Utopian ideas. They want their answers, and the frequency of such questions and the insistent demands to have them answered or to be put in the way of obtaining the answers, leaves Mr. Lee little time to work upon the construction of a royal road to anticipating all answers for all time to come.

Somewhat akin to the preceding are several of the following: (1) Discount on Cyclopedia of Applied Electricity for cash payment. (2) Standard works on financial matters, currency, banking systems, etc. (3) Should coal mine earnings be charged as railroad earnings where a railroad owns the mine? (4) Rates of interest of Interborough Railway notes. (5) Compound interest tables for annuity calculation. (6) The financial side of the Chicago traction situation. (7) Bank clearings for Seattle for 1905. (8) Assessed valuation of Seattle. (9) Comparative statements of the call and time money rates for the last six months of 1906, also the combined reserves of the clearing-house banks of Montreal. Finance is perhaps the common factor of business life, and a certain routine of reference books and experience enables one to put the questioner readily in touch with the answers to many questions of this kind, though one or two of the above proved to be puzzlers.

Again and again Mr. Lee has found that an apparently easy question has proved hopeless to answer. Look for the date of opening of the first interurban and see if you can readily find it. So also try to find in the ordinary rhetorics the proper way to address a woman's association: whether "Dear Madames," "Dear Mesdames," "Dear Sirs," "Ladies," or what not. In the actual case of this kind that came up the answer was obtained by telephoning the association in question and thus getting the answer from headquarters, "Dear Mesdames."

The inter-reference of office departments is of vital importance in the solution of many questions. The following were thus conjointly answered; and presumably the work of the Library in these instances was discharged in a few words, at a saving of much time: (1) Laws and ordinances governing Seattle elections (Ref. to Corporation Dept.). (2) Information on galvanizing (Ref. to Statistical Dept. and to Mass Institute of Technology). (3) Shall we buy the earlier volumes of transactions of Am. Institute of Mechanical Engrs.? (Ref. to Eng'g Dept.). (4) Capitalization of Turners Falls Pr. Co. (Ref. to Securities Dept.). (5) Cost of electric railway construction (Ref. to Statistical Dept.). (6) Trade catalogues or bulletins on file giving details of alternating current elevator equipment (Ref. to Purchasing Dept.). More questions are thus referred than the record shows, while of course the inter-working of all parts of the organization is something to be encouraged. Significant is the following extract from an address at a recent dinner of members of the office:

"One of the best known Americans to-day is our fellow-citizen of Boston, Edward Everett Hale. He has certain phrases that mean much, which he uses over and over again. They are the keynote of one of the most useful lives that has ever been lived. The principal phrases are, perhaps, 'Lend a hand' and 'Together.' In that way—together—an organization can accomplish more than in any other way, and we are here tonight to emphasize that word."

Libraries, clubs, societies, public depts., etc. The following questions were answered, successfully or otherwise largely by an appeal to resources without the office sometimes merely by telephoning, sometimes by a visit to the public or other library, club, etc.: (1) Book on hydraulic accumulators (Books from Public Library). (2) Description of patent granted to W. N. Patten and others on leather machine about four years ago (Ref. found at Public Library). (3) Hermann's map of Oregon (Not found in office or in Public Library). (4) Growth of region near Philipsburg, Pa., through which Center and Clearfield Railway runs (Letters to local library and newspapers without satisfaction).

Kindred to the above are the following, some of whose sources of information are discussed later: (1) Concrete dwelling houses (This was in 1905, when a trade catalogue obtained of an agent seemed best source of information). (2) Latest specifications for structural steel of the American Association of Steel Manufacturers (Obtained Pocket Companion from Carnegie Steel Co.). (3) Resistance of steel wire (Information obtained by letter from manufacturers). (4) Cost of heavy machine tools (Advised to appeal to manufacturers or dealers). (5) Balanced draft system, referred to in the Electrical World of 12|23|05 as to be used by Hudson River Power Co. for Utica plant (Information obtained from the publisher by letter). (6) Practice in interurban bridge design for various live loads (Learned from publishers of Street Railway Journal that articles thereon were about to appear in their publication).

The following suggest particularly the problem of how to develop the Library: (1) Bauxite in Ga. and Ala. and areas of deposits. (2) How to dispose of 51 volumes of the Transactions of the American Society of Civil Engineers? (3) Effect of crowded English cities on public health. (4) Efficiency of transmission lines. (5) Resistances of alloys. In considering the above the following questions arise:

(1) How far shall we stock the Library with data on mineral resources? Out of our usual line, but likely to come up, are questions similar to the one regarding bauxite, as experience has shown.

(2) What shall we do with good things that take up room but are not in immediate demand? With the mass of literature that is out of date, superseded, dead, or otherwise supernumerary so far as our purposes are concerned? At present we have what we call a "give-away sale," which means that most of the material is thrown into the waste-basket. The particular question of disposing of the 51 volumes was personal, being asked by one of our engineers. Likely enough, in the near future we would gladly purchase them at a high price. Meantime supply and demand fail to meet.

(3) The question as to the effect of crowded cities characterizes the wide range of the work and the need for bearing in mind general articles that may have to do with the extension of trolley lines for increasing the suburban population. How shall we keep in touch with these broad ideas without spending on them more time than is justifiable? It is almost the same question as "What shall we read in the magazines?"

(4) The efficiency of transmission lines was a question soon dropped as not at the time likely to be answered. It suggests, however, the need for keeping alive to the literature of efficiency. Often data of this kind are so much the stock-in-trade of its possessors that they are loth to publish them. How much, then, shall a private library attempt to publish of what the concern has obtained as a business asset? The concern itself must settle that. There are those who say, "Get all you can and tell as little as you can." If therefore we tell everything, who is going to confide in us?

(5) Resistance of alloys. Data on this point were readily found in several books a little differently stated in each. Why not go to the same book as often as possible and in the future assume that this is the book responsible for the data which may be disputed.

The following questions came up more than once, sometimes however in a little different form. They emphasize the importance of keeping a copy of each bibliographical list that is made, lest there be a subsequent call for it; also the importance of better team work throughout the departments, so that if one man studies a special subject the fact will be known before others start to study it. (1) Copy of contract to build Panama Canal (Obtained once or twice before, but mislaid). (2) Air lift pumps for water (Wanted by two or more engineers at different times). (3) Auxiliary station uses (Seems to have been asked from the engineering and also the advertising standpoint). (4) Books on municipal ownership. (Demands for such literature would warrant some good bibliographical work). (5) Articles on depreciation (Requested by several specialists). (6) Motor cars on steam railroads (This and the two following show a series of kindred questions). (7) Gasolene car on Delaware & Hudson R. R. (8) Literature on gasolene cars, such as tried on Union Pacific.

The following requests were fulfilled in a variety of ways. In two or three cases some one happened to remember that somebody else knew the answer; in others a good guess was made at what the questioner intended, or luck in some form helped out. The human element enters into business of every kind, and we can hardly hope, in this generation at least, to solve all our questions by the luxury of a push-button or nickel-in-the-slot machine.

(1) References on electrical fountains. (2) Household refrigerating machine and electrically operated carpet-cleaner said to be advertised by Edison Co. of Boston. (3) Equation of hysteresis. (4) Article in Street Railway Journal a few months ago on "long-distance engineering" (i. e., "designing at arm's length"). (5) Volume of an engineering magazine (not American) that the petitioner had borrowed two months ago or so. (6) World's Fair official guide giving altitudes (i. e., World Almanac). (7) Bullinger's buyers' directory (i. e., "Hendricks' Commercial Register"). (8) Get me that sheet of paper which I said, "Look out or it will be lost." (9) Please file this paper in such a way that it can be found even if the one asking for it "don't know what they want."

Sources of Information.—The sources of information may be classed as follows: a, Documents, mostly typewritten, the records of the business. b, Books, pamphlets and periodicals. c, Maps, atlases, etc. d, Indexes, catalogues, lists, etc. e, Other departments. f, Other libraries. g, Business undertakings, institutions and people in general. h, Miscellany: some unappreciated publica-

tions, emergencies, and matters of that sort.

One naturally expects that books and periodicals are the chief sources of information in a business library as in any other, else the term "library" were a misnomer. And yet misnomer it may in fact be when applied to this library; for the printed literature was taken on several years after the document file had been established, and in numbers there are perhaps fifteen times as many documnts on file as books and periodicals combined. Hence more properly the Library is called the Filing Department of the office, where literature is kept that may be needed for the purposes of the business. (There is also a Mailing Department where the correspondence is kept.)

In round numbers there are some 2,500 books and periodicals and 35,000 documents, the collection being added to at the rate of perhaps 25 a day in the proportion of something like one to fifteen—not a large Library, but one that aims to be and ought to be efficient for its purposes. The library force of six persons may seem out of proportion to the number of pieces on file or the results obtained; yet we are asking for still another to help us out.

The document file need be considered but briefly. It is largely typewritten matter, including propositions, statistical and financial papers of various kinds, legal papers such as franchises, petitions, mortgages, contracts and the like, also reports estimates and a manifold variety of engineering papers all bound in such documentary fashion as convenience requires. Maps and photographs, though considered as belonging to the Document File, are often of such sizes and make-ups as to require their own cabinets.

Up to 1900 there were a few bound journals and a small but growing list of reference books, precariously looked after and borrowed with little regard to their ever getting back. In the course of two or three years it seemed wise to have a goodly collection of technical journals dating from the beginning of the century. Later on it was deemed a convenience to have at hand a set of duplicate indexes (also dating from the first of the century) to obviate taking from the shelves volume after volume of the heavy and often dusty books in the process of looking up some fussy little reference.

The Library subscribes for upwards of sixty periodicals, including such popular ones as the World's Work and such technical ones as the London Electrician; and for about forty newspapers local to the cities in which the company has business interests. The Library makes much use of indexes and aims to keep in touch with book reviews while in the Purchasing Department are a large number of trade catalogues.

The Library tries to have all the topographic maps that the Government has published, for who knows whence a proposition may come? It needs to know the nature of the country in considering an electric railway scheme; to know the course of rivers in considering water power electric transmission schemes. It would like to have to-day the topographic maps that were published yesterday; but how can we arrange this, since the Geological Survey is not allowed to open accounts? The present method is to send three dollars about twice a year for "all the maps that have been published since our previous order," (asking for the balance in sheets that are usually duplicates for us and often of mere waste paper value). In addition to these Government maps there are the Rand-McNally state and city maps, besides those of the Scarborough Company and of many other publishers for the different localities in which the company is interested; so also the Century Atlas and the yearly Rand-McNally Business Atlas, also some atlases local to Massachusetts. There is also the List of Maps of North America published by the Library of Congress, and when recently a map of the Arctic Ocean was wanted this publication was a suggestive source for reference.

The Engineering Index, of several volumes, from 1884 to the annual of 1906, inclusive, with also its monthly issue, makes a good starting point for engineering research. Not satisfied, however, with even the annual volume, the monthly issues are clipped and pasted in classified form, so as to have ready references as nearly to date as practicable. Another great convenience is a collection of duplicate indexes, which has proved a great time saver at little extra expense. Ten to fifteen cents is the usual cost of such indexes as we care to keep in duplicate, while several of them are incidental to our subscriptions to two or more of the journals that we refer to oftenest. An index to the more general periodicals, including also some of the important engineering and statistical monthlies and a few of the weeklies, is the Reader's Guide, most familiar to librarians. The very inefficient or careless indexing of some of our most important journals emphasizes the need for having at hand more than one source of reference. Frequently an article is found in one journal through a digest or abstract of it in another. Notably the convention papers of the engineering societies are found first through their abstracts in the trade journals whose indexes appear earlier and are of wider scope than those of the societies' transactions.

The office is decidedly departmental, the other departments being (alphabetically) the Accounting, Auditing, Corporation, Executive, Mailing, Securities, Statistical, Stenographic, Transfer, and Treasury. The managers in the field, the men sent out to take charge of interests in various parts of the country, and all who are under their control, should be included as having the Library directly or indirectly to assist them. By the way of indicating the size of the organization Mr. Lee quotes from the address of the chairman at the dinner recently held for the office members. He said: "I have made some calculations as to the extent of this Stone & Webster organization. There are about 350 men at present immediately connected with the organization as it is established here in Boston. That includes all the men here, the men of the Stone & Webster Engineering Corporation, the Managers and some others in the field. Now under the control and subject to the direction of these 350 men there are some 12,000 to 15,000 employees, or something over an army division usually placed under the leadership of a Major General."

The above signifies that here are not only many people for the Library to serve, but many from whom it may obtain facts, for whom, therefore, it should act more and more as the clearing-house of information. On request for a description of the Taylor Underfed Gravity Mechanical Stoker, the Library referred to the Purchasing Department for a trade catalogue. When asked as to the best books on gas it referred to the manager in charge of the Fall River Gas Works Company. To decide whether it is worth while to add this or that book to its files, the matter is frequently referred to such departments as have the subject of the book for their specialty. To obtain statistics, maps, etc., of the various cities in which Stone & Webster are interested, circular letters have from time to time been sent to managers in the different localities.

The Boston Public Library, the several libraries of the Massachusetts Institute of Technology, the State Library, the library of the Boston Society of Civil Engineers and a few other local libraries, have been helpful sources of reference. Of these the Boston Public Library is used far the oftenest, not only for emergencies, but habitually for looking up new books.

The Document Catalogue of Government publications, the encyclopedias in general, the Statesman's Year Book, the almanacs, the city directories, the pathfinders, the telephone books (of other cities especially) are among many sources of information that we fail fully to appreciate. Mr. Lee called particular attention to the telephone book as a convenient directory.

Mobilizing and specializing are, of course, important features of a business library. For instance, when the company began to consider sociological questions such as municipal ownership and the like, the Library was weak in the number of books of this kind. One of the potentates expressed himself in strong language regarding the Library's weakness on this point, and so a sweeping order was given which soon equipped it with all the books particularly wanted.

The filing is geographical as far as practicable, that is, the Library assigns the number 1100 to the State of Maine, 1110 to a tenth of it, 1111 to a tenth of that; 1200 to New Hampshire, 1210, 1211, etc., to its divisions, and so on throughout the country. The first figure to the right of the decimal is assigned to the company, the rest are for class divisions, 1 for estimates, 2 for statistics, 3 for legal matters, etc., with their subdivisions. Books defy geographical classification for the most part, so that they are shelved generally with numbers only to the right of the decimal. The decimal idea prevails in the Library, though not the Dewey system.

The items of the "Engineering Index" are clipped and pasted in sub-classified form, on convenient sheets for reference purposes. The classification was provisionally made four or five years ago by playing a long game of solitaire with the clippings of the monthly indexes of some two years and a half. With the progress of engineering new terms and ideas appear so that the classification needs continual revision. In the main this classification is a sub-dividing of the general divisions and sub-divisions as given in the Index, the asigning of the number 10 to civil engineering, 11 to bridges; 12 to construction, etc.; 20, etc., to electrical engineering; 30, etc., to mechanical engineering; 40, 50, etc., to other branches; and to the minor divisions, under bridges, 11.1 for arches, viaducts, trestles, etc.; and 11.11 for arched bridges and arches in general. So it is throughout the whole, the 60's and over being reserved for personal matters and sources of information that are not covered by the Engineering Index.

The "Stone & Webster Current Literature" is a private engineering index made from noting on slips, of card index size, articles of interest in the current periodicals, book accessions and various announcements and memoranda, and listing them on typewritten sheets—or printed ones as a recent innovation—with nearly the same classification as used for the Engineering Index. The items are selected as being of interest to the Stone & Webster organization, and, though distributed to a certain extent gratuitously, its usefulness to others is necessarily limited. This printed form is planned as a quarterly publication, but it lags too far behind for current purposes. Hence, in mimeograph form there is issued for office reference what are called Semi-Weekly Specials. These, of course, do not admit of the same refinement of classification as the less frequent ones, though the main general divisions are used and serve for convenience in back reference.

Of what worth in dollars and cents is the Library to the organization? It is charged in the accounts as an expense, and some members of the office regard it as a colossal expense. Once in a while, however, just such persons may have some question answered which enables them to see that thereby plans in their work have been changed to effect the saving of thousands of dollars, and for this reason there seems to have been a healthy growth of the idea that the Li-

brary is a good thing and ought to be maintained in spite of all objections. Mr. Lee feels that when his department is more closely in touch with other libraries and getting information from various parts of the country to a much greater degree than heretofore, there will be decided evidence of what this department is, what it does, and what it can do for the benefit of the organization. It is too much in its infancy as a feature of business life to be accepted as a matter of course.

A Sewage Disposal Problem at Hanley, England.

The new sewage disposal works at Hanley must fulfil some unusually troublesome conditions. The engineers who designed them, Messrs. Willcox & Raikes, of London, were obliged to construct them on a very small site, within a short distance of numerous houses where any odor would cause serious annoyance. In designing the works it was necessary to provide treatment for dry weather sewage amounting to 1,800,000 gal., and wet weather sewage of 10,800,000 gal. In addition to making this provision for a wide range in capacity, the effluent must be discharged into a very small stream, which has a flow during the summer equal to but a small part of the volume of sewage reaching the disposal works. The sewage is first delivered into a screening chamber, from which it passes through three grit chambers having a total capacity of 410,000 gal., about a quarter of the dry weather flow. From the detritus tanks the sewage is discharged by gravity to low-level works or pumped to high-level works, any volume in excess of 10,800,000 gal. being allowed to pass into the river directly from the grit tanks, on the ground that it is too dilute to cause nuisance. The high-level works consist of four septic tanks of 2,460,000 gal. capacity, or 1⅓ times the dry weather flow, and 3¾ areas of bacteria beds. The low-level works consist of four septic tanks of 2,640,000 gal. capacity, and 5¼ acres of bacteria beds. These beds have walls of 14 in. of brick reinforced every 12 ft. by buttresses. They have concrete floors 6 in. thick with 6-in. semi-circular drains 6 ft. apart to carry off the effluent into a chamber where provision is made for allowing samples to be taken from the discharge of each ¼ acre. The filtering material consist of saggers, or refuse from the potteries in the vicinity. The beds are 4 ft. 9 in. thick and the material ranges in size from 2½ in. at the bottom to a top layer of particles from ¼ to ⅛-in. in maximum diameter.

The New Steel Plant at Gary, Ind., is to be developed immediately on an even greater scale than was originally contemplated, according to a statement issued last week by the United States Steel Corporation. The original appropriation to provide for the construction of the steel plant and the municipal works of the new industrial town adjacent to it was $75,000,000. The recently issued statement announces that an additional $45,000,000 has been set aside to be used in widening the scope and extent of the steel plant proper. Since the very extensive municipal works of the new town, which were described in The Engineering Record for July 20, 1907, are practically completed, and the vast amount of preliminary work required to develop the site of the steel plant is well under way, the additional funds will accordingly all be available for buildings and equipment for the steel plant. When it is considered that in the neighborhood of $120,000,000 is to be expended at once in forming this nucleus of the new industrial center at the southern end of Lake Michigan, the magnitude which that center may be expected to assume within the next few years is difficult to overestimate.

A Buttressed Concrete Dam.

The Beacon reservoir, a part of a gravity system of water supply, is situated just above West Point, N. Y., but on the opposite side of the river, on Mount Beacon, some 1,200 ft. above the high water level of the Hudson River, immediately back of the village of Matteawan, and was built for storing and furnishing a portion of the water supply for Matteawan, Fishkill-on-the-Hudson, the New York State Hospital at that place, and some important manufacturing establishments.. A storage reservoir is of course calculated to equalize the run-off-from the water-shed and the variations in the quantity of water flowing in the stream so as to produce so far as practicable, a sufficient supply the year through. The capacity of a storage reservoir, to be completely efficient when situated upon a moderate or small stream, should amount to the daily consumption multiplied by the probable number of summer and fall days during which the stream will be practically dry, or at least very much lower than the needed supply calls for; that is, during the hot months of August and September certainly, and perhaps during July and October as well, so as to provide against the actual use and wastage of water, besides the evaporation and whatever, if any, unavoidable leakages there may be from the reservoir itself and its conduits.

Also, the matter of spillway where the heavy rush of storm water is far above the ordinary flow of the stream needs careful attention, and, although the average rainfall per annum for the part of New York State under consideration is only about 48 in., it will be necessary for safety to provide spillway capacity for an impounding reservoir sufficient for the easy accommodation of the greatest quantity of water possible to reach such a spillway at any time; and this necessity was dramatically illustrated in a rather startling manner a few years ago at this very dam, when, in its form of construction previous to its present rebuilding and enlargement, the entire length of the dam was overtopped by a flood of storm water from an extremely heavy thunder shower, commonly called a cloud burst. In the reconstruction and increase in the height just finished, the new spillway was calculated for the heaviest known rainfall upon the water shed, was doubled in length, and was made about four times as deep as before, so that in all probability the area of watershed available, will be fully accommodated under the most extreme circumstances of storm water and run-off. From records kept since 1866 it is no doubt safe for supply to reckon upon 38 in. of water as the minimum rainfall for any year in this region, as 38 in. is the minimum for the period from 1866 to 1898, and very likely this amount will be greatly exceeded most of the time, and it will certainly be exceeded some of the time, as the average rainfall is 48 in. during the above-mentioned period for the Hudson Valley, from say, 10 miles south of West Point to 10 miles north of Newburg. The greatest rainfall for this period was 63.51 in. in 1888, the least rainfall was 38.33 in. in 1895; during 16 years of the 33, the annual rainfall was above the average, and during 17 of the years it was below the average. In 1869 and in 1891 it was very close to the average, just a trifle above; it was below 40 in. only two of the years, 1880 and 1895; and was below 44 in. during 8 of the years, 1872, 1873, 1874, 1875, 1876, 1880, 1883 and 1895.

The watershed of the Beacon Reservoir, on account of its lofty situation, is of so moderate an area that there is a limit to the profitable dimensions of the dam, but from the short and rapid run-off, the rock nature of the watershed surface, etc., it is no doubt safe to calculate upon 65 per cent. of the rainfall as available for collection in the reservoir. The water falling as rain upon the surface of the reservoir to the amount of 100 per cent. would not quite cover the evaporation for the low year, and the low year with corrected evaperation will yield a storage of 103,000,000 gal. For the average year there will be a yield of 134,000,000 gal. from the shed, and about 2,000,000 gal. over and above the evaporation from the surface of the reservoir, making in all say 136,000,000 gal. of water available for an average year.

The above figures indicate that the original height of the dam, which was 23 ft. above the bed of the stream, was about 6 in. higher than was actually necessary for the lowest record of rainfall; was more than 4 ft. too low for the collection due to the average record of rainfall; and could be filled if 12 ft. higher than originally built, at the high record rainfall of 1888. There might be some slight variations from these figures, probably towards the high side, but they are according to the best-known methods for determining such facts. The original dam might have been built for the low record, if not built previously to 1888, for in that year the rainfall was nearly down to the lowest (shown in 1895) for the 33 years. The Beacon is a reserve supply calculated to fill between November and the following July, against the time when the other gravity supplies of this system fail in the summer months, and it must be considered that it is not necessarily emptied every year and therefore the dam could be higher than the figures actually indicate for a complete filling, especially as a wet season preceeding and succeeding a dry season would give a larger storage than the average, and with even two dry seasons successively, a very large storage at the start would be of great advantage. Considering all of the facts, it was deemed good judgment in concluding how much higher it would pay to build the dam for the accommodation of this rather limited watershed, to take advantage of the average rainfall in excess of 48 in. (48 in. being the average for 33 years) as a basis for calculation, and this was found to amount to 54 in. Then allowing for evaporation, it was determined that the dam could be raised 7 ft., giving a total storage of 186,000,000 gal., including the new slopes to be covered by the rise of the water level. Therefore the plans and specifications were prepared for an increase of 7 ft. above the original height of crest, and made of sufficient resisting power to permit of still further height being obtained, in case it was found that the run-off from this unusally rocky and impervious watershed proved to be of still greater percentage of the rainfall than had been allowed for.

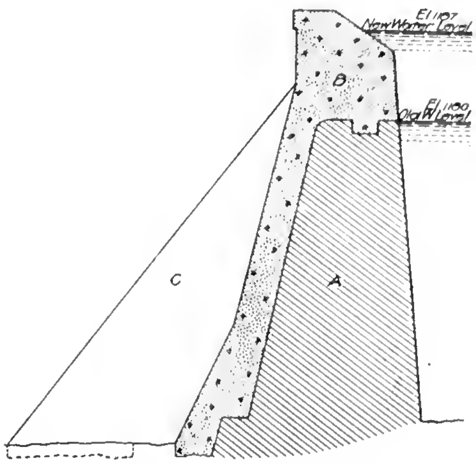
The accompanying diagram shows in the diagonal shading *A*, the typical or full section of the original dam, built of trap stone quarried near the site. The portion *B*, of the figure, indicating concrete, shows the addition to the dam in its fullest section, and also an outline *C*, of the buttresses. It will be noted that there is a groove or dovetail cut into the top surface of the original dam to provide a cut-off for the water and also to completely lock the old and new work together; also that the outer edge of the older dam is rounded to add strength to the concrete jacket at this point.

One of the views illustrates the method of putting up the forms for ramming the concrete in during construction, it being thought best to place all of the necessary forms at once, instead of ramming and shifting as is often done in concrete work; the complete series of forms permitting a continuous building of the work which was considered to give a better and closer knit character of fabric.

Another illustration gives a view of the enlarged and completed dam, showing the but-

tresses and spillway at the downstream face, and it will be noticed that the original dam is completely covered up and hidden by the buttressed reinforcement of concrete which now really forms the dam at the downstream side. The back of the original stone dam, or the side not here seen, still shows beneath the line of the new concrete work, but at some future day it will probably be sheathed either with concrete or new stonework, as this older work heretofore gave evidence of considerable leakage through the masonry, which although practically stopped by the front facing will be further improved by a new back lining.

The original stone dam was built probably over twenty years ago, and was located upon a solid rock foundation bed, the rock extending well up the slopes at the ends of the dam, in fact to a sufficient height for the safe support



Section of Enlarged Dam.

Completed Dam of the Beacon Reservoir, Matteawan, N. Y.

of the new work. The original spillway was simply a shallow notch of very moderate length formed through the crest of the dam near the middle of the length, and permitted the outflow to fall from the top to the bottom of the dam at its greatest height of section. The spillway for the new work is of very liberal dimensions and is situated at the easterly end of the dam where the fall of the outcoming water is comparatively little and where a natural rock bed forms an excellent passageway for the storm water coming over the spillway, down to the stream bed below the dam.

The new concrete structure is about 350 ft. long and 33 ft. high at its greatest depth of section, the depth of the water immediately back of the dam being about 30 ft. The peculiar

Engineer's Estimate on Beacon Dam Rebuilt, at Matteawan, N. Y.

Quantity of concrete in place in completed work	1,500 cu. yd.
Concrete mixture—1 cement, 2½ sand, 5 crushed stone.	
Quantities of materials—	
Cement	2,400 bbl.
Sand	6,000 "
Crushed stone	12,000 "
Cost at the dam—	
Cement per bbl., bags	$1.85
Sand per cubic yard	4.50
Crushed stone per cubic yard	5.00
15,000 ft. B. M. lumber	450.00
Labor on lumber	600.00
Estimated cost of the dam—	
Crushed stone	$7,500.00
Sand	3,375.00
Cement	4,440.00
Labor	2,070.00
Forms for concrete	1,050.00
Foremen, expenses, etc	1,065.00
Stone cutting	500.00
Valves and fittings in place	165.00
	$20,165.00
Contractors profit, expenses, etc., 10%	2,016.50
Total of estimate	$22,181.50

buttress design was suggested naturally enough by the extremely high cost of material delivered at such an out-of-the-way site; the prime object being to reduce the amount of materials to the lowest terms, the labor being quartered upon the premises reaching scarcely above normal. Materials such as cement, sand, crushed stone and lumber at the ordinary points of rail and water delivery were reasonable enough in price, but transportation to the site of the work was nothing less than heroic in character, and brought the costs of such materials up to the figures exhibited in the accompanying estimate.

In round numbers, this is $23,000, and the contract was let for about 7 per cent. less.

This estimate was made in the spring of 1904 just after prices of all kinds of materials had begun to fall; they have gone considerably higher since that time, but even at present prices the above given cost would probably be safe. Considering the difficulties of transportation up a grade of 1,200 ft. within 2 miles, the contract price for the work was considered quite satisfactory, to the buyers at least; a part of the saving on the cost of the dam was probably due to the fact that the successful bidder calculated upon taking a stone crusher up to the work, which he did, and as the trap rock was obtained upon the premises without any cost to him, he also saved the cartage upon a good many tons of material, bearing only the small expense of operating the crusher.

The concrete improvements were designed, and the plans, specifications, and estimates were prepared by Mr. Charles A. Hague, Mem. Am. Soc. C. E., consulting engineer, New York.

A Stream Pollution Decision.

The pollution of streams by mining operators was recently before the Alabama Supreme Court in Ala. Con. Coal & Iron Co. v. Vines, 42 Sou. Rep. 377, when it was decided that, though mining companies may use a stream for mining purposes, they must not place in it anything which will materially pollute the water where it passes the land of a lower riparian owner, or which, being deposited on his land, by an overflow of the stream, will injure the land. The

Forms for Buttresses and Addition to Dam in Place.

measure of damages due to coal dust deposited by such an overflow includes loss of crops already sustained, as well as permanent injury to the land, though the loss of crops cannot be added to permanent damages as such.

Economical Methods of Highway Bridge Construction.

The constantly advancing prices for all kinds of timber have made the cost of falsework expensive for light bridge erection, and serious study has been given to different methods for reducing it. A novel and ingenious scheme for making wooden falsework adjustable to different heights and adapting it to be used over and over again for successive bridges, so that it is shipped from place to place like hoisting engines or other parts of the bride erector's appliances, has recently been developed and satisfactorily used by the York Bridge Co., of York, Pa., Mr. Guy Webster, President, and Mr. F. W. Bigger, engineer.

For ordinary work transverse bents are made with two vertical and two battered posts 10x10 or 12x12 in. The timber for these is purchased in as long lengths as are available and the joints between successive stories at each end of the transverse horizontal struts, corresponding to the caps and sills of ordinary construction, are made with a pair of steel plates about 18 in. wide and 5 ft. long in vertical planes with their long dimension horizontal. Vertical 12-in. channels 18 in. long are riveted across one side of each plate with clear spaces of 1 in. between them, and the 1-in. spaces are punched for 7/8-in. horizontal tie bolts connecting the pairs of plates on opposite sides of the horizontal struts and of the vertical posts.

The vertical and battered posts and horizontal struts are arranged side by side between the inner faces of the plates and the latter are clamped very tightly together by bolts passed through them in the spaces between the timber. These can be drawn up tight enough to develop friction sufficient to hold the entire load on the falsework and thus enable the connection to be made absolutely without cutting or boring the timber and provides for it to be made at any point of the vertical posts, thus enabling the latter to slip past each other and make a telescopic joint which permits of any height of falsework within the limits of the length of the material. The plates have slotted holes to receive the hook ends of diagonal rods with sleeve nut adjustments and with sections made with pin-connected flat bars enabling the lengths of the diagonals to be varied by increments of 3 in. in the pin holes and of smaller distances by the sleeve nut adjustments. Falsework assembled with these connections has been found very rigid and satisfactory and has been taken down and moved from one site to another with greater economy and convenience.

An important advantage of this type of falsework is the opportunity it affords of compensation for any irregularity of settlement in the different posts. If one of them goes down farther than the rest, or if irregular scour exists underneath it, it is very easy to loosen the clamp bolts adjacent to it, insert a jack on top of it with reaction pieces reaching up to the next joint, and force it down readily as far and as often as may be required without interfering with any other part of the falsework. The adjustable diagonals also lend themselves very satisfactorily to the distortion of panels and can be changed as often as the falsework may require it to provide for settlement or any other variation in the panel.

This falsework is erected by a special traveler with a horizontal rolling platform and two stiff-leg derricks mounted on the forward corners with sufficient reach to overhang one panel in advance, and sufficient strength to lift together a completed bent of falsework, and put it in position. The steel work is erected by a second 2-bent traveler running inside the trusses and provided with four booms, one at each corner. The bents have no bottom transverse sills, but are connected by longitudinal top and bottom sills and X-bracing. Their transverse X-bracing is arranged so as to give clearance enough in the center for material cars to be run through the traveler on a track laid between its posts, and thus deliver directly to the forward booms. The hoisting and topping-lift tackles of each boom are operated by separate individual electric hoists making altogether 8 for the traveler, besides which there is an additional hoist suspended from the jigger beams at each corner of the traveler, making a total of 12.

The hoists are of special construction, designed by the York Bridge Co., and manufactured for them by the Westinghouse Electric Co. They consist essentially of a small drum with spiral grooves to guide the steel cables used. They have pinions integral with them which engage a worm thread cut on the shaft directly connected to the motor, the latter being made special for the purpose and adapted to instant reversal. This arrangement keeps the load always under absolute direct control with no possibility of back-slide or overhauling, allows the motor to be started and stopped at any point or to be reversed instantly and dispenses with the use of brakes, friction clutches, and other complicated parts of an ordinary hoisting engine. They are so simple that they require little or no attention, and do not suffer when exposed to severe conditions and inclemencies of very bad weather. The same hoists are used on the derricks of the falsework traveler and for all other hoistng purposes in the erection work done by this company.

The erection appliance considered standard for bridges of any magnitude includes a boiler plant shipped direct to the site and installed in a special power house built for the purpose at any convenient location on shore near the bridge site. An air compressor driven directly by steam is also installed there and a Westinghouse generator of 35 k.w. capacity furnishes the electricity for operating all of the hoists and makes the plant entirely independent of local electrical power. Riveting, reaming, and steel drilling are done by tools built by the Cleveland Pneumatic Tool Co., and facilities are thus provided for handling highway bridge erection as rapidly, economically and thoroughly as is customary with railroad work. A recent bridge erected with this plant is the State Bridge at Berwick, Pa., and another, now in course of erection, is a fourteen-span bridge at Sunbury, Pa.

Steel Inside Traveler with Twelve Hoists.

The Berwick bridge, across the Susquehana River, is 1,800 ft. long and carries a highway at an elevation of about 60 ft. above the water and on a 1½ per cent. grade. It comprises six 250-ft. channel spans and three 100-ft. approach spans with a roadway 22 ft. in the clear carried on transverse wooden joists, and contains about 3,000,000 lb. of steel and 270,000 ft. b. m. of lumber.

The very irregular river bottom is of shale rock with vertical seams filled with gravel and coal culm which washes in and out with varying stages of the water. A survey and careful soundings were made for each of two lines parallel with the bridge axis and 10 ft. distant from it in the planes of the falsework vertical posts. From these data profiles and cross sections were prepared and the falsework was accurately designed to suit the location. All posts were made with

8x8-in. timber with the corners slightly chamfered to fit the fillets of 8-in. channels riveted to the insides of the clamp splice plates previously described. The posts were assembled with struts and diagonals complete in horizontal planes near the traveler track. They were run through the traveler on trucks and lifted and swung forward one panel in advance by the traveler booms which maintained them in a vertical position until their lower sections were driven to solid bearing by a hammer (consisting of a 6-ft. section of old rail or equivalent weight), operated by a whip line from the hoisting engine and guided by a man standing on the joint. The braces and diagonals were connected making the bent stable, stringers and track laid and the traveler advanced to the next panel and so on. In each bent the center transverse strut was pin-connected to the splice plates on the first post and at the other end was temporarily lashed to the top of the post. The lower strut was similarly connected to the other post, so that when both posts were in position it only remained to add the top strut and longitudinal braces.

The falsework traveler was made of steel with clearance through it for material cars and had two-story rear extension platforms on both sides for the four electric hoists which operated the booms and were all controlled by one man on the bridge platform overhead, where he could see all parts of the work. The falsework posts were lifted and swung out by both booms together, after which one tackle was slacked off faster than the other to drop the foot. This traveler was also used to erect the low trusses of the approach spans.

Material was unloaded from the cars by an 80-ft. guyed steel derrick, which arranged it in assorted piles and loaded it without unnecessary handling on the service cars which delivered it to the erection traveler. This traveler, also of steel, is about 60 ft. high, weighs 20 tons, and has four wheels. It is of adjustable width and in this case was framed with a width of 16 ft., leaving 3 ft. clearance on both sides with the trusses. Small working platforms on both sides are adjustable to any heights convenient for making the truss connections, and the twelve electric hoists are all controlled by one man on the upper platform. The traveler was provided with arc lights run from the dynamo in the power house at the end of the bridge, and used early in the morning and late at night of short dark days. Before the trusses were assembled by the main traveler the floorbeams and joists were set by the falsework traveler, great care being taken to place them very accurately, for which purpose they were adjusted to line and level by an instrument set up on the pier masonry. After the trusses were swung the falsework bents were removed by tackles suspended from the superstructure; their removal and transfer from one span to the next proved to be a difficult and expensive task.

The erection of this bridge was described and illustrated in an interesting and valuable address made by Mr. Webster at the annual meeting of the Bridge and Structural Society at Chicago, Jan 15 and 16, 1907. He spoke from a practical and commercial standpoint and strongly urged the importance of careful investigation and study, thorough preparation and the best and strongest appliances for erection work. He criticized the tendency to dispense with permanent erection organization and asserted that a good erection is the best salesman. Careful examination of all conditions, analysis of the requirements and provision in advance for all successive stages and operations of the work are essential to satisfactory work, and it is economcal to make new appliances of ample size and strength. He emphasized the superiority of a poor idea well planned over a better idea with no preliminary thought, and advised a system of accounts classifying the costs of different items of the work. He suggested improvements in removing and transferring falsework and in a light traveler that should be adjustable to pass under transverse struts, for painting, riveting, etc., at any height.

The Pig Iron Output of this country during the first half of the current year was 13,478,000 gross tons, the largest production during six months in the history of the American industry, and greater than any year before 1899.

A Submerged Power Station.

A submerged power station that rivals in interest, although much smaller, the famous plant constructed at Snoqualmie Falls a few years ago has recently been put in operation on the Patapsco River, near Ilchester, about 15 miles from Baltimore. It is the first example of a type of power station which the designers, the Ambursen Hydraulic Construction Co., of Boston, and Mr. H. Von Schon, of Detroit, consulting hydraulic engineer, have suggested for a number of places. In reinforced concrete dams of this type, there is a large space within the structure, and the desirability of utilizing this space for power machinery is evident in those cases where other local conditions do not permit a greater head to be developed by constructing the station elsewhere.

The cross-section of the dam near Ilchester is shown in the accompanying cut, which also indicates the position of the water wheels. The dam is 220 ft. long and 26½ ft. high from normal tail water to the overflow of the spillway, which is 168 ft. long. At each end of the spillway the buttresses and deck are carried 10 ft. above its crest, making a total height of 36½ ft. at these places. The buttresses supporting the deck are 12 ft. apart on centers, 2 ft. thick at the bottom and 16 in. thick at the top. The deck is 18 in. thick at the bottom and 10 in. at the top and reinforced with corrugated bars in the usual manner adopted by the builders.

The apron extends only half way down from the crest, the remaining downstream portion being entirely open and provided with windows so that the interior may be lighted. The shape of the apron is such that the water is thrown away from the windows, and, on a clear day the illumination is all that could be desired, although it is poor during rainy weather and at times when the water is muddy.

The water-tightness of such a station has to receive special care, because electrical apparatus will not give the best service in the presence of considerable moisture. Up to the present time no trouble whatever has been experienced from dampness at this plant. The concrete of the deck is a 1:2:4 Portland cement mixture laid very wet, but without any particular precaution to insure tightness. Nevertheless, very little water finds its way through the concrete, and that little trickles down the under surface of the deck to a drain at the bottom. In order to make it certain that no water falls on the equipment of the station, 108 ft. of the dam which houses the power plant is fitted with a false ceiling, as shown in the cross section. This completely protects the apparatus.

The station contains two 34-in. horizontal Leffel wheels with Woodward governors, each wheel direct-connected to a 300-kw., 11,000-volt, three-phase, 60-cycle alternator. Each alternator drives by a belt a 125-volt exciter. The water for the wheels is taken from the deck of the spillway about 5½ ft. below its crest, through a 7-ft. flume, which runs directly into the shell of the wheel. It is discharged from the latter through a draft tube carried down into a well about 3 ft. below the river bed, from which it flows away through a channel cut in the rock. The advantage of such an arrangement in eliminating losses due to long pipes and bends is manifest.

The plant is owned by the Patapsco Electric & Mfg. Co., Ellicott City, Md., and supplies current for lighting and power purposes.

Permanent Bench Marks established by the City of Chicago in 1898 have settled in the district honeycombed by the operations of the Illinois Tunnel Co., but not elsewhere.

Letters to the Editor.

Results at the South Bethlehem, Pa., Filter Plant.

Sir.—The following are the results of the bacterial analyses of the water furnished by the Bethlehem City Water Co. to its consumers, as per reports submitted by Mr. F. W. Green, bacteriologist of the East Jersey Water Co., Little Falls, N. J., to Dr. H. S. Drinker, president of Lehigh University, South Bethlehem, Pa.

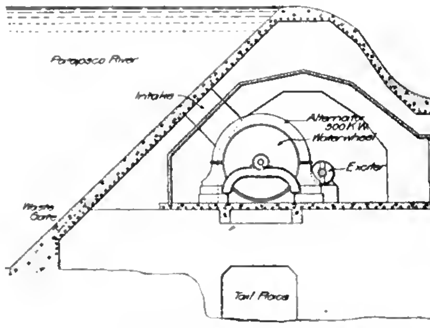
[The South Bethlehem slow-sand filter plant was described in detail in The Engineering Record of July 15, 1905. It was designed by Mr. P. A. Maignen and has an ultimate capacity of 4,000,000 gal. per day at a uniform rate of about



A Submerged Power Plant.

7,000,000 gal per acre per day. The settled water is passed through preliminary scrubbers before it is delivered to the slow-sand filters.]

The Topographical Party.

Sir—I have noticed that the most disputed topics in a railroad preliminary camp in mountainous country are the proper organization and the methods of the topographical party. The reason is largely because many of the men were educated on prairie work and try to introduce the methods to which they are accustomed.

Many of the older railroad surveying manuals and field books give a somewhat elaborate organization for the topographical party, and prescribe the duties of topographer, assistant topographer, rodman and tapeman. Most field engineers have concluded that such an organization is not economical and on many roads, where hand level and tape are used, the party consists of two men. While it is true in general in open flat or gently rolling country that the four-man party is unnecessary, it may not always be true in mountain districts. Where there is little sketching to be done, a topographer and a rodman can do fairly well in open country where there are few buildings, and contours are taken for only a short distance each side of the center line. But, on the contrary, where much sketching must be done the opening of the note book and fumbling for a pencil every few feet is costly in time, and tends toward slovenly note keeping, while the amount of detail work required of the topographer introduces a considerable liability to error.

But not satisfied with using the two-man party in its proper field, level country, the prairie-educated engineer when transferred to the mountains often fails to recognize the new conditions and sticks to his pet organization, arguing that it saves in the total number of men on the work. He does not recognize that the vital points are the cost of the survey per mile, and the reliability of the data, and on these bases the three or four-man party demands consideration. I have seen mountain preliminary parties laid up one or two days every week in order that the transitman and the levelman might help the topographer catch up in his work. Many engineers fail to recognize the value of specialization and expect the transitman and levelman and their crews to take as much and as good topography in a day as the topographical party. In few cases is this realized. Of all the positions in the field, that of topographer requires more experience and the greater exercise of judgment than any save that of locating engineer or chief. This practice of "catching up" has the further disadvantage of breeding discontent among the cheaper men on the party, who, as a rule, dislike topographical work.

From the writer's experience a return to the larger organization of the topographer's party is desirable in mountain country for economy and improvement in the quality of the work. The topographer should be given at least three men, and where the mountains are steep and the brush thick, four men, the last man carrying an ax and acting as rear tapeman when there is no cutting to do.

Any man of ordinary intelligence can be taught to use a hand level with accuracy and a $50-per-month man once given the height at the center line above or below the contour can pick out the succeeding contours with more reliability than the topographer himself, since his sole duty is to carry his elevations, while the topographer must sketch, note the character of the land, and record all the data. A 5-ft. stick, on which to rest the hand level, and a 7 or 8-ft. rod, with the alternate feet painted in different colors, are the best "instruments" in mountainous country.

The rodman in going uphill acts as head tapeman and the topographer, levelman or extra man, when one is provided, reads the tape. Going downhill the levelman drags the tape, and one of the other men reads it. The most rapid work can, of course, be done with two tapemen and a hand levelman, in which case the topographer does nothing but handle his note book. But even with three men the topography in quite hilly country can be kept up pretty well. This saves laying off both transit and level parties, a costly procedure, and requires only one or two extra men, depending on whether three or four men are used in taking topography, at the lowest salary paid, the regular topographer's rodman acting as hand levelman. I have heard it objected that a rodman is not paid to bear the responsibility of a levelman, but the average rodman is able and anxious to do the work.

The improved quality of the work can be judged when it is considered that under the two-man method the topographer acts as levelman and carries his elevations in mind, reads the tape and carries distances metally, records all data, sketches, and makes necessary topographical notes, while with three or four men his duties are confined to sketching and recording.

Very truly yours,

Transitman.

Missoula, Mont.

Condenser Troubles in a station having two surface condensers employing sea water for cooling have been overcome by placing pencils of zinc about 6 in. long in the suction chamber. Formerly the galvanic action between the iron base and the other metals in the condensers led to the rapid corrosion of the iron. This has apparently ceased entirely since the zinc pencils were introduced, although the latter are eaten away rapidly.

SUBSCRIPTION RATES.

United States, Cuba and Mexico..........$3.00 a year
Canada..................................$4.50 a year
Foreign subscription....................$6.00 a year
25 shillings. 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGES OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,250 copies are printed. Total circulation for 1907 to date 507,750 copies, an average of 14,507 copies per week.

TABLE OF LEADING ARTICLES.

The Function of Light Railways.

No country more than our own has felt the need of a complete transportation system and none has more railways to show for it. Yet it is a fact that even in old and rather densely populated sections transportation is very unevenly developed, leaving large districts without adequate facilities. Railroads have grown over the country in a sprawling, irregular fashion ever since the zig-zag war dance of the Union Pacific over its land allotments. The result is that while the major transportation is fairly well taken care of, barring delays of six or eight months in side-tracked freight cars, the minor transportation that affects most intimately the life of the people as a whole has been in many cases badly neglected. Until the coming of the electric railway, rural communities had little chance for decent service, and even now they have not received the full benefits that are their due. Many interurban roads have been been built, it is true, but generally with an eye to important termini rather than to the intermediate country. There is a splendid service to be done by rural roads when the situation shapes itself so that they can be profitably built. The greatest present obstacle to this improvement is a certain species of megalomania among both promoters and the people to be served.

So far as the promoters are concerned they are naturally enough looking for profits. If they would confine themselves to operating profits all would be well, but the bankers who stand behind them are looking not so much for hard earned dividends as for a rake-off on the roads they underwrite. The practical question often asked is not how the proposed line can show the best earning capacity on the investment, but how large a bond issue it can stagger along under with due allowance for the probable growth of traffic. On the other side, it is hard for the enterprising citizens of Luggage City to realize that their town, population 2,311, is not to become in due season a metropolis second only to Chicago or St. Louis. Hence they view a franchise for an electric line through the main street as the source of indefinite future wealth, not to be granted without large concessions. When a railway proposition comes along through the country, it is hard hit by the local authorities, and having something of a swelled head itself, the total cost rapidly mounts to a figure that is entirely inappropriate save for a line between really important centers. Electric roads can be, but seldom are, built at cost low enough to secure adequate returns in sparsely settled communities, and until their cost can be kept down they will fail of their maximum usefulness. Now and then a light road is built with a proper appreciation of its legitimate functions, and it nearly always proves extremely valuable to its patrons and reasonably profitable to its promoters.

When a community is approached with a proposition for an electric road to bring it into communication with its neighbors, it may reasonably and properly ask good service and ordinarily favorable fares. It may also very properly insist that the capitalization on which the road must make its earnings out of the community shall represent a real investment in money or its equivalent, and that its projectors shall build and operate the road for legitimate transportation and not as a stock-jobbing proposition. If this is assured the community can very well afford to work hand in hand with the projectors and take its profit in increased business and valuation without demanding any considerable direct return from the franchise. In this way the community and the road are in a species of informal partnership that leads generally to good results. It has often happened that a well planned road has increased the value of property along its line to an extent that more than balances the cost of construction. This benefit is too often forgotten in striking a bargain for the future. A town gains far more in this way than does the railway, and, therefore, can afford to be generous. But the town should insist that the earnings to which it contributes shall be based on investment and not on water. To this end it should seek skilled advice on any propositions with which it has to deal and hold the project down to a conservative basis before it enters into any alliance whatever. If the promoters squeal when asked to squeeze out the water, they disclose their intentions at once and the more quickly they are thrown out the better. If they are willing to put their enterprise on a conservative and honest basis, the community will gain by helping the cause along in any proper way. Some of the best lines have been built with local aid in the taking of securities by enterprising citizens and when a proposed road starts in such wise it is pretty sure to give the community a square deal. But beware of the concern that places its bonds with a construction company and tries to unload its stock (very common stock) upon local investors.

The Clermont and the Lusitania.

It was on August 17, 1807, that Fulton's "Clermont" made her trial trip, at an average speed of about 5 miles an hour. She was 133 ft. long and measured 160 tons by the custom-house rules of that day. Her engine had a single vertical cylinder, which drove the side paddle-wheels through connecting rods and a bell-crank lever, and was rated at 19 h.-p. She was not the first steamboat, by any means, nor was she the first vessel propelled by steam to run in regular passenger service. Fitch drove a small boat by steam in 1786 and a larger one during the following year, the engine in each case actuating paddles on each side of the hull. In 1788 he built a third boat and 1790 a fourth, which was placed in passenger service between Philadelphia and Trenton for some months, probably being the first steam vessel to undertake such business. Rumsey built boats in this country and England about the same time as Fitch, and Patrick Miller also did the same in England. In 1802 the "Charlotte Dundas" made successful trips on a Scotch canal. Col. John Stevens' twin-screw boat of 1804 is almost as well known as the "Clermont," so it is evident that the achievement of Fulton has brought him enduring fame for some other reason than that of a strikingly original invention.

Almost one hundred years after the trial trip of the "Clermont" the new Cunard steamer "Lusitania" was given a series of trial runs that a good many marine engineers regard as equally significant to that on the Hudson a century before, in their influence on floating steam plant of high grade. This enormous ship, which will shortly start on her maiden voyage to the United States, is 785 ft. long over all and 760 ft. between perpendiculars. She has a molded breadth of 88 ft., a depth of 60⅓ ft. and a gross rating of 32,500 tons. She has accommodations for 552 first-class passengers, 460 second-class and 1,186 third-class. Her turbine engines have a nominal capacity of 68,000 h.-p. and she was designed for a speed of 25 knots. She is unique only in her great size, but this is not her important feature, which is the adoption of turbines under conditions far more severe than anything hitherto imposed on engine builders. The splendid showing made by this ship on her trial runs, when all contract requirements were exceeded beyond the expectation and even the wildest hopes of owners and builders, is a very significant indication of the fact that engineering will find some new tool or process to overcome difficulties that are insurmountable by anything available among past precedents. The "Lusitania" is very far from being the first turbine-driven ship, for many of them have been in service in the waters about Great Britain and some in the trans-Atlantic trade. But the problem presented to the designers of the "Lusitania" and her sister ship was not one of merely reaching forward from the safe footing of experience with these existing turbine vessels, but to make a bold jump for a distant goal, reaching which would be success,

but failing which would be a disaster of the most serious kind. It is a tremendous advance from the 36,000 and 38,000 h.-p. rating, 23,600 and 26,000 tons displacement and 23½ knots maximum speed of the crack German liners to the 68,000 h.-p., 38,000 tons and 26.45 knots of the new Cunarder.

These two events in marine engineering gain their significance from their timeliness. Fulton was a great adapter and improver, as well as an inventor, and he was aided by Robert R. Livingston, whose business ability supplied the incentive for the "Clermont." The latter foresaw what steam propulsion would mean if commercially successful, and in 1798 he had secured from the New York legislature an exclusive franchise for the navigation of the Hudson by steamboats. It was the existence of this franchise which compelled Col. Stevens to abandon his project to establish steamboats on the river, for which service he completed, almost as soon as the "Clermont," the "Phœnix," which is credited with having made the first deep-sea voyage under steam in her trip from Hoboken to Philadelphia in 1809. Fulton and Livingston together were masters of the art of utilizing and improving existing apparatus and finding a commercial purpose for it, and were thus real captains of industry, in the modern sense. In the same way, it may be said that the owners and builders of the "Lusitania," with their technical staffs, have accomplished a great beneficial work. Just as Fulton and Livingston showed that commerce need not be fettered by the caprice of the winds but could utilize to its advantage the steam engines which had already thoroughly established themselves on land and made some attempt to win recognition afloat, so the British shipmasters and shipbuilders have proved that commerce need not be fettered by the limitations of the reciprocating engine, but will find in the steam turbine a means of driving ships as large as harbor channels will admit and as fast as passengers will pay to be carried. The beautiful ship recently turned out from the Clydebank yards may therefore be considered to open another century of marine engineering with a promise of achievements that cannot even be sensed now.

Grade Crossing Elimination in New Jersey.

The crossings of railways and highways at grade in New Jersey have a number of features that make their elimination a matter of more than usual difficulty. There are many of them in the State, as might be expected from the great railway mileage per 100 square miles and the early date at which a large part of the lines were constructed. These death traps are now numerous in districts which had only a few country roads when the railways were built, and, in many cases, the crossings have been put in at grade against the vigorous protest of the companies. Their danger was appreciated by the railway officials, but the county and town authorities failed to foresee it, and consequently there has developed a sort of disregard, as something inevitable, of fatalities and injuries due to the collision of trains with vehicles. Recently there has been some local half-hearted opposition manifested in a few places to a continuation of these serious conditions, but no real study of them has as yet been undertaken except by the railways themselves. The latter have already carried out some extensive works at a heavy expense, the most recent undertaking being the elimination of grade crossings on a large part of the Morris & Essex division of the Lackawanna R. R. This elimination work has only been begun, however, for in the places where grade crossings are most dangerous it is extremely difficult and expensive. In these districts there is an enormously heavy train movement at certain hours of the day, when people are traveling between New York, Jersey City, Hoboken and Newark and their suburban homes. Any interference with this passenger traffic affects a large number of people, many of them men of large affairs whose time is extremely valuable. It is also necessary to keep streets open in some way at many of the worst crossings, for otherwise serious inconvenience would result to important business interests.

A new State Railroad Commission has recently been appointed, which has shown indications of a desire to take up the problem of eliminating grade crossings, along with other features of railway affairs. It is a matter of considerable doubt just what powers this body posessses, for it was created by the legislature in a hastily drawn and manifestly crude act. In some respects, it is apparently merely an advisory commission, but it seems to have definite authority to order railway companies to make such reasonable changes in their roadbeds, tunnels and bridges as it considers in the interest of safety. Whether it can compel the companies to execute such orders remains to be seen, and it is open to question whether the elmination of grade crossings can be legally included under such a classification as that mentioned, for grade crossing accidents rarely hurt the train crews and passengers whose safety is supposed to be the purpose of this provision in the legislative act. It will be a good thing, however, for the commission to ascertain by test cases as soon as practicable just what powers it has, for until it has done so its work will be of problematical value. It seems certain that some State commission should have liberal powers in connection with grade crossing betterments, in order that the problem may be thoroughly investigated as a whole and the work may be directed in the interests of the people of the whole State rather than those of a single city or borough. It is often impracticable to alter grades materially in one city without introducing conditions that make changes necessary elsewhere, for otherwise a succession of short ascents and descents will disfigure the profile of the track. As conditions are now, one community can make so much trouble that improvements affecting the safety of travel in an entire district are held up indefinitely. The law should be so drawn that the commission will have power to authorize a railway company to go ahead with an important improvement under such conditions, leaving the settlement of the disputed matters to arbitrators whose decision shall be final.

For some reason that it is hardly worth while to attempt to discover, there is an apparent prejudice against any division of the expense of grade-crossing elimination between the railway companies and State and local treasuries. Whether this feeling really is a general one, or is held only by that portion of the community which supports the local newspapers expressing it and is not shared by the much more influential suburban population of the Northeastern part of the State, is open to doubt. It seems to be the prevalent opinion, however, and it ought to be generally made known that until this opinion is materially altered the progress of grade-crossing elimination will be distressingly slow. There is nothing equitable about forcing all the expense of eliminating these crossings upon the railways, for in many cases they have been made by local public authorities against the desire of the companies, and in other cases they are the result of the development of a town which has been made possible only by the service given by the railways. In Massachusetts, where more work of this nature has been done than elsewhere, only 65 per cent. of its cost is charged to the railways; New York and Ohio charge 50 per cent. to the companies, and Connecticut and Rhode Island have also made provision for a distribution of a part of the expense among public bodies. There is the more reason for hoping that the equitable practice of other States may soon be introduced in New Jersey for the reason that before long the electrical operation of surburban trains into the terminals on the Jersey side of the North River will become necessary in order to handle the greatly increasing passenger traffic, and the adoption of electrical operation must wait upon the elimination of grade crossings. It would be far better for the traveling public, which forms by far the most important part of the population of Northeastern New Jersey, to bring about something like the Massachusetts system of apportioning the expense of grade-crossing elimination than to continue to obstruct railway work, which is directly in its own interests, by fostering a sentiment not based on justice and equity, but dug up from the wording of old charters granted in the days when a mail coach could give a railway train a good stiff race. The problem is one of present necessities and not a subject for library research into ancient legislation and the opportunities for legal hair-splitting.

Rejecting Low Bids.

It is quite a common impression that in competitive bidding for municipal contracts the award should be made to the lowest bidder, or at least that it should be so made unless there is glaring lack of responsibility. There are, however, many cases in which the statute governing awards not only does not require the contract to go to the lowest bidder, but distinctly charges the awarding power to select such a responsible bidder as will execute the contract to the greatest advantage of the municipality. The City of New York is a marked instance of this kind. Two of its boards at least, one the Aqueduct Commission and the other the Board of Water Supply, act under statutes giving them a wide latitude in the award of their contracts, but laying upon both those bodies a far heavier obligation and a duty of far graver responsibility than if they were rigidly bound to award their contracts to the lowest bidders. As the matter stands, both the Aqueduct Commission and the Board of Water Supply must consider seriously whether they are properly discharging their duties in awarding any competitive contract to the lowest bidder. In other words they must scrutinize most thoroughly and carefully every feature of tenders made to them for constructing the public works under their charge, and determine, in view of all the considerations involved, which offer they will accept. The laws governing their action do not even direct them to make the award to the lowest responsible bidder. It is difficult to conceive of graver responsibilities placed upon public officials in rendering such a kind of service. A political commissioner might consider these conditions admirably adapted to serve his puprose, in favoring his friends, but a conscientious officer will realize that his action under such circumstances must be guided by the most scrupulous regard for the public trust imposed upon him.

Some rather unusual experiences in connection with the contracts under the Aqueduct Commission and Board of Water Supply have lately been observed. It will be remembered that the former body awarded the contract for the Cross River dam to the highest bidder but one, out of five, while the contract for the Croton Falls Dam went to the bidder next higher than the lowest, both awards being in accordance with the recommendations of the chief engineer. The first of these instances was so unusual as to receive approving editorial comment in this journal. The wisdom of the recommendations of the engineering organizations of both the Aque-

duct Commission and the Finance Department of the City of New York has been shown by the present practical completion of the Cross River dam within the prescribed contract time, in spite of serious legal delays for which the contractor was in no way responsible. This is probably the first instance of the completion on contract time of any great public work in the history of the City of New York, or at any rate for so long a period that "the memory of man runneth not to the contrary."

The result of the bidding for the main dams of the Ashokan reservoir apparently placed the Board of Water Supply in much the same condition which confronted the Aqueduct Commission when the tenders for the Cross River dam were opened, with the additional complication of an amount of public money several times larger being involved. As has already been announced in The Engineering Record there were five responsible bidders for this work, the tenders varying from a little above ten millions to a little below fifteen millions, the extreme difference being nearly fifty per cent. of the smaller sum. The Engineer's estimate of the cost of this work is reported to be about two and a half millions above the lowest bid. In other words the latter was probably somewhat under the actual cost of the work, assuming that all the exigencies inevitably developing in connection with such operations are reasonably favorable. When it is remembered that such exigencies are on the whole practically certain to be unfavorable, there is the same practical certainty of a material loss resulting to the contractor who should attempt to execute the contract at the lowest bid. The next highest bid was about $2,300,000 above the lowest. The serious question arose whether the Board of Water Supply should award this large contract at a price below cost, even to parties entirely responsible.

In the first place, as is well known, it is not only desirable but absolutely imperative to bring the Catskill water to the City of New York in the shortest possible time. No person experienced in the execution of contracts for the public works of this city can suppose for a moment that that imperative condition would even be approximately fulfilled by any contractor losing money in doing it. No matter how responsible he may be the work would lag and lag seriously when its prosecution incurs a loss. Further than this, experience has shown with equal certainty that a losing contractor will use every means within his power to recoup such losses. Every contract furnishes opportunities for such efforts, and the larger the contract and the more powerful the contractor, the more those efforts will be made, and the greater will be the success attending them. The final results, therefore, would be a greatly delayed completion of the work with costs so greatly increased over the contract price as easily to overcome the difference between the original bid and that next above it. At the present time heavy judgments against the city have been secured by contractors under precisely the conditions outlined above and this case would certainly be added to those by any contractor doing the Ashokan work at a loss.

The statute governing the Board of Water Supply is absolutely clear in requiring its members to act in the best interests of the city largely independently of the prices bid, and there are already exact and weighty precedents for their guidance. The Board of Water Supply could not have rendered a better service to the city or more wisely have discharged its resopnsibilities than by awarding the contract for the Ashokan dams to responsible contractors of experience in this line of work, as reported in this issue of The Engineering Record at a price which, with good management, will yield a fair profit, even at an apparent sacrifice of $2,300,000 by rejecting the lowest bid.

Notes and Comments.

THE USE OF STREETS by interurban electric cars in Indianapolis was recently considered by the Indiana Supreme Court in Kinsey v. Union Traction Co. The decision was one of the most voluminous ever handed down by that court, but its most interesting feature to city engineers is summed up as follows in 81 N. E. Rep., 922: "A street railway company operating on a city street, for the carriage of freight and passengers, interurban trains of three cars, each 60 ft. in length, at a rate of 20 to 30 miles an hour, thereby rendering the use of the street dangerous and causing the house of an abutting owner 60 ft. from the track to shake so as to cause the plastering and ceilings and the pictures on the walls to fall, and to disturb the comfort of the owner and his family occupying the house, is liable to the abutting owner for the special damages sustained, the operation of its cars in such a manner by a street railway being unlawful and unjustifiable."

THE CHICAGO & ALTON change of ownership has been inevitable for some time, although just who would take the property has been in doubt. Its ownership by the Rock Island has been possible just so long as the Government refused to let it come within the scope of its official knowledge, for the Rock Island and the Alton are competing lines and one could not acquire the other without running into legal complications and dangers that are not gratifying to the stockholders The line has been purchased by the Toledo, St. Louis & Western R. R., better known as the Clover Leaf road, and the companies associated with it under the control of Mr. Edwin Hawley, namely, the Minneapolis & St. Louis R. R. and the Iowa Central R. R. With the Alton, a system is thus formed with something over 3,000 miles in the best part of the Central States, reaching over its own lines into Chicago, St. Louis, Kansas City, Minneapolis, Des Moines, Toledo and Detroit. It is a system that can be developed into a very strong competitor for business between Chicago and Kansas City and western points, while its local business in some sections will always remain large. The purchase is not yet definitely closed, for the Hawley interests do not care to buy a law suit, such as is possible until the Government definitely determines whether it will take action against the Alton in connection with the rebates which resulted in the $29,000,000 fine imposed on the Standard Oil Co. It will undoubtedly be a good thing for shippers and travelers to have the deal carried out, for it is much easier to do business with a large system capably managed than with a number of short independent lines.

PROFESSIONAL ETHICS are now receiving the attention of the American Bar Association, in some respects the most influential professional organization in the country, and it is reasonable to expect important results from its deliberations. At present there are codes in force in Alabama, Colorado, Georgia, Kentucky, Maryland, Michigan, Missouri, North Carolina, West Virginia, Wisconsin and Virginia. Eight canons of professional conduct are incorporated in the charter of the Louisiana Bar Association and the oath administered to lawyers admitted to the bar in the State of Washington contains a brief outline of professional duty. A committee representing all sections of the country has been investigating the subject and at the meeting of the American Bar Association on Tuesday of this week, it presented a rough draft of a proposed code in order that all interested in the subject may have an opportunity of sending their views to the committee. The adoption of such a code is deemed to presage such important effects on the development of the legal profession that the committee believes it should be done only after mature and careful deliberation, and much fuller consideration than can be given it at an annual meeting. This wise recommendation and cautious procedure is recommended to those who are interested in the subject of professional ethics among engineers, a class which must eventually come to some code, although there does not seem at present to be any early prospect of the adoption of such canons. If those who feel the need of a code were to act with the deliberation and the regard for all criticism which mark the work of the American Bar Association's committee, there would probably be a better chance of securing an engineering code that would be of real use as a stimulus to higher professional conduct.

THE LONDON WATER-WORKS, which have been under public ownership for about three years, now supply a population of about 6,800,000. Part of the people living outside the administrative County of London doubtless obtain water from private wells or other sources, for the average daily consumption of the public supply is only 261,600,000 gal., or 38 gal. per capita. About one-quarter of the supply is ground water and the remainder is from the Lea and Thames. As a result of centralized public ownership, the various districts formerly served by independent companies have been coupled together, so that any extraordinary conditions in one district can be met by drawing on the resources of others. As a result of these new connections there has been a great increase in the quantity of water taken from the Thames for two districts. These results have led to hearty approval of the management of the works by those usually opposing municipal ownership.

FOREST PLANTING in the northeastern states is receiving particular encouragement from the Forest Service of the Department of Agriculture, for large areas in this section of the country are fit for forest growth only and from an economic standpoint it is important for these lands to be put into a state of productiveness. There are large lumbered areas on which successive fires have destroyed all young trees of valuable species, and inferior trees have sprung up. While this land is worthless in its present condition, forest planting will bring it into a useful state where adequate protection against fire can be provided. There are also large tracts, once cleared for farming, but since abandoned on account of loss of fertility or through the greater attractiveness of cities to their owners. In places these abandoned farms are now covered with white pine, but this crop is being removed rapidly and little reproduction will follow, owing to the absence of seed trees. Such lands offer exceptionally fine opportunities for forest work, owing to their nearness to markets and freedom from brush. There are also large barren sand plains in the New England states and New Jersey which cannot be cultivated, but will support in many cases a fair growth of white pine or other species of pine. The high price of good timber, which is sure to steadily increase, coupled with the presence of these lands near good markets, should be an incentive to take forestry up earnestly. It will accordingly be strange if far-sighted men with enough capital to undertake the work do not take advantage of the opportunities afforded in the northeastern states to make an investment which is likely to bring in a good revenue and also furnish an opportunity of supervising about the most interesting outdoor work that can be undertaken. From a purely engineering point of view, it is to be hoped that the suggestions of the Forest Service will be put into immediate practice, in order that the local timber supply may be increased instead of considerably depleted.

THE WALNUT LANE BRIDGE, FAIRMOUNT PARK, PHILADELPHIA

A Description of the Methods Employed in Constructing a Concrete Arch of 233 Feet Span.

The highway bridge carrying Walnut Lane over Wissahickon Creek in Fairmount Park, Philadelphia, is a concrete structure 585 ft. long, 60 ft. wide and about 150 ft. in height above the surface of the water. The main span, 233 ft. long in the clear, has a rise of 70 ft. 3 in., and is flanked by five full-centered approach spans of 53 ft. The main span is the longest concrete arch in the world and the third longest masonry arch of any description; its general features were illustrated in The Engineering Record of November 17, 1906.

It is made with two ribs, each 18 ft. wide and 18 ft. in the clear from the bridge axis. The radial thickness of the ribs diminishes from 9½ ft. at the skew-back to 5½ ft. at the crown and each is made with 22 long voussoirs and 17 short ones, the latter serving as keys, and all of them being cast in forms built on the regular arch lagging. The vertical faces of the voussoirs are scored 1¼ in. deep in radial lines from 24 in. apart at the crown to 33 in. apart at the skew-back to give them the appearance of cut stone course joints and the outer faces are grooved with a curved concave moulding of 5 in. radius, parallel to the soffit, above which the vertical face projects 2½ in. farther than it does below it.

Ten vertical transverse walls built up from the arch ribs to the level of the crown carry at their upper ends the 20-ft. longitudinal spandrel arches, the cornice and parapet and four lines of longitudinal spandrel walls supporting the roadway platform. Transverse I-beams 6 ft. apart are seated on the longitudinal wall spanning each rib and the space between the ribs, and carry the transverse floor arches 9 in. thick at the crown above which there is a cinder concrete filling and asphalt roadway. The arch ribs are made without reinforcement except for three 1-in. horizontal transverse rods at the foot of each transverse spandrel wall and six 1-in. rods bent at right angles to bond the horizontal seat for each transverse wall with the rib. The transverse spandrel walls are reinforced with 1-in. horizontal rods 3 ft. apart vertically.

The skew-backs of the main span and the vertical piers at the same point are both seated on a common foundation 58 ft. 2 in. long and 29 ft. wide, with its footing carried down to offset seats in the solid rock a few feet below the sloping surface of the ground.

The approach arches and their piers are of ordinary simple construction, and, like the main arch, are made with two separate ribs joined by the continuous roadway platform. The abutments are of solid concrete masonry with heavy cross sections to act as retaining walls for the embankment behind them, their faces are paneled to give the effect of piers for the ends of the approach arches above which recesses are formed to receive the spandrel walls. The wing walls are curved, the faces are vertical and the rear is offset to the required thickness, making, altogether a somewhat elaborate construction of large dimensions, their height being over 50 ft., and the length more than 100 ft. transverse to the axis of the bridge. The wings and the faces are reinforced with 1-in. horizontal rods 2 ft. apart vertically, curved around the corners.

The floor platform is uniform over the main and side arches, and the 20-in. transverse I-beams which support it between the arch ribs are spliced to the 15-in. beams which support it over the arch rib by horizontal angles bolted to the webs and flanges of the beams, as shown in the detail. The lower flanges of the I-beams are protected with 3-in. of concrete reinforced by loops of 3-16-in. wires, 3 in. apart, spaced by 2 pairs of horizontal transverse ⅛-in. wires. The floor slabs have transverse expansion joints on the center lines of all the transverse spandrel walls.

The bridge is proportioned throughout for a live load consisting of 100 lb. per square foot or a concentrated load of forty tons on two axles 20 ft. apart, the wheels 6 ft. apart on the axles, and for a wind pressure of 50 ib. per square foot of vertical surface. The dead load of the center span is about 26,000 tons, nearly one-half of which is due to the weight of the arch ring alone. The maximum unit stress in compression on extreme fibres of the arch at the points of greatest eccentricity of the center of pressure is 500 lbs. per square inch, which includes temperature stress, and the maximum total stress at each skew-back is 16,500 tons.

The vertical shear at the skew-back gives a unit stress greater than is allowable on plain concrete, and a much higher value in shear is obtained by embedding in the concrete radial one-man stones. The form of the arch curve was determined by and follows closely the curve of the line of pressure, which is contained well within the middle third of the arch ring.

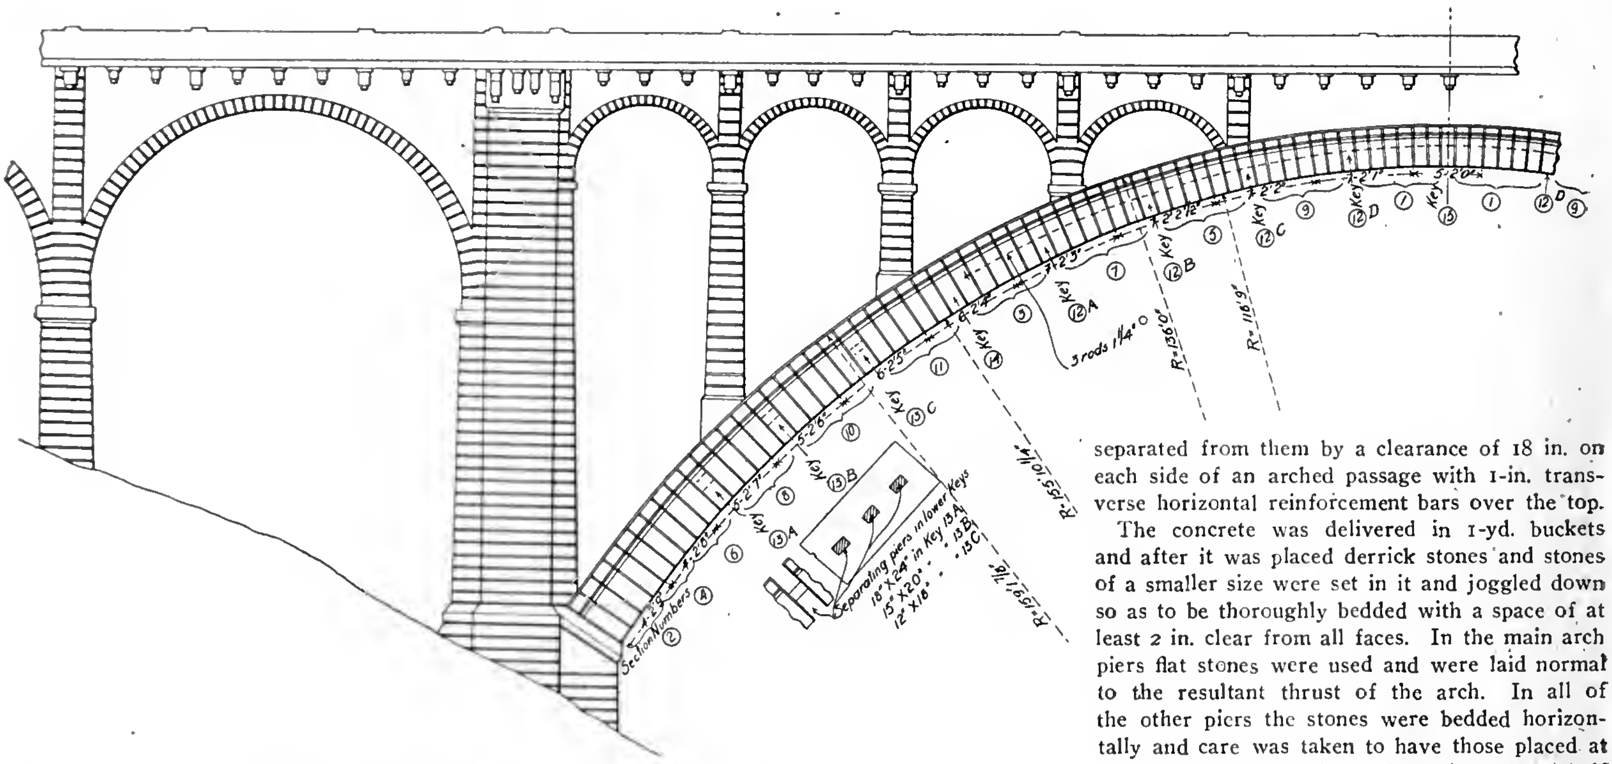
The footings of all piers and abutments were carried down in open excavation to solid rock, which in all cases was dry and developed ideally rugged surfaces in sound hard material from about 5 to 20 ft. below the original surface of the ground. The foundation pits were excavated by hand and only in a few cases required any sheeting. The footings were built with 1:3:6 concrete and were made solid to a level above the surface of the ground where for each pier they receive two shafts carrying the separate arch ribs. A 30-in. water main just above the surface of the rock passes through all of the foundations in a line parallel to the axis of the bridge and is separated from them by a clearance of 18 in. on each side of an arched passage with 1-in. transverse horizontal reinforcement bars over the top.

The concrete was delivered in 1-yd. buckets and after it was placed derrick stones and stones of a smaller size were set in it and joggled down so as to be thoroughly bedded with a space of at least 2 in. clear from all faces. In the main arch piers flat stones were used and were laid normal to the resultant thrust of the arch. In all of the other piers the stones were bedded horizontally and care was taken to have those placed at the end of each day's work project about half of their height above the surface of the concrete so as to form dowels bonding the concrete with that to be laid the next day.

Above the surface of the ground the piers were built in ordinary forms made with 2-in. horizontal boards 18 in. wide, planed on the inner face and on the edges and secured as usual by vertical outside studs with tie rods through the upper ends. The lower ends were secured by ¾-in. bolts 12 in. long with their inner ends engaging nuts and washers permanently embedded in the pier concrete 8 in. back from the face.

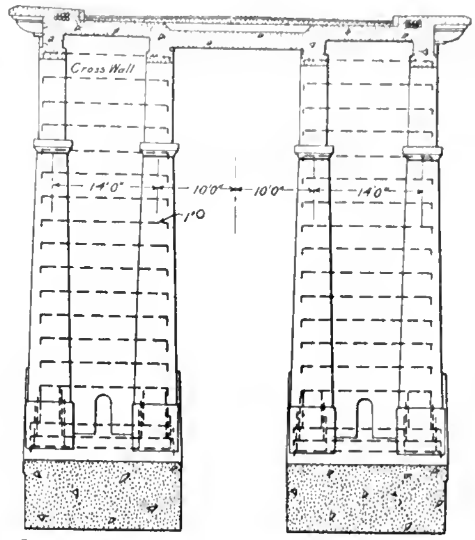
Courses of concrete four boards deep were laid daily and the bolts securing the lower four boards of the forms were unscrewed from their nuts and taken out and the boards removed and built on top and the holes left in the concrete were filled with plaster. Triangular horizontal strips 2½ in. wide and 20½ in. apart vertically were attached to the inner faces of the forms to produce course joints in the face of the concrete. On the day after the concrete was placed the form boards were removed and the surface was scrubbed with a brush and rinsed with water, which produced a very uniform color and texture and entirely removed all traces of the form boards.

The centering for each of the 53-ft. arch ribs was made with seven triangular wooden trusses 4 ft. apart on centers which spanned the full width of the arch and were carried at the spring-



Walnut Lane Bridge Showing Voussoir Scoring.

ing line on transverse horizontal 10x10-in. yellow pine upper sills, supported by pairs of oak wedges under each truss on 10x10-in. lower sills scabbed to vertical 10x10-in. posts set on the rock bottom adjacent to the mould for the pier foundation. The trusses were like scissors rafters with straight lower chords made of two spliced 3x12-in. planks with zig-zag bracing to the top chords which consisted of ordinary scarf boards made with two 3x12-in. planks bolted together. Forms were built on the lagging and loaded with stone at the crown and the arch rings were built up from both skew-backs simultaneously to the crown, care being taken to finish the work each night on radial planes parallel to the axis of the arch. The false-work and forms for each of the 53-ft. spans was built by a party of seven men in about four days and the 140 cu. yd. of concrete in the arch ring were laid in one day. When the concrete was one month old, the centers were struck by carefully slacking the wedges and no settlement



Cross Section through Spandrel Arch.

proper is 232 ft. long and 42 ft. high and has twenty-one transverse bents. Except at the ends the bents are all two stories high and all are made with ten vertical posts and two panels of 2x9-in. X-bracing in each story.

The upper section of false-work 30 ft. wide has its 15 transverse bents in the same planes as the center bents of the lower section of false-work and each bent is made with six vertical posts in one, two, or three stories, each with a single panel of X-bracing. The ends of the first story caps are braced by batter posts to the ends of the first story sills, thus giving an extended base for lateral stability. False-work is braced longitudinally by six lines of double panel X-bracing and horizontal ledgers in the upper section of the false-work and eight sets in the lower section.

All X-braces are 2x9-in. planks, the upper and lower ledger pieces of each section are 4x12-in. and the intermediate ones are 3x12 in., and all other timber in the false-work is 10x10-in. yellow

Construction of First Rib of Main Arch, Walnut Lane Bridge.

at the crown could be perceived. No especial delay was required before commencing the 53-ft. spans after the completion of their piers. It was, however, required that the main piers should be completed at least 30 days before commencing the concreting of the main arch rib.

Each main arch rib with its transverse spandrel walls contains about 2,400 cu. yd. of concrete and imposes a maximum load of about 6,000 tons on the false-work. The application of this great load varies with the changing condition of the concrete as it gradually drys and sets and develops different frictional resistances on the lagging. To provide for the somewhat indeterminate stresses and prevent deflection the false-work was made heavy. The upper part of the false-work was trestled separately from the lower part and divided from the latter by a space for the adjusting wedges. From this line down to a level considerably below the skew-backs, where it was supported on a steel and masonry sub-structure, the false-work was braced to form a lower section.

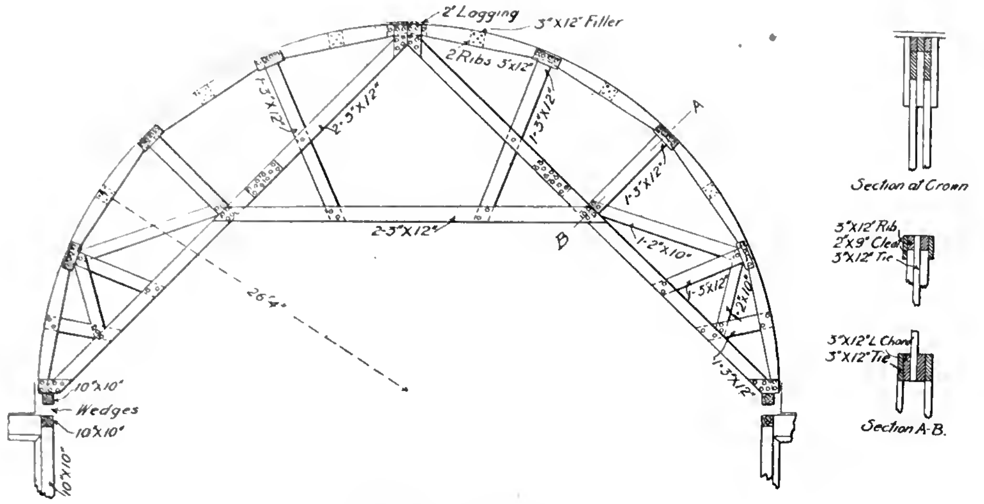
The sub-structure is carried on concrete piers about 85 ft. long and 2 ft. wide on top. All of them have their footings carried down to solid rock and have their faces battered 1:12. On shore the rock is near the surface of the ground and the heights of the piers vary from 2 to 8 ft. The four piers in the creek are about 12 ft. high and were built in cofferdams made with cribs sheeted inside and filled with puddle. Each of the creek piers carries a transverse steel bent 50 ft. long and 20 ft. high, made with ten 12-in. 31½-lb. vertical I-beam posts bolted to top and bottom pairs of horizontal 12-in. 25-lb. channels forming caps and sills, between which they were X-braced with two sets of 6x3½-in. angles. The caps carry ten lines of 24-in. 80-lb. longitudinal I-beams, the five panels of which have a total length of 132 ft., and are supported at their extremities on the shore piers. The false-work

pine, except the 10x16-in. caps of the upper story which carry 6x16-in. and 6x18-in. scarf timbers spaced 12 in. apart on centers and covered by 1½-in. tongue and groove lagging 28 ft. long, planed on the upper side. The falsework contains about 370,000 ft. b. m. of timber. Fire protection is provided by a 1½-in. water main under 75 lb. city pressure, which extends from end to end of the bridge and is provided every 50 ft. with a tee having its outlet closed by a screwed nipple with the outer ends flattened and welded. These nipples were removed and streams were played on the false-work, soaking it thoroughly for 48 hr. before the keys were concreted between the arch voussoirs. At this time the weather was hot and during the succeeding five weeks the timber dried out so much as to cause considerable shrinkage but not enough to release the false-work from the concrete arch. It is considered, however, that the shrinkage afforded a very slow and delicate diminution of the pressure and was very desirable

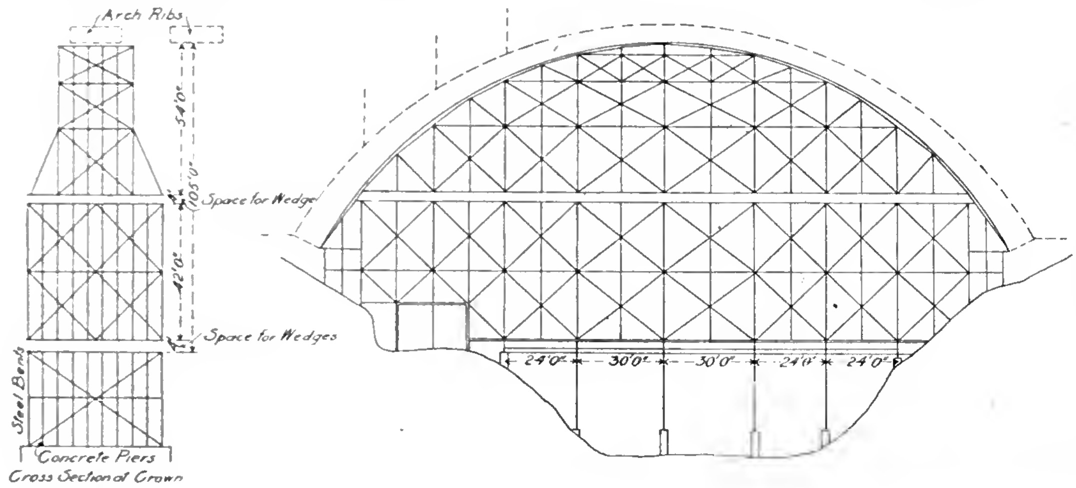
in transferring the stresses from the falsework to the arch ring.

The steel sub-structure, and the end main bents of the lower part of the timber false-work, take bearing on fifty 6-in. steel rollers 18 in. long, parallel to the axis of the bridge which are engaged on top of the concrete piers between continuous 19 × ¾-in. top and bottom back plates. While construction work is in progress all bents are anchor bolted to the piers and the rollers are immovable.

A ladder and a wooden hand rail is provided along each edge of the lagging to safeguard the men working on the false-work, the maximum height being nearly 135 ft. The forms 18 ft. wide, about 8 to 11 ft. long and 5½ to 9½ ft. high, are built with 2-in. tongue and groove planed horizontal boards set on the lagging in the positions indicated by the numbers showing the sequence of construction of the voussoirs. The transverse faces of the forms are in planes radial to the intrados of the arch and all four sides are made with panels having transverse cleats. The inclined faces of the forms are heavily braced by inclined struts to 6x12-in. cleats thoroughly bolted to the lagging.



Center for 53-Foot Arch.

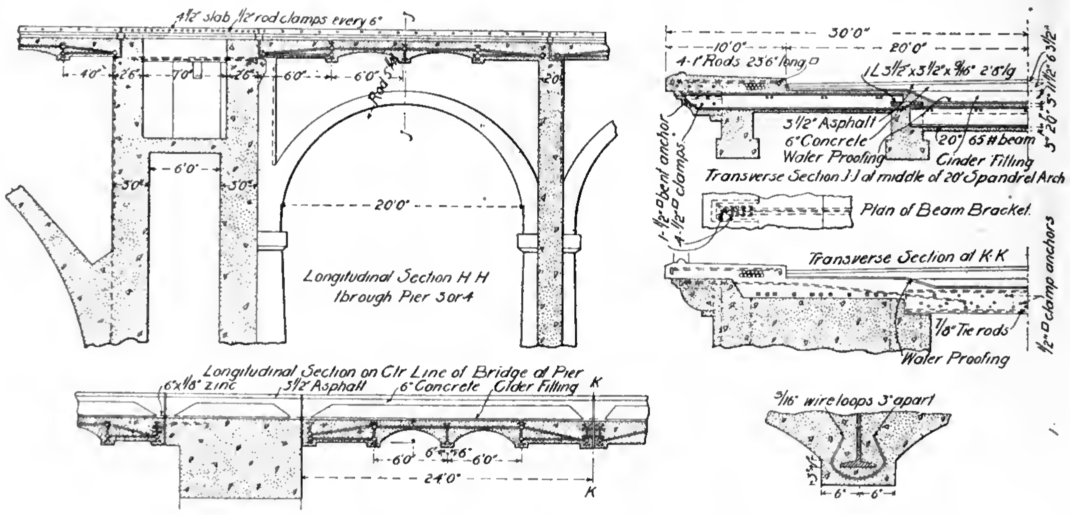


Centering for 233-Foot Arch.

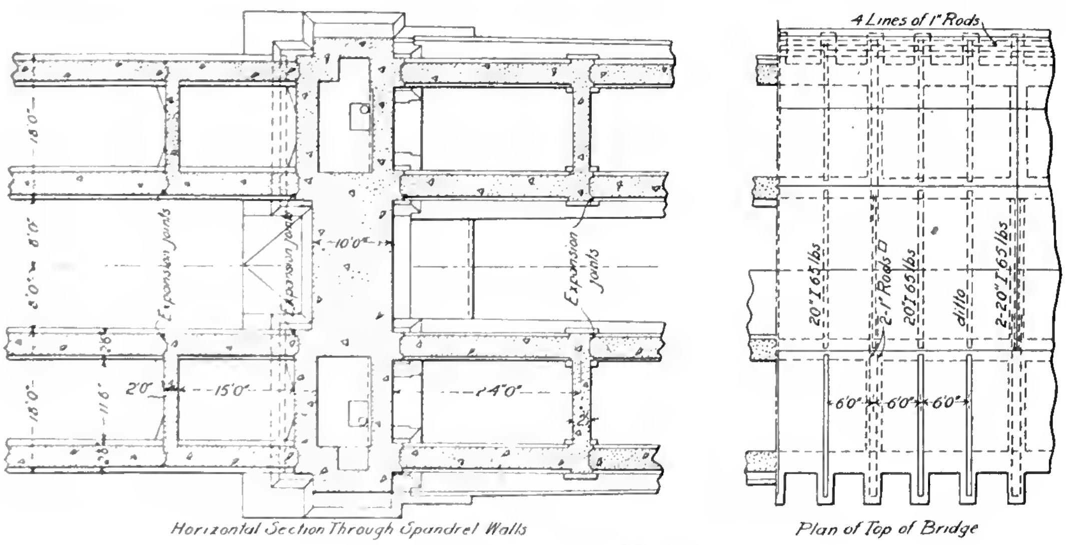
Except at the crown the surface of the lagging is an inclined plane of varying steepness, much of it exceeding the angle of friction. In order to prevent the voussoirs from slipping together before the keys between them are filled, sets of three concrete struts were built between adjacent voussoirs and transmitted the dead load stresses continuously from crown to skew-backs after the mould braces were removed. The struts were 18x24 in., 15x20 in., 12x18 in., in three successive keys from the skew-back up. When the keys were filled in the struts remained in position forming part of the permanent arch ring.

As some of the voussoirs weigh as much as 170 tons each and are seated on steep inclines the workmen were distrustful of the frictional resistance of such as were placed before the lower ones and therefore could not be supported by concrete struts, so, to inspire in them a feeling of absolute security three lines of 1¼-in. steel longitudinal bars, curved parallel to the intrados were bedded into the concrete at the mid line of the arch ring from the crown to the quarters providing balanced anchorage for all the blocks engaged. The rods were made in convenient lengths and their overlapping ends had nuts bearing on reaction plates in radial planes.

The 1:2:5 concrete for the arch ring was delivered to the voussoir forms by the cableway in four 1-yd. bottom dump Stuebner steel buckets, which delivered it directly into the voussoir moulds where it was spread and spaded by two ten-men gangs, who also placed in it one-man



Floor Details of Walnut Lane Bridge.



Horizontal Section Through Spandrel Walls *Plan of Top of Bridge*

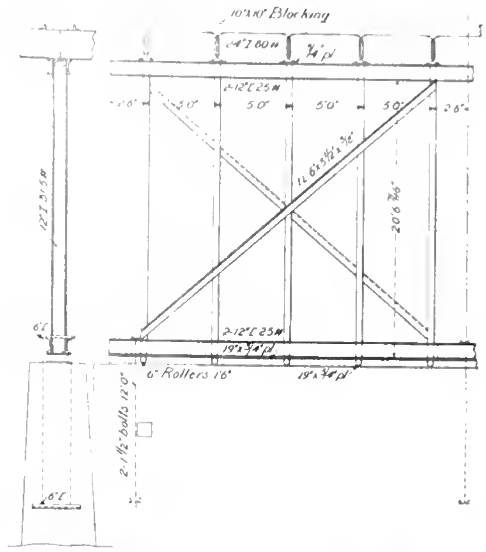
Horizontal Section Through Walls and Top Plan.

Conshohocken flat stones with a thickness equal to about one-fourth of their average dimension. These stones were placed edgeways to the lagging in radial planes as close together as possible. They were bedded in the concrete and worked down into it. The concrete was flushed against the outer face forms with hand mixed 1:2:3 granolithic mixture delivered in buckets to landing platforms just above the voussoirs from which it was lowered in coal buckets as required. The one-man stones were delivered to the same receiving platform by the cableway skips and packed in so closely as to form about 40 per cent. of the volume of the arch ring. Work was maintained continuously on each pair of voussoirs from the time they were started until completed, days being from 8 to 14 hr. long. The corresponding voussoirs on the opposite sides of the crown were always made simultaneously in order to load the false-work systematically, and about 3 weeks were

required for making all of the voussoirs of the first rib.

The deflection, settlement and expansion of the false-work was considered merely moderate. At the haunches it was noticed that as the successive voussoirs were concreted, the lagging sprung clear of the skew-back voissours making a clearance of perhaps 1-16-in. with them. Vertical wooden gauge rods were suspended from the false-work in four places with their lower ends registering with stakes in the ground and the middle one showed a settlement of 13-16 in. at the crown due to the weight of the first pair of voussoirs which were placed at the crown. Levels were taken daily on the top of the false-work and the ultimate total deflection of the false-work at the crown when all voussoirs were placed was 2 in.

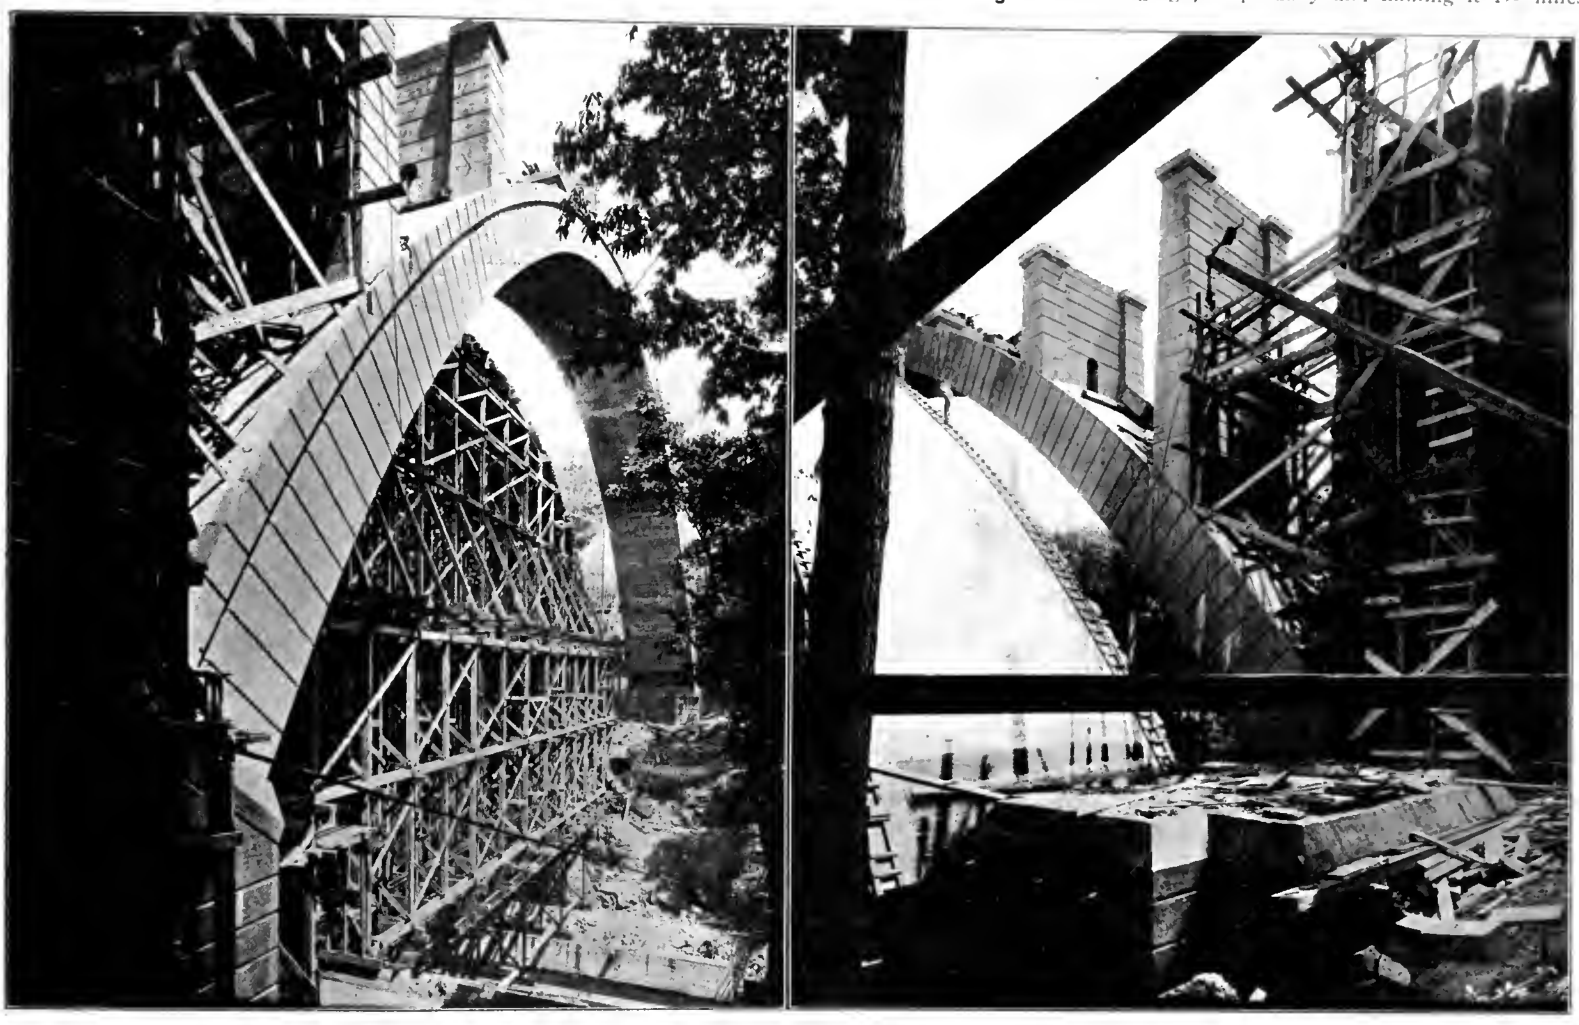
The voussoirs were always stripped when they were one day old and scrubbed on the faces. When the last voussoir of the first rib was 14 days old and all settlement had taken place in the false-work and the voussoirs had fully shrunk the



Steel Bent of 233-Foot Arch Centering.

the concrete commenced to set. When 24 hr. old the balusters are taken out of the mould and scrubbed and are then immersed in water where they are kept for one week. They develop a very hard, smooth gray surface with sharp corners that are not inclined to crack or chip and which resemble handsome cut stone work. The reinforced concrete hand rail will be cast in position on top of the balusters in lengths of about 22 ft. with expansion joints between the ends of the rail and the balustrade piers filled with asbestos felt, a device which has proved effective in preventing crushing and distortion of similar hand rails in other bridges built by the same designer.

The contractor's plant has been establised at grade near the Roxborough end of the bridge and comprises office, repair shop, carpenter and smith shops, storehouse, storage bins, concrete plant, stables, derricks and a cableway. Trap rock broken to pass a ¾-in. screen and be rejected by a ¼-in. screen is delivered by 15 teams, each averaging 7 trips daily and hauling it 1½ miles



First Rib of Main Arch after Removal of False Work, Walnut Lane Bridge.

17 keys were concreted as nearly simultaneously as posible. Thirty days later the centering was struck by slacking the wedges. This operation was commenced at the middle and progressed towards each end. Eight men with sledges lowered the false-work sufficiently to free the arch in six hours. This was very successfully accomplished and caused a further settlement of only ⅛ in. of the concrete at the crown of the arch.

After the false-work was clear of the first arch rib the achor bolts connecting the transverse bents to the concrete false-work piers were removed, a 35-ton ball-bearing ratchet jack was set horizontally against the rear end of the bottom sill of each transverse bent of the false-work or substructure and reacted against blocking secured by the anchor blocks in the concrete piers. The jacks were simultaneously operated by two men each and pushed the falsework and sub-structure, having an estimated weight of 900 tons forward on the rollers 34 ft. in three days. The voussoirs were anchor bolted to the concrete piers as at first and the upper and lower sections of false-work were raised on the wedges on both sides until the lagging was at the required position for the second arch rib and the concrete was carried on as for the first rib.

All parts of the structure are concreted in place except the 884 balusters. The latter, about 23 in. long and 10 in. square are cast vertically in cast-iron molds at the rate of 20 daily by a gang of 5 men. The bottom is recessed to engage a projection in the coping to which it is bonded with a vertical steel dowel. At first considerable difficulty was occasioned by cracks appearing just under the upper fillet. These were thought to be caused by the internal stresses caused by the setting and adhesion of the outer portion of the baluster first and were finally overcome by troweling down the sides at the top of the mould when

from the railroad to a platform at roadway level where it is dumped through double trap doors into a 200-ton hopper bottom bin. Sand is similarly received in a 100-ton bin adjacent to it and both are delivered through bottom gates to the hopper over a bucket elevator driven by a 5-h.p. Reading engine. The buckets discharge on opposite sides of a partition into an elevated storage bin. The bins deliver through 10x12-in. horizontal steel gates to twin charging hoppers with measuring strips on the inner surface to gauge the amount of material required for different proportions of concrete.

Portland cement stored in an adjacent house with a capacity of 1,500 barrels is wheeled from it to an 18-in. belt conveyor which is inclined at a steep angle with the horizontal and is provided with transverse wooden shelves 8 in. wide and about 24 in. apart on which the bags are placed by hand. The belt reverses and deposits the bags

on the measuring platform where they are emptied by hand into the mixing hopper. When the hopper is filled the cement man operates the levers that control the hopper gate and delivers its contents to a 1-yd. McKelvey mixer below, a measured quantity of water is added from a barrel and delivered through a foot valve into the mixer. The concrete is delivered from the mixer into 1-yd. steel buckets on flat cars on a 20-in. gauge track about 20 ft. long, the ends of which project about 5 ft. beyond the sides of the concrete tower and clear of it to enable the buckets to be hoisted by the cable-way trolley without danger of swinging against the tower. Granite grits for the 1:2:3 granolithic surface are stored at ground level in a 50-yd. bin adjacent to the concrete mixer and shovelled from it and is chuted to a hand mixing platform in the bottom of the bucket pit where sand and cement are also received and the small quantity of a mixture required is prepared and delivered in buckets by the cable-way.

The 785-ft. Lambert cable-way is anchored at the ends to dead men made with logs in the bottom of a pit covered with a reaction platform loaded with 40 tons of stone. All machinery is operated by steam furnished by the central power plant in which there are installed one 30-h.p. and three 20-h.p. boilers for the concrete mixer, elevators and cable-way machinery. There is also a 10x10x10-in. Ingersoll-Rand air compressor, driving pneumatic hammers used for bush hammering the arch soffit. There are four 10-ton derricks with 60-ft. booms which are moved from pier to pier and are operated by three 20-h.p. Lidgerwood engines and one Mundy engine, each with an individual boiler.

The main quantities are 19,200 cu. yd. of concrete and 96,000 lb. of reinforcement steel in the bridge, 6,000 cu. yd. of excavation, 370,000 ft. B. M. of yellow pine in the falsework, 270,000 lb. of steel in the falsework sub-structure and 800 cu. yd. of concrete in the falsework piers. Whitehall Portland cement has been used on the work. The contract price for the finished bridge is $253,551 and it is required to be finished in 18 months. Excavation was commenced August 1, 1906, the first concrete was laid September 20, the construction of the falsework was commenced January 1, 1907, and finished April 1. The concreting was commenced on the first main arch rib April 29, and finished June 7, the rib was swung July 22, and the centering was removed for the second rib August 3. An average force of about 125 men is employed and the largest amount of concrete laid in one day was 100 yd.

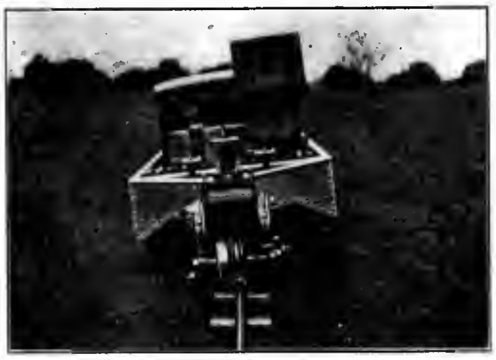
Great care is taken to execute the work in the best possible manner and make it conform strictly to specifications, efforts in which the contractor co-operates heartily with the engineer. One inspector is constantly stationed at the concrete mixing platform and one at each concreting gang. All cement is sampled at the storehouse and is not used until after it has successfully pasesd a 7-day test. Six inch concrete cubes are made as samples of each day's work for test in the city laboratory. The bridge was designed and its construction is supervised by the Bureau of Surveys of the City of Philadelphia, Mr. George S. Webster, chief engineer, and Mr. Henry H. Quimby, assistant engineer in charge of design and construction of bridges. The contractors are Messrs. Reilly & Riddle, the general supervision of the work is under the personal direction of Mr. T. H. Riddle. Mr. Moriz Bernstein is their engineer and Messrs. Chambers Lattimer and O. G. Hoover are assistant superintendents.

A Railroad in Nigeria, Africa, will be constructed by the British colonial government to develop the resources of the country, and in particular to stimulate the cotton growing industry. The road will be about 400 miles long.

The Brennan Monorail Car.

By C. O. Burge, M. Inst. C. E.

Some years ago there was an agitation for reducing the standard gauge in railway extension in many parts of the world, unfortunately only too successful in many instances. This was advocated on the three principal grounds that (1) friction on curves would be diminished, thus enabling sharper ones to be used; (2) lighter construction would be made possible, and (3) dead weight in proportion to paying load would be reduced. Experience has since proved that by reducing gauge the first object, which, however, is only really important in hilly districts, has been practically the only one gained, for strength of road bed construction does not depend on the distance apart of the rails, but on the load and speed, whether on broad or narrow gauge; and lastly, aside from exceptional cases, the loads, especially in new countries with raw produce of low specific gravity forming much of the freight, are more favorable to the ordinary gauging; that is to say, if the narrower cars were to be loaded to their full weight-carrying capacity, by wool, cotton, cattle and similar light freight, the height would cause instability, while



Effect of Side Loading.

full loads as to both weight and capacity can be, in such cases, conveyed safely by the wider car. Now, however, when Mr. Brennan, of torpedo fame, ingeniously and boldly proposes to reduce the gauge to zero, the first advantage, reduction of curve friction, is secured to a very much larger degree; the second object is partly attained, and the third very much more so, for, through the action of the main feature of the invention—the gyroscopic principle—perfect stability independent of width is attained by the automatic preservation of the position of the center of gravity of the car and its load relatively to the single rail support. That the invention, notwithstanding some obvious drawbacks to which we shall refer later, has a good deal to say for itself, is shown by the fact that the Indian government, which makes its own railways and has an experienced consulting engineering staff in London, has, after due inspection, advanced £6,000 to Mr. Brennan, to assist him in experimental work. When, therefore, on Aug. 10, the present writer, with about half a dozen other experts, visited, at Mr. Brennan's courteous invitation, his beautiful home in Kent, England, to see further experiments with a model car, he was intensely interested.

The general principles of the application of gyroscopic action in this case, have already been widely published, and it is only necessary here to say that in the 5 ft. 9 in. by 1 ft. 6 in. model car, two 5-in. vertical wheels, normally parallel to each other and to the length of the car, are revolved in opposite directions at a speed of 7,000 revolutions per minute, this proceeding whether the car is in motion or not. This stability mechanism occupies but little space and is placed concealed under the seat of the cab in the front, the weight being only 5 per cent. of the gross load. The particulars of the automatic device by which the gyroscopes recover their parallelism after the required couple has been exerted, have not been published and are believed not to be yet perfected, but the effect is something not far short of the miraculous. The loading was all heaped up on one side of the car, and as each piece was transferred, the vehicle arose automatically on that side, so as to throw the center of gravity vertically over the rail, while when the car was tilted over by hand and then released, it recovered its position at once, showing how oscillation of speed was dealt with by the gyroscopic influence. Similarly, when the car was put in rapid motion over one of the numerous sharp curves on the model line, the centrifugal force generated was at once automatically opposed by a righting tendency, and the requisite cant inwards, ordinarily effected by super-elevation, was developed. The road wheels are grooved and are fixed to a pair of tandem two-wheel bogies, one at each end, pivoted for vertical as well as horizontal curves on the track, so that inequalities in level are not much felt—the motive power for these, of course, may be that most suitable for the service required.

The car went round easily a curve so sharp that while the leading bogie had passed over it, the trailing one had not reached it, though the tangents of the curve were at right angles, the axis of the car forming the chord of the curve from springing to springing. In fact, the small rigid wheel base of the bogie alone limits the curvature, and mountain lines on this system can be constructed with a facility as regards curves, gradients, and cost of works, to which even the narrowest two-rail lines cannot approach, while the width of the car, as far as stability is concerned, is unlimited in the one case, and not in the other. But there is not only the practicability of negotiating unusually sharp curves, but the almost entire abolition of frictional resistance on all of them, on the monorailway. So much for curvature.

As to the second point, it has been claimed that inasmuch as one rail only is required, the road bed may be lighter, but this is the old fallacy of the narrow-gauge advocates, the weight of rail and bearing of tie being approximately regulated by the weight and speed of the load irrespective of the number of the rails or their distance apart from each other. We say approximately, for the double rail construction suffers under the oscillation arising from the practical impossibility of keeping the two rails exactly level transversely. Hence, each rail has to be strong enough to bear more than half the load, with its impact, while the single rail cannot have any more than the whole to deal with. The same considerations apply, with modifications, to bridges, for some sort of floor would be necessary in any case, and in large structures wind stresses must be provided for, so that the usual width could not be much diminished.

On the whole, not much advantage would be gained in this system by cheapening cost of road-bed.

On the third point, as to economy in dead loading, it is very clear that stability being insured by Mr. Brennan's apparatus, the capability of the car as regards weight and space can be made harmonious, and the machine can be thus worked to its full power in both ways. As this result is, on the whole, well attained on the standard and wider gauges, this particular advantage is limited to countries where the narrower gauges exist.

Generally, as far as the system can be judged at this stage, its chief scope will be for lines in mountainous countries in which economy of construction through reduction of curvature, and of traction thereon, will be great. The absence of the effects of the oscillation which limit velocity on the two-rail line may be a recommendation

for the adoption of the monorail for high speed interurban service also.

Mr. Brennan is now constructing a car approximately eight times, in linear dimensions, the size of the model, in which he calculates that the gyroscopic speed will be reduced to 3,000 revolutions per minute, though he states that 850 is enough to maintain stability. He has had placed at his service land adjoining his property belonging to the British War Department, on which to build an experimental full-size mono-railway, when the investigations, now being gone into for improvement, will have their full effect, possibly within a year or eighteen months.

Side View of the Brennan Experimental Monorail Car.

There is no doubt, from the experience gained, of the absolute perfection of the gyroscopic action while in operation, and if the small motive power requisite to produce it happened to fail, the gyroscopes, being on ball bearings and working in vacuo, would retain sufficient momentum to revolve at a high speed for a long time, giving ample opportunity for providing stability by other means. But there is the possible failure of the gyroscopic mechanism itself, or of the ball bearings, unlikely in the latter case in the absence of crank or belt stresses as in the case of an ordinary flywheel, but still a contingency, though remote. However, no human contrivance is infallible, and such an occurrence is certainly not more likely than that of an axle breakage, impossible in the mono-rail car, which we risk every day and which would equally lead to disaster.

The danger might be got over by providing a double set of gyroscopes for each vehicle, but this of course involves extra space being sacrificed, and extra cost in construction, the necessity of one set in each car being sufficiently objectionable in these respects. Trial on a much more extensive scale will alone show whether the undoubted advantages gained will not be counterbalanced wholly or partially by the extra cost of construction and maintenance of the gyroscopic mechanism.

The adoption of the monorail for branch feeders to a main line of the ordinary type and gauge, has one advantage over those of narrow gauge, which latter system has been, somewhat unwisely, carried out in some countries, thus involving transhipment, and what is more, isolating the branch rolling stock. This advantage arises from the possibility, with some slight modifications at stations, bridges, tunnels, etc., of running the monorail vehicles over one rail of the main line, so that transhipment of freight, difficulty of access to workshops, etc., inherent in the other case would be avoided.

There are certainly sufficient possibilities in the new invention to cause all engineers concerned in railway construction and working to await with deep interest, the result of the larger experiments which are promised.

A Tar and Feathers Road.

Road improvements in Athens, N. Y., have not found favor with the conservative majority of its people, and the progressive element considered strong measures necessary. One morning the center of the town's leading thoroughfare was found planted with several rows of cabbages. The town council was stirred to action and consulted a local inventor as to what should be done. He decided that the street had a gravel bottom and by pouring tar on it a good pavement would result. He was so confident in the success of the method that he offered to furnish the labor if the council would supply the tar. Two blocks were covered in this way on the first day, but the conservatism of the town revolted and the next morning the street was found coated with feathers.

An Infiltration Water-Works Intake Under the Ohio River.

An infiltration water-works intake built of well point strainers buried in the sand bottom of the Ohio River, has been in successful operation for nearly a year in connection with the system of the Owensboro, Ky., Water-Works Co. The system is owned and operated by this company, embracing a pumping station on the bank of the Ohio River and distribution mains from which the city of Owensboro is supplied. The pumps in the station are in dry wells and formerly drew water directly from the river. While the raw river water is unsatisfactory for domestic purposes during a large part of the year, and at certain times it is even dangerous for such uses, when clarified it furnishes a very satisfactory supply. Although the company desired very much to secure better water, it preferred not to build a filtration plant of any type, or resort to any means of purification which would require maintenance and operating expenses, if a desirable supply could be obtained by other means. A broad, deep bar of clean sand and fine gravel which exists on the opposite side of the river from the pumping station, has its surface kept comparatively free of mud and silt at all times by the current in the river. After considerable investigation the decision was made to build an infiltration intake in this sand bar near the line of extreme low water in the river, and to connect the intake with the station by a suction main laid in a trench in the bed of the river.

The suction main which extends across the river from the pumping station to the intake consists of 20-in. hub-and-spigot cast-iron pipe, with a flexible joint to each fourth 12-ft. length. This main is laid nearly at right angles to the channel

Laying Cast Iron Pipe in 24-Feet of Water in the Ohio River.

of the river and connects at the outer end through a 20x16-in. tee with a 16-in. cast-iron pipe laid at right angles to it and in both directions from it. This 16-in. pipe extends 175 ft. downstream and 225 ft. upstream from the end of the suction main. A four-way special connection, having two 8-in. and two 16-in. legs, is placed in the 16-in. pipe every 50 ft., starting 25 ft. on each side of the end of suction main. A 12-ft. length of 8-in. cast-iron pipe is placed in each 8-in. leg of these connections, forming at each 50 ft. two laterals

at right angles to the 10-in. branch of the 20-in. suction main. Flexible joints are used on the 8-in. laterals. An 8x6-in. tee connection is leaded into the end of each of the latter and carries in each 6-in. leg a standard 6-in. No. 8 Cook well point strainer, 10 ft. long. The thirty-six strainers thus provided are, therefore, in two rows parallel to the 10-in. branches from the 20-in. suction main, the two rows being 28 ft. apart on centers and the ends of the strainers in the rows 18 ft. apart.

The strainers have the usual slots at right angles to their axes, cut in them, the slots in the strainers used being 0.008 in. in width. The whole system of strainers and connections is buried 4 ft. 7 in. below the natural surface of the bar of sand and fine gravel, the backfill being carried 18 in. above that surface to allow for settlement. A bed of filtering sand and gravel 60x450 ft. in plan and 4 ft. 7 in. deep is thus obtained. Owing to the location of the sand bar relative to the position of thr river channel, and to the current over the bar, the surface of the latter is kept clean at all times so no trouble is expected from the sand bed becoming filled with silt. In fact, during the time the system has been in service a clear, safe water has been obtained, which it is believed will improve after the sand over the strainers has had an opportunity to settle. The cost of operating the pumps in the station has been considerably reduced by the removal of the sand from the water. Formerly the pump plungers had to be packed once a week, but they have been packed only once since the intake has been in service and are still in good condition.

The important feature of the infiltration intake is its capacity to produce pure, clear water from the river at all stages of the latter and all conditions of the raw river water, without expense after the installation was made. Although the details of this intake are a departure from what has been done along these lines, they could be utilized in obtaining a supply from a river wherever a sand bed formation of suitable character is available.

The intake has an estimated capacity of 12,500,000 gal. per day under normal conditions, some allowance being made for a reduction in capacity. The 20-in. suction main is capable of supplying 5,000,000 gal. of water per 24 hours under economical operating conditions at the pumps. The average daily consumption supplied by the Owensboro water system, however, is only 2,500,000 gal., so it is believed the present intake will furnish an adequate amount of water for some time to come.

The intake and suction main were both laid with the assistance of a diver, from a scow on the surface of the river. The original intention had been to place the intake 48 ft. toward the shore from the extreme low water line. Conditions existing at the time the work was done necessitated a change of plans, however, the intake being placed about 50 ft. off shore from the low water line. The site of the intake was excavated to the desired depth with a floating dipper dredge. The latter was also used in opening up the trench for the 20-in. suction main which was laid at a minimum depth of 2 ft. below the surface of the river bed. On the Kentucky side of the river a ledge of sandstone rock was encountered for a length of 150 ft. in making the trench for the suction main. An 8-in. wrought-iron pipe, fitted with a sharp point and heavily loaded, was used to break up this rock by dropping it from a hoisting block on the scow used in laying the pipe. The rock was successfully broken out in this manner and was then removed by the dredge.

All of the work on the suction main and the intake was carried on with no small amount of difficulty. The water was from a minimum of 6 to 30 ft. in depth to a maximum of 10 ft. above that level during the time the under-water work was in progress, the current varying from 3 to 6 miles an hour at different places. The dredging work was done with the almost continuous assistance of a diver who worked at great disadvantage in the deep water and swift current. In the section of the trench for the suction main where rock was encountered, the operation of the pointed and weighted pipe used in breaking the rock was done under the direction of the diver, and the latter also directed the removal of the rock.

The suction main and intake were laid from a 24x80-ft. scow carrying a guyed A-frame at one end and a hoisting engine. The suction main was laid in sections consisting of four 12-ft. lengths of pipe, extending from one flexible point to the next. The three hub and spigot joints between the four lengths of pipe to each section were made on the shore on skids. The ends of the section were then blanked with wooden bulkheads to assist in floating it when first placed in the water. After the scow had been anchored over the position the section to be laid was to occupy, the section was swung over its designated site by the derrick and lowered to place from a triple block on the latter. The flexible joints between the sections were then made by the diver.

The intake pipe and strainer system was laid in sections 50 ft. long, a flexible joint being placed every fourth length of the 16-in. branches from the suction main. These sections were assembled on the scow and lowered into place from the derrick, after which the strainers were placed by the diver. High water interfered with the backfilling over the intake, which was finally done with a suction dredge.

A 12x12x8-ft. valve chamber built of concrete was built at the end of the suction main. The latter leads to a 20-in. four-way connection in the valve chamber, a 16-in. and a 20-in. line leading out of two legs of this connection to the pumps. A 20-in. pipe extending to the river directly from the fourth leg of the connection provides means of obtaining a supply in case the suction main is out of service. The valve chamber is just inshore from the low water line and is submerged 50 to 60 ft. during high water. Sediment and drift are kept out of the chamber by a heavy timber cover well anchored to its side walls. A hydraulically-operated valve, manipulated from the pumping station, is placed on the 20-in. emergency intake and one on the 20-in. pipe leading to the pumps. The usual arrangement of such valve chambers along the Ohio River, where high water is about 70 ft. above low water level, is to build a tower over the chamber to a point well above high water, this tower being connected to the shore by a bridge. The submerged valve chamber with the hydraulically-operated valve avoids such a tower and bridge and has been satisfactory in service.

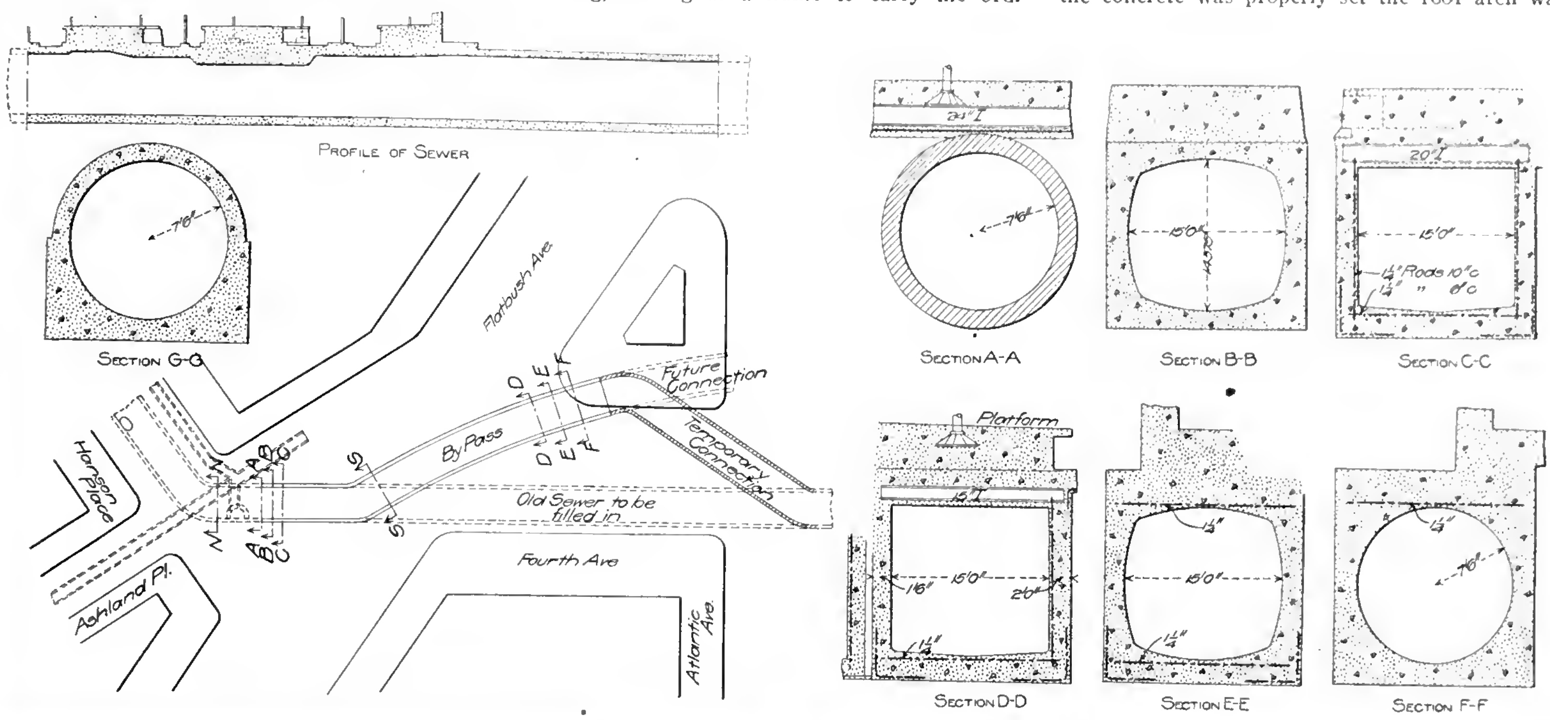
The infiltration intake, suction main and other improvements to the system were designed by Mr. Owen Ford, consulting engineer of St. Louis, Mo., and were installed under his direction. The suction main and intake were laid by Mr. Joseph G. Falcon, of Evanston, Ill., who also furnished the flexible pipe joints used.

The Railways of the World had a total length of 563,772 miles on Jan. 1, 1906, according to German statisticians. Of this amount 215,713 miles were in the United States and 192,248 miles in Europe. New construction during 1905 added 12,524 miles to the total, of which 2,485 miles were in Europe. Germany showed the largest increase, building six times more road than Great Britain. Considerable progress was also made in constructing railways in Africa, particularly in the German possessions. The compilers of the statistics estimate that the entire capital invested in the world's railroads amounted on Jan 1, 1906, to 43⅓ billion dollars.

Constructing a Sewer Under the Brooklyn Subway.

The tracks of the Rapid Transit R. R., in Flatbush Ave., Brooklyn, will pass through a standard rectangular reinforced concrete four-track subway to the intersection of Flatbush and Atlantic Avenues where they will enter a station communicating with the adjacent Long Island R. R. Depot. At this point a short depressed spur will be built dropping under the grade of the main tracks and crossing them to provide for a future connection with a subway which may hereafter be built on Fourth Ave. At this point a 15-ft. circular brick sewer coming down Hanson Place, is deflected about 45 deg. and continued through Fourth Ave., at a clear depth of about 23 ft. from the surface of the streets to the top of sewer. The straight portion on Fourth Ave. is low enough to pass clear beneath the main tracks of the subway, but is not low enough to clear the depressed tracks, the center lines of the subway for the latter and of the sewer itself being about in the same horizontal plane. As the grade of the sewer could not be altered it was necessary to deflect it for a short distance to clear the sub-subway before the construction of the latter was commenced. The new work is very simple and consists merely of a curved by-pass 290 ft. long forming two sides of a triangle connected at both ends with the old sewer and permitting the intersected portion of the old sewer to be removed to leave clear space for the construction at the same level of the single track depressed subway spur which will at present terminate in the triangle enclosed by the two sides of the by-pass and the connecting center line of the old sewer. Practically the new construction and the whole of the by-pass is permanent construction and it is built like regular standard sewer work and will not be modified unless the depressed spur is hereafter continued to connect with a subway in Fourth Ave., in which event it will intersect the by-pass and it will be necessary to cut off one side of the latter and continue the other or up-stream side for some distance parallel to the subway through Fourth Ave., until a point is reached where the ascending grade of the subway carries it high enough for a connection to be made between the by-pass and the existing old sewer, thus virtually lengthening the present by-pass as occasion may demand. On this account the angle of the by-pass where such a future extension may be made is indicated by dotted lines in the general plan and is there noted as a future connection.

In order to maintain the grade of the sewer and to carry it through the limited head-room under the main subway it was necessary to increase the cross-sectional area by transforming it from a circle to a rectangle for a length of about 172 ft., beyond which it resumes the regular circular section. The change of cross section at each end is made in a 20-ft. length of concrete construction which enables the curved surfaces to change smoothly and gradually to flat surfaces. The rectangular cross-section has an inside width and height of 15 ft. and 12 ft., respectively, thus affording a somewhat increased area. The invert and vertical side-walls are reinforced with 1¼-in. square rods 6 in. and 10 in. apart on centers. The rectangular section corresponds closely with that of the depressed subway and is built adjacent to it, resembling very much a twin structure, both structures pass underneath the tracks and station of the main subway and support on their roof numerous of the latter structure. The roof of the sewer has a variable thickness and elevation according to the requirements of the structure above and it is formed with a solid concrete slab from 2 to 3 ft. in thickness, which is car-



Location, Profile, and Principal Sections of By-Pass Sewer.

Anchorage of Steel Pipe.

Timbering over Old Sewer.

ried on I-beams with a depth of 15 to 20 in., and a spacing of 7½ to 24 in., according to the superimposed columns and other loads. Except for these irregularities and special features the sewer design is simple and the principal features of interest are comprised in the methods adopted for constructing it and for safeguarding the old sewer and maintaining its service uninterruptedly during the new work.

The sewer carries so much storm water that it is sometimes under pressure sufficient to blow off the man-hole covers, and it was considered unsafe to demolish it completely in ordinary open trench. A method was therefore devised for reconstructing the invert before disturbing the roof arch at the two points where it unites with the ends of the by-pass. Transverse falsework bents of 10x10-in. timbers, 15 ft. apart, were seated on the invert of the old sewer and supported a pair of continuous longitudinal girders 5 ft. apart on centers, each of them having a T-shaped cross-section made with a 20-in. I-beam and a 15-in. channel, both breaking joints and spliced with cover plates bolted on the webs. These girders carried upper transverse bents 5 ft. apart, made with vertical and inclined posts supporting arch-like transverse timbers, carefully wedged against the brick work and forming altogether a system of underpinning similar to that used by the same contractors for the rectification of the Battery tunnel which has been described in several articles published in these columns.

After the completion of the underpining of the sewer roof at the upper end of the by-pass a dam about 4 ft. high was built across the sewer invert with bags of sand and cement, and through the bottom of it was carried one end of a riveted steel pipe 3 ft. in diameter and 64 ft. long, serving as a flume to carry the ordinary flow of the sewer. The upper end of the pipe was chained securely to a 12x12-in. transverse beam with the ends concreted into recesses cut in the sides of the sewer to serve as an anchor and resist the tendency to displacement, which was found to be considerable. The lower end of the pipe emptied into the old sewer through a similar dam, thus allowing the space between the two dams to be pumped dry and the inverts cut out and connected with that of the by-pass.

At the point where the change in cross-section of the old sewer commenced, just above the by-pass, a 7½-ft. length of the old brick invert was cut out to a level a little above the springing line on both sides, the old brick work removed and the necessary excavation made and carefully sheeted with horizontal boards and vertical rangers braced by inclined struts to the feet of the underpinning bents. The new concrete invert was then built and care was taken to have the reinforcement rods in the side wall project far enough above the surface of the concrete to form 4-ft. lap joints with the reinforcement bars in the upper part of the sewer. Alternate 7½-ft. sections of invert were thus built for the full length required and after the concrete was properly set the roof arch was carried from them by means of bracing, reacting against longitudinal timbers with vertical shores placed between the jack screws. The transverse false work bents were then shifted to seats on the new invert and the intermediate sections of old inverts were replaced by new inverts built in the manner already described, the remainder of the roof was supported from the side walls, transferring the roof weight entirely to the vertical shores.

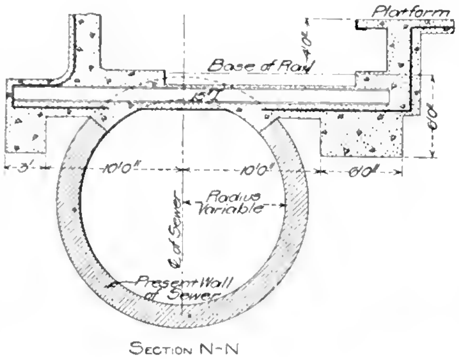
Several elevated railroad columns are located over the line of the sewer and in order to carry them and provide clearance for the excavation and construction below street surface, nine 6x6-ft. pits were sheeted down from the surface of the street to the top of the sewer arch

which was cut through and a corresponding hole cut through the invert of the sewer and the excavation continued a little below subgrade of the new sewer. The bottom of the excavation was concreted to form part of the footings for the new invert and receive a timber grillage on which were seated four 12x12-in. vertical posts extending through the sewer roof arch where they were enclosed with concrete completely sealing the hole and capped to receive two 12x12-in. timbers about 22 ft. long, which reach to the surface of the ground. Here they were capped and braced to receive one foot of the adjustable A-frame, described in previous articles, for the support of the main transverse girder of the elevated railroad structure. The Elevated Railroad column remains suspended from the transverse girders after its footing had been removed until the new sewer and subway above it is constructed and a pier built on the I-beam roof girders of the latter is ready to receive the column pedestal. A full width trench was then sheeted down in the usual way on the center line of the sewer, the old roof arch removed and the new roof constructed, completing the new sewer.

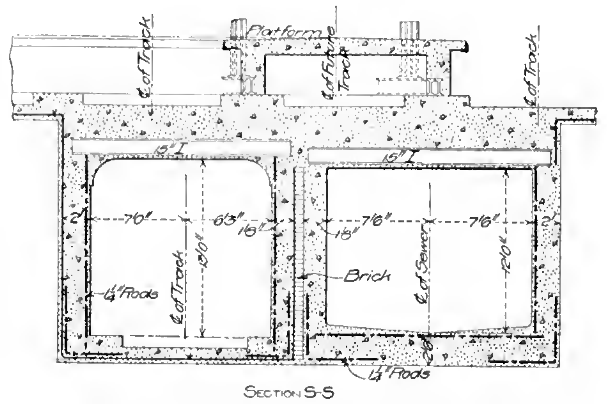
The old sewer thus replaced was built about 17 years ago by the Anderson & Barr pilot method with its brick lining constructed inside a riveted steel shell with segments about 15 in. wide and 3 ft. long, made of ⅛-in. plates and 2x3x¼-in. flange angles. These were found to be little rusted from their long exposure to the comparatively dry soil and many of the ordinary wooden barrel staves used as poling boards in the original excavation were found in perfectly sound condition. There were, however, many cavities unexpectedly encountered in the earth just above the old sewer, some of them having a capacity of 6 cu. ft. or more, one of them being so large that two men fell into it up to their waists. Much of the planking used as a cradle for the invert was also found perfectly sound, although it had not been continuously saturated.

Unusually heavy pressures were developed against the sheeting and it was necessary to provide extra numerous and heavy rangers well braced by cross-struts and diagonals. The by-pass sewer between its connections with the old sewer was entirely built in open trench, the invert being completed before the construction of the roof was commenced. No difficulty was encountered from ground water and pumping was only required in cases where excessive storm water was delivered by the old sewer and flooded the excavation. All water and gas mains and other conduits encountered were supported from beams and girders across the top of the open cut, and no special difficulties except those already described were encountered in the construction which involved about 12,000 cu. yds. of excavation, 200 cu. yds. brickwork and 1,650 cu. yds. of concrete made with 1-3-4 Portland cement, mixed on the surface of the ground and delivered where required through 8-in. galvanized iron chutes. The excavated material was removed from the trench in 1-yd. steel buckets handled by a mast and boom derrick, operated by a Lidgerwood hoisting engine, and was dumped into wagons in the street and into cars provided by the Brooklyn Rapid Transit Co., and carried away as fast as hoisted. As a matter of convenience part of the depressed subway alongside of the sewer by-pass was built at the same time as the latter, although independent of it and part of the old sewer was demolished to give clearance for it, the remainder of the old sewer remaining intact beyond the upper end of the by-pass. The sewer work was commenced Oct. 18, 1906, and was completed July 15, 1907.

The sewer work was designed and its construction supervised by the engineering department of the Rapid Transit Railroad Commission, Mr. Geo. S. Rice, chief engineer; Mr. Alfred Craven, deputy chief engineer; Mr. Sverre Dahm, general inspector of designs. Mr. Amos L. Schaeffer, division engineer, and Mr. Thad. L. Wilson, assistant engineer, in charge of work The Rapid Transit Subway Construction Co., Mr. George H. Pegram, chief engineer, and Mr. Percy Litchfield, division engineer, are the general contractors. The work was executed as a sub-contract by Messrs. Cranford & McNamee, Mr. J. C. Meem, chief engineer, and Mr. M. B. Loonie, superintendent.



Old Sewer under Subway.



Sub-Subway and By-Pass.

Underpinning for Sewer Roof and Temporary Pipe.

Cantilever Construction of the Wear Bridge.

Two tracks of the North Eastern Ry. of England will shortly be carried over the River Wear on the upper platform of a double-track bridge which, with its approaches, has about 9,000 tons of steel in the superstructure. It includes a 330-ft. clear channel span, 85 ft. above high water, and three 200-ft. approach spans. The double inter-section riveted trusses of the channel span have horizontal bottom chords and curved top cords and are 45 ft. deep at the center. They are 32 ft. apart on centers and have cantilever floorbeams about 64 ft. long, with sidewalks outside the trusses and a street car track and roadway between the trusses. The trusses have three webs in the top and bottom chords and a center rib in the vertical post.

The work is chiefly interesting on account of the method of erecting the center span as a cantilever. The approach spans on both sides were first erected on falsework and from their river ends the main span will be built out panel by panel, with the bottom chords supported by guys from the tops of temporary steel erection towers weighing over 600 tons and seated on the main piers. A large full-width solid floor working platform and a smaller riveting platform will be suspended from and travel on the lower chords.

The Baltic-Black Sea Canal scheme seems to have improved in character, for the U. S. consul at Riga states that Mr. M. S. J. Maxinovitch of the Department of Ways of Communication has been orderd to prepare plans for this route, long the plaything of Belgian promoters. It is intended for use by 900-ton barges, and in its length of 1,525 miles there will be numerous locks and canalized river sections as well as strictly artificial canals. The construction of this waterway will also permit a large amount of power to be developed at several places along the Dwina and Dnieper Rivers.

The Water Purification and Softening Works at New Orleans, La.

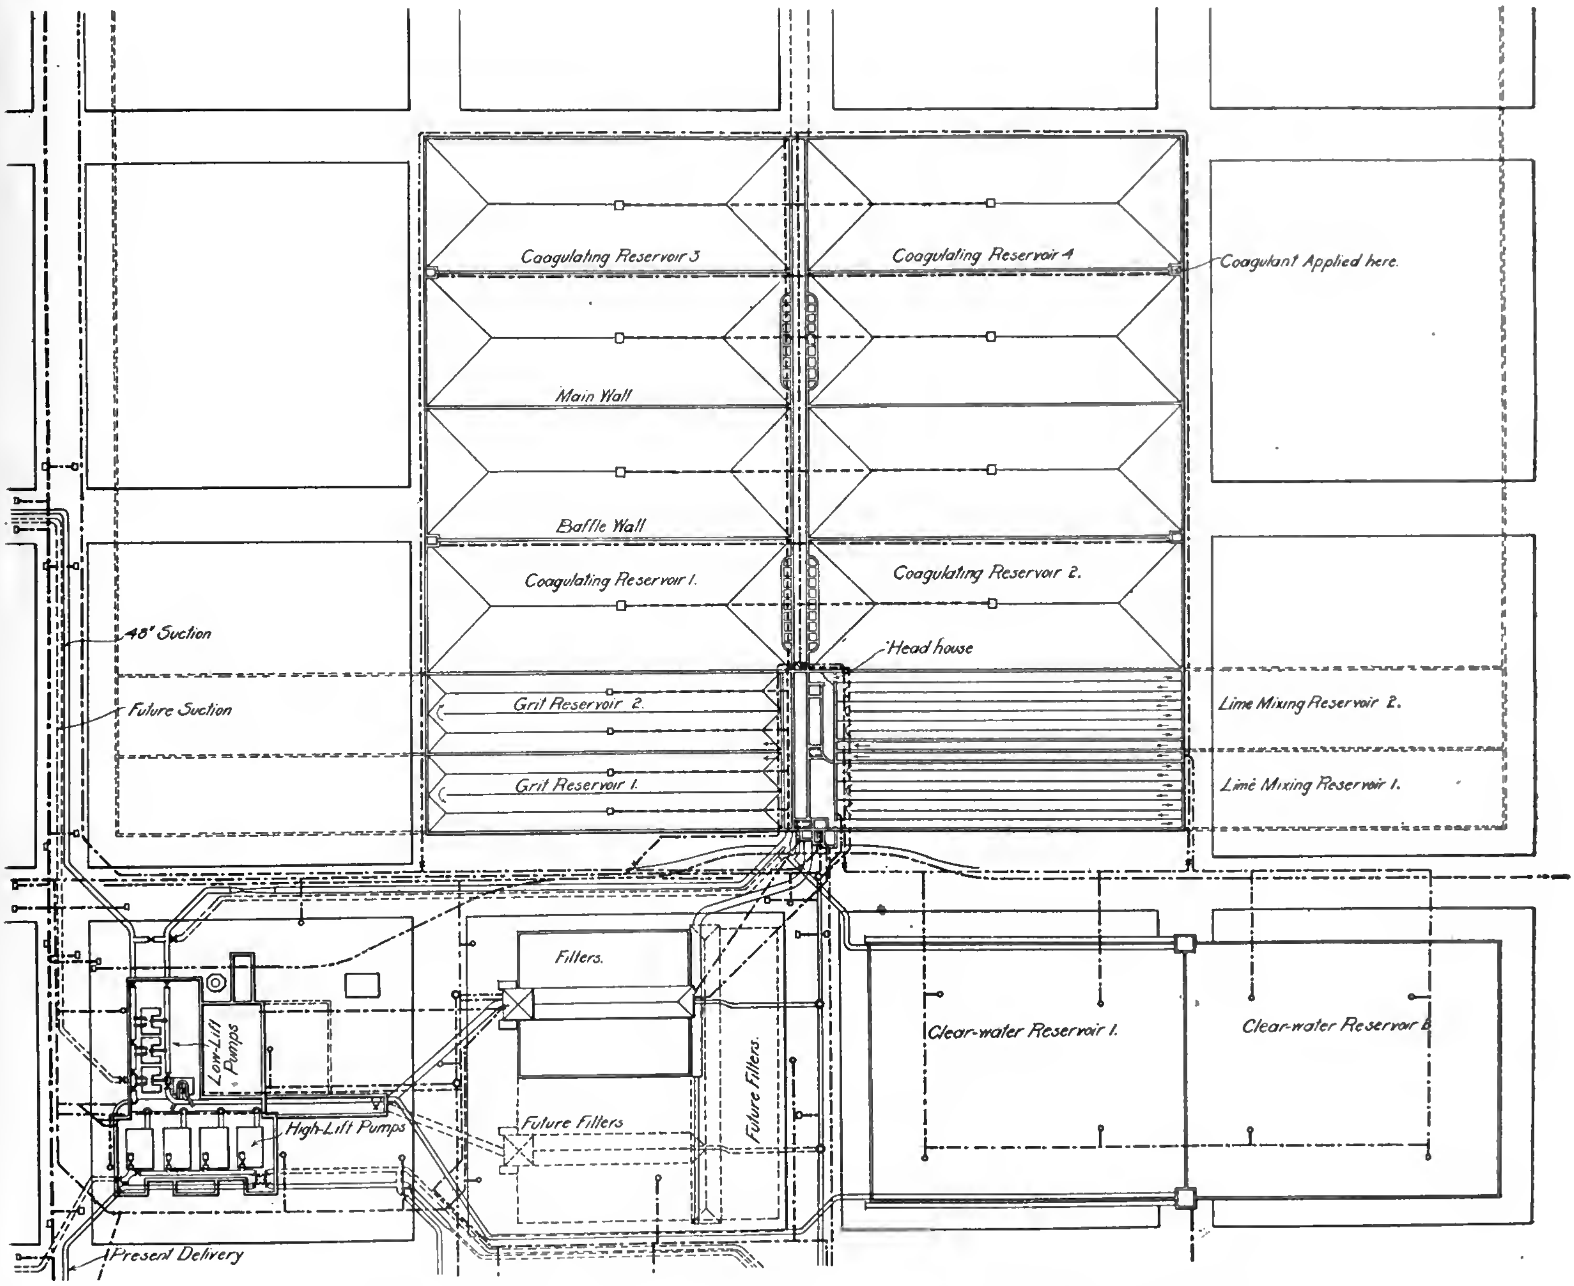
In connection with the extensive water works now under construction at New Orleans, La., two plants for filtering and softening the Mississippi River water are being built, of 40,000,000 and 4,000,000 gal. nominal daily capacity, respectively. They are similar in their general plan of construction and operation, both being designed to reduce the sulphate or permanent hardness as well as the carbonate or temporary hardness and both using mechanical filters to remove the precipitates resulting from the softening process. Sulphate of iron will ordinarily be used as a coagulant.

The larger plant will cover an area about 1,000 x 1,350 ft. It comprises a combined low-lift and high-lift pumping plant; two 72x338-ft. grit chambers, 18½ ft. deep; two 72x320-ft. lime-mixing reservoirs; four coagulating reservoirs, each about 246x342x12½ ft. deep; ten 31x53-ft. filters; and two 262x311-ft. clear water reservoirs, 14 ft. deep. The various reservoirs and the filters will be made mainly of reinforced concrete and the buildings of brick and concrete. These structures will be founded for the most part on piles, as the average bearing power of the ground at New Orleans is only about 1,200 lb. per square foot.

Raw water will be taken from the river through a surface intake, and will be drawn through 4,000 ft. of 48-in. level pipe line, laid with its top about 3 ft. below low water level, by low-lift centrifugal pumps driven by horizontal compound condensing engines. These pumps discharge into a headhouse through a 48-in. cast iron main in which is a Venturi meter. On one side of the headhouse are two grit reservoirs and on the opposite side are the two lime-mixing basins. When the river water is very muddy it will be admitted first to the grit chambers where subsidence will remove the heavier suspended matter consisting of sand and silt. Each grit chamber has a longitudinal baffle wall on its center line which makes the water travel double the length of the tank. The total capacity of the grit chambers is equivalent to about one hour's flow. Returning to the headhouse, the somewhat settled water will pass through submerged orifices into the lime-mixing reservoirs, each of which is divided into sixteen longitudinal passages by seven vertical longitudinal baffle walls and one horizontal baffle midway between the top and bottom of the reservoir. At the entrance to this reservoir, lime will be added regularly to reduce the carbonate hardness and to assist in the coagulation. Soda when necessary for the elimination of the sulphates will also be applied as the water flows through this reservoir, although the latter will not be used save during low-water stages in the river when the sulphates are high. The quantity of chemical solutions added will be automatically regulated in proportion to the varying volumes of water treated by the flow through a series of submerged orifices. The automatic controlling apparatus throughout the plant is one of its distinguishing characteristics.

Lime will be added, not as lime water but as a milk of lime containing about 5 per cent. of lime by weight, which will be kept thoroughly stirred by motor-driven rakes and paddles. The coagulant department in the headhouse contains besides a storage room, three slaking tanks 7 ft. in diameter and 6 ft. deep, and three milk of lime tanks, 11 ft. 3 in. by 11 ft. by 11 ft. deep. Ventilating arrangements are provided to remove the steam and lime dust from the slaking room. Sulphate of iron will be prepared as solutions containing 5 per cent. by weight in three tanks, 8 ft. by 10 ft. 6 in. by 10 ft. deep. A similar set of tanks is provided for the application of soda. Compressed air will be used for stirring the solution of soda and sulphate of iron. All of the tanks in the headhouse are of concrete. Lead-lined iron pipe will be used for the sulphate of iron solutions, for the most part, several connections being of copper or brass. Iron or vitrified pipes will be used for the soda and lime.

The headhouse, 150x50 ft. and two stories above the water level, will contain in addition to the coagulant department the main office for the purification works and a suite of laboratories. The latter, four in number, occupy an area of 1,000

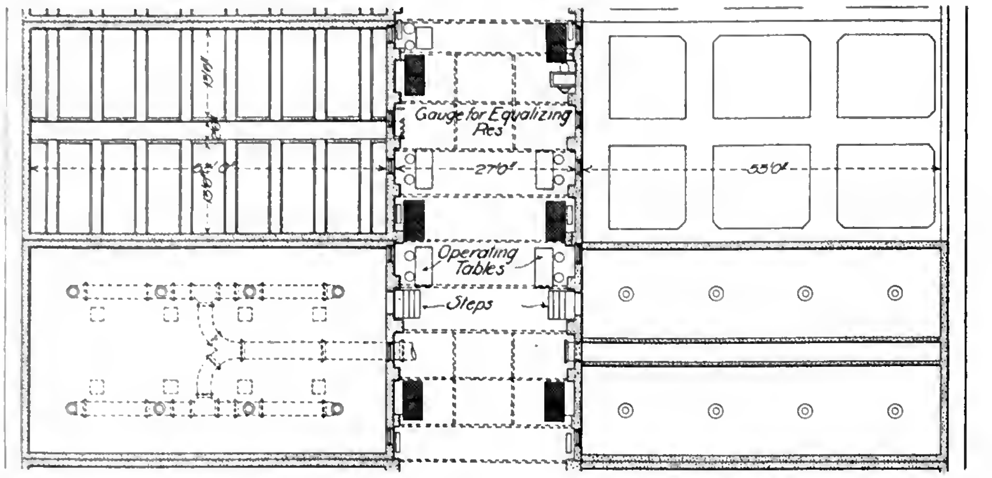


General Arrangement of Water Purification and Softening Plant at New Orleans.

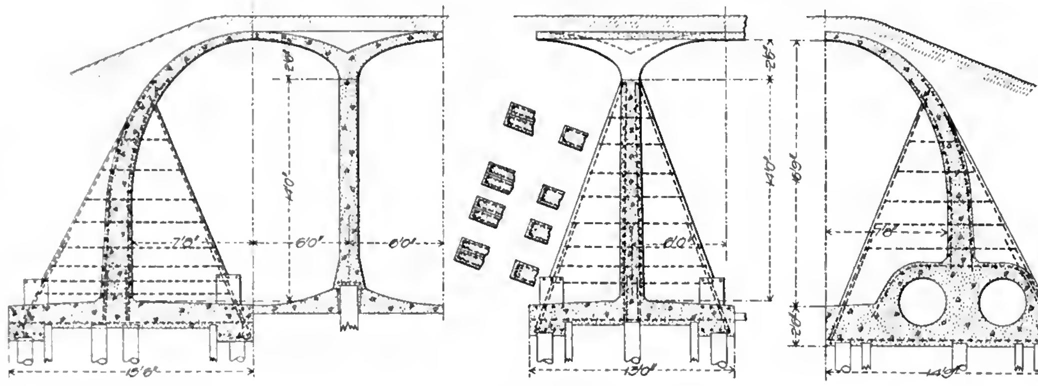
square ft. and will constitute an important part of the plant from the standpoint of efficient and economical operation. Beneath the main floor of the headhouse will be a chamber for the sludge pumps and numerous compartments or waterways to facilitate the flow of water to various connecting portions of the plant in a manner best suited to the varying character of river water.

The flow through the lime-mixing passages will normally require about one hour and the velocity will be such as to facilitate the solution of the applied milk of lime, the reaction of the resulting lime water with the river water, and the thorough mixing of the resulting precipitate with the silt and clay. The water will then reach the head house again and will be passed into the coagulating reservoirs, holding about 7 hours' normal supply, where subsidence due to the coagulating effect of the lime will take place and where sulphate of iron will be added to complete the coagualtion and to eliminate the caustic alkalinity. River water will also be conducted to the coagulating reservoirs to assist in reducing caustic alkalinity, if required. These reservoirs are in several compartments so that the period of subsidence can be varied as desired. The treatment of the water in the grit, lime-mixing and coagulating reservoirs will be a continuous process, the water flowing through each compartment constantly. From the coagulating reservoirs the water will pass through the headhouse and on to the filters.

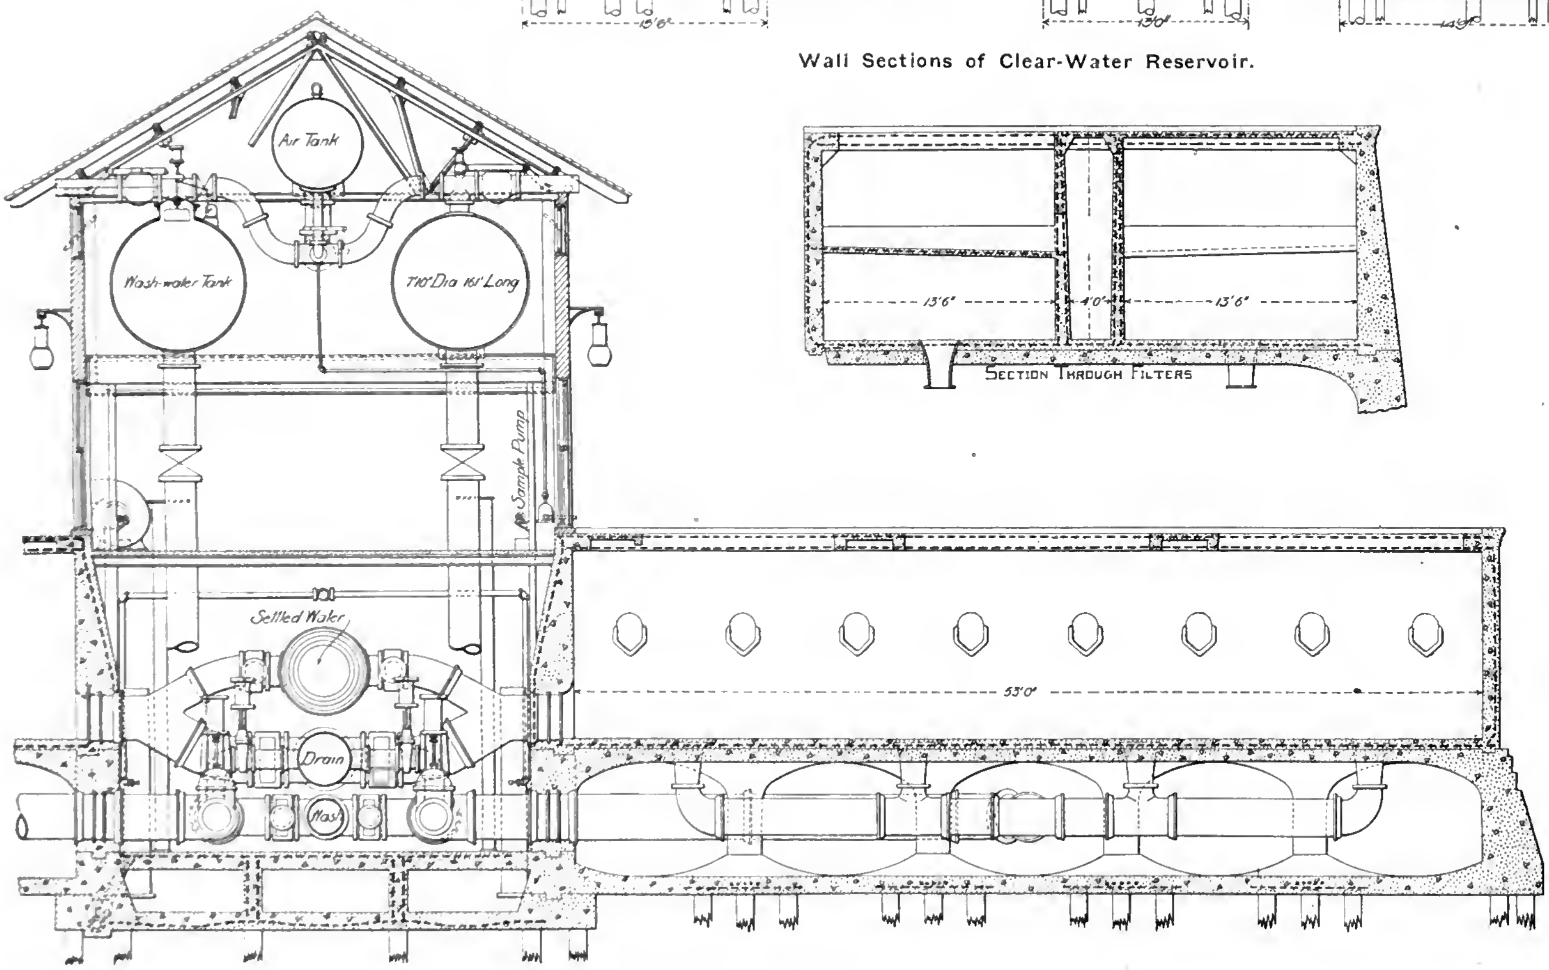
The flow through the filters will be automatically regulated between fixed limits, ranging from a 50 per cent. underload to a 50 per cent. overload. The normal daily yield per filter unit of 1,430 sq. ft. will be 4,000,000 gal. corresponding to a rate of 125,000,000 gal. per acre per day, or about 2 gal. per square foot per minute. By a gradual change in rate so that their efficiency will not be affected, the filters will tend to respond to the demands of the distribution pumps, filtering at a high rate when the water level in the equalizing clear water reservoir beneath the filters is low and at a low rate when it is high. The equalizing reservoir is directly connected with the pump well, and each filter can be placed under this form of control or can be set to any required rate regardless of the height of water in the pump well.



General Arrangement of Filters on Operating Floor.



Wall Sections of Clear-Water Reservoir.



Section Showing Piping Layout in Filters and Filter Gallery Building.

Other than as regards their comparatively large size of unit the filters will be characterized chiefly by being uncovered and by being washed with water without the aid of agitation of the sand layers either by compressed air or by mechanical stirrers. They are designed to receive wash water at a vertical velocity of 30 in. per minute. Wash-water will be supplied from two steel tanks placed beneath the roof of the filter house, and into which water from the distribution system will be allowed to enter slowly. Above the wash-water tanks wil be a third tank, with suitable regulating valves, to receive the air forced from the wash water tanks. This air can be compressed to about 60 lb. pressure and will be available with the aid of reducing valves for increasing the rate of flow of water from the wash-water tanks to the filters as desired.

To insure a constant supply of water in the pump well, and a fairly uniform rate of filtration, the covered clear water reservoir, holding about 6 hours' supply, will be pumped full at night

when the consumption is low. These are connected to the pump well by a 48-in. pipe line in which is an automatic valve which will open whenever the water in the well falls below a predetermined level. The water is forced into the distribution mains by vertical triple expansion crank and fly-wheel pumping engines supplied with steam by water-tube boilers equipped with automatic stokers.

The 4,000,000-gal. plant, which in general design and operation is very much like the larger one, is situated on the west bank of the river and will serve the Algiers district with a population of about 20,000, about one-fifteenth of the city.

The construction of these works is in the hands of the Sewerage and Water Board of New Orleans, Mr. Geo. G. Earl, General Superintendent and Chief Engineer. The purification plants were designed by Mr. Geo. G. Earl, Messrs. Geo. W. Fuller and Rudolph Hering acting as consulting engineers. Messrs. Black & Laird, Ltd., New Orleans, are the contractors for the two plants, exclusive of the pumping machinery. Their bid was $1,840,727.30. The equipment of the filters was sublet to the Roberts Mfg. Co., of Philadelphia.

The Use and the Abuse of Sewage Purification Plants.

A paper read before the Ohio Engineering Society by Mr. A. Elliott Kimberly, Special Assistant Engineer, Ohio State Board of Health.

The adequate protection of inland streams and lakes from pollution by the sewage of cities and towns has become one of the great problems of the present day. From the early nineties the advance in knowledge of the art of sewage purification has been so great that to-day as a result of research and of experience gained by the operation of sewage purification plants upon a large scale, it is generally considered practicable to carry the purification of domestic sewage to such a state that the once foul liquid is rendered stable and no longer shows putrefactive tendencies. In a further discussion of the subject, which is no doubt familiar to the members of this society, the thought suggested itself to the speaker, that some benefit might accrue from viewing it from the standpoint of practical results, that is, with this question in mind: By the use of the sewage plant has there been afforded a protection of rivers and bodies of water; or if not, what are the causes underlying the failure of the sewage purification plant to accomplish this end?

Problem of Sewage Purification.—Shortly after the introduction of the water carriage system of sewerage in 1855, it began to be recognized that the withdrawal of the liquid wastes of the community from the immediate neighborhood of the city or town did not entirely effect their satisfactory disposal, especially where such communities were located on the banks of streams of small flow subject to summer drought. During such low flows, offensive odors would emanate from the sludge deposits on the drying shores, affecting the health and welfare of the inhabitants of the community itself or of others located below upon the same stream. For the benefit of the community itself, or as a result of suits on the part of the lower riparian owners, it became necessary to adopt such means for the purification of the polluting discharges that the original purity of the stream would be restored to as great an extent as practicable. Such, in a general way, is the case to-day, especially in inland cities and towns located upon the banks of small streams. A dilution of from 36 to 45 to 1, such as is usually considered to be sufficient to prevent putrefaction on the part of mixed sewage and river water, is usually obtainable only in the case of cities or towns situated on the shores of the larger rivers, hence in other cases the problem of the purification of sewage presents itself for consideration.

As it well known, the extent to which it is necessary to carry the purification of domestic sewage is governed largely by local conditions. By this is meant that according to circumstances of flow of a stream, the character of its waters and their subsequent use as a source of water supply, the needed degree of purification of the sewage discharged into the stream may vary within wide limits. Aside from the discharge of sewage into the sea, where after rough screening, putrefaction is overcome by processes of dilution, the needed degree of purification of domestic sewage may be said to be governed by three general rules. These are as follows:

1. Where the sewage effluent is to be discharged into running streams subject to floods and with a water containing considerable turbidity at all seasons of the year, the degree of purity required need not be more than that of an effluent which undiluted will no longer putrefy under summer conditions.

2. In streams the waters of which are clear except at times of flood, the purification of the sewage should be such as to remove from it the largest practicable quantity of suspended matter, so that the visible purity of the stream will not be affected, the non-putrefaction of the effluent being taken as coincident with a degree of purification which will afford an absence of all but small amounts of turbidity.

3. In drinking water streams, and in certain cases of sea discharge where shell fish layings must be protected from contamination, the purification of the sewage must needs be carried out to its fullest extent, and besides the production of a chemically stable effluent, the problem practically reduces itself to the destruction of all the disease-producing bacteria present in the raw sewage, by subjecting the well-purified effluent to some form of sterilization process.

The conditions referred to in the first instance are such as obtain quite generally in Ohio and the Middle West. In practically all of the plants in operation in this State, the attainment at all times of a non-putrescible effluent would satisfactorily accomplish the purpose for which the sewage plant was installed. That is to say, in this section of the country where the glacial drift formation is absent and where abound clayey soils subject to easy erosion, practically all streams are muddy throughout the year, and except in a few cases where there is involved the protection of a water supply, the abatement of a nuisance from the discharge of sewage into small streams with but low dilution, is readily effected by processes of purification, depending upon the use of filters of coarse material operated at fairly high rates and yielding effluents, which, when clarified by subsidiary subsidence, mixed with river water, successfully pass tests for ultimate stability.

In cases where streams are of low turbidity except in flood stages, processes of sewage purification looking merely to the ultimate stability of the effluents therefrom, owing to the suspended matters incidental to their effluents, will tend to impair the general appearance of the stream, and in these, advantage must be taken of types of purification processes involving the use of materials of fine grain and operated at comparatively low rates. Such conditions are generally found in New England and in some of the States upon the Atlantic coast line, where, fortunately, sandy areas of suitable size and character are usually available, and under proper supervision and intelligent management, the use of these areas produces effluents of a high degree of purity containing but small amounts of suspended matters for the greater part of the year.

In streams used subsequently as a source of water supply, the discharge of sewage therein must be prevented whenever possible. Many instances are to be found, however, of sewage discharge under such conditions as the above, and hence there becomes necessary a form of sewage treatment that not only will prevent what may be called the chemical pollution of the stream, but such as will destroy all bacteria of pathogenic origin as well. As yet, but little practical knowledge has been developed in this country as to the practicability of destroying the bacteria of disease which the most thorough practical sewage treatment fails to remove. Considerable recent work, however, has been done along this line in England and in the United States, and experiments have been conducted in several places in this country looking to a solution of this phase of the sewage problem. A number of disinfectants have been tried thus far, chief of which may be mentioned: Lime, acids, ozone, permanganate chlorine as bleaching powder and also produced electrolitically, and copper sulphate.

Data are yet too meagre to enable conclusions to be drawn as to the practicability of the disinfection of sewage effluents, in part as to the most efficient reagent to be employed, and in part on the grounds of cost, but with the accumulation of evidence from experiments carried out up to the present time, it appears to be quite generally recognized that the day is not far distant when drinking-water streams will be rendered free from pollution by sewage bacteria of disease origin by the use of sterilizing agents, before the sewage effluent carried to a non-putrescible state by a modern process of sewage purification, shall be allowed admission into a stream used below the outfall for domestic consumption.

Ohio Sewage Plants.—At the present time the Ohio plants comprise eighteen municipal, town or village plants and nineteen institutional plants; seven are under construction and the number of proposed plants appears steadily to increase.

The sewage plants in this State embrace practically all the principal methods of sewage treatment from simple clarification by the use of chemicals followed by settling tanks (chemical precipitation), a practice followed so largely in the earlier days of sewage treatment, to the modern continuous filter composed of particles of coarse grain and operated with settled sewages at high rates of filtration per acre. In fact, within about a year, the city of Columbus will be treating its sewage in a plant which represents the most advanced type of sewage purification plant, wherein the screened sewage, settled in septic tanks, will be applied to filters of coarse grain material 5.0 ft. in depth, the application of the sewage being effected by means of nozzles operating under a head of about 5.0 ft., causing the sewage to reach the filters in a spray or in fine drops similar in effect to the action of lawn sprinklers. The Columbus plant when completed will be the largest of its type in operation in this country, as it will comprise septic tanks of 8,000,000 gal. capacity, ten acres of filters and subsidiary settling tanks of 4,000,000 gal. capacity, the ultimate capacity of the design being 20,000,000 gal.

General Efficiency of Ohio Plants.—In view of the great variety of sewage purification treatments carried out in this State, it is not surprising that the degree of purification obtained varies within very wide limits.

The older chemical precipitation processes at best effect a clarification of the sewage with a removal of from 50 to 60 per cent. of the suspended matters, but, of course, the resulting effluents are highly putrefactive, of foul odor and require a high dilution with river water to prevent the rise of a nuisance along the shores of the streams into which they are discharged. In some instances, moreover, the effluent appears to be more highly putrescent after chemical treatment than before, due, it would appear, to the well-known solutionizing action of lime in excess upon suspended organic matters.

In general, it may be said that the treatment of sewage by chemical precipitation alone will probably be productive of foul odors and obnoxious conditions, in addition to the heavy burden of sludge disposal, and in the speaker's opinion, the process, except in rare cases, is to be considered superseded by those of more recent origin.

In the smaller plants, sewage is treated either upon areas of sandy soil, at times also heavy with clay, or upon sand filters of artificial construction, according to the well-known process of intermittent filtration. The variation in the details of a sewage plant of this type is very great, especially as to the character of the filtering medium, the method of flooding the filters, the amount of sewage applied at each dosing, and the amount of preparatory treatment to which the applied sewage has been subjected.

Excellent results are being obtained by the intermittent filtration process in cases where the material is of suitable grade, the quantity of sewage to be treated is not excessive, and where

the supervision is such that the filters receive the proper amount of attention, by which is meant the raking of the surface material, the operation of the filters upon a strictly intermittent basis, in the absence of automatic flooding devices, and the thorough cleaning of the filters in case there develops evidence of ponding due to over-dosing or to clogging on the part of the surface layers.

As a general rule, the filters composed of material of fine grain now in operation in Ohio may be said successfully to purify the sewage applied to them, except in the case of a number that need enlargement or to which but little attention has been paid on the part of those in charge. The clear-cut effluent obtained from the intermittent sand filter is met with occasionally, but requires optimum conditions with respect to the quantity and the quality of the applied sewage, rigid intermittence in the flooding and careful attention to the filter surfaces to ensure the ready admission of the oxygen essential to a maximum of oxidation.

In a number of plants constructed in the last eight years, some form of preparatory treatment has been included in the design aside from the older chemical precipitation processes. Chief of these processes is the treatment of the crude sewage by sedimentation in septic tanks, wherein there is effected a removal of about 50 per cent. of the suspended matter of the crude sewage with the resulting liquifaction of from 25 to 50 per cent. of the deposited sludge. At the present time there are fifteen septic tanks in operation in this state; of this number, twelve are covered and three are open tanks.

The general appearance of the different septic tanks varies greatly. Of those mentioned above, some appear to destroy sludge readily, while in others the accumulation of sludge is quite rapid. The presence or absence of scum on a septic tank is somewhat difficult to foretell, as it seems to be dependent upon several conditions, chief of which perhaps is the relative strength of the sewage, dependent on the per capita sewage flow. With a small per capita flow, sewage tends to possess a turbid, milky appearance, is strong smelling after but short storage and contains a relatively large proportion of colloidal suspended matters. Highly diluted sewage, especially where large amounts of surface water are included, generally carries suspended matters of a flocculent character, capable of rapid subsidence under a reduced velocity and at times carries a small amount of dissolved oxygen through the septic tank. Broadly speaking, sewages may be separated into the above two classes, the division between which is rather indefinite. From the observation and the experience of the speaker, however, it has been noted in many instances that scum formation and highly concentrated sewage are in some way intimately related, as in the case of tanks treating weak sewages, the rising sludge forced upward by the gases incidental to sludge fermentation generally falls back again before a permanent scum has an opportunity to be formed.

The efficiency of the septic tank may now be said to be dependent upon the relative quantity of suspended matters that may be removed by the tank, the older view of the modification of the liquid portion of the sewage itself having been disproved by a number of instances in recent years. Without the aid of chemical analysis and carefully averaged samples extending over a considerable period, it is of course difficult to judge of the actual efficiency of the septic tank. At the same time, from the general appearance of the oxidizing devices and from the fact of the successful operation of the plant at rates considerably higher than would be possible were the raw sewage applied to the filters, it will be apparent that the septic tank as a preparatory process for the removal of a part of the suspended matters in many instances has proven itself an important factor in sewage purification.

There is another side of the treatment of sewage in septic tanks that deserves considerable attention, namely, the disposal of the residue from the hydrolysis of the sludge. The first advocates of the septic process were firm in their convictions that at last there had been devised a process for sewage treatment that would effectually solve the problem of the sewage problem, the disposal of the sludge. Many statements were made and many views were expressed that a septic tank, when installed, would never require cleaning; that in some manner not clearly understood it was capable of destroying the sewage solids to be subsequently applied to it. Such views are now known to be untenable. While the process does effect the destruction of a certain proportion of the deposited suspended matters, yet there always remains an ever-accumulating quantity of sludge which in course of time requires removal, in fact in the most modern designs sludge areas are provided for the cleaning of the tanks.

Considerable experience has been gained relative to the cleaning of septic tanks, and the undertaking is not generally considered to be attended with the production of a nuisance, as might be supposed. In fact the removal of the sludge from a septic tank which has been in service for a considerable period, may readily be handled at any plant without particular discomfort on the part of the workmen or of the people in the immediate neighborhood. The absence of odor in well-matured septic sludge is such as to cause considerable comment when for the first time an opportunity is afforded to witness the cleaning of a septic tank. As reported by Mr. R. W. Pratt, C. E., the Mansfield septic tanks were cleaned in the spring of 1906. In all there was removed about 1,200 cu. yd. of sludge. This sludge was of a pasty nature, it had been compacted during its four years' storage to a water content of only 82 per cent., and, further, its putrescent components had been so altered by bacterial decomposition that the wind blowing over a comparatively large surface of the sludge ponded to a depth of a foot and freshly deposited, brought therefrom practically no noteworthy odors. Such then is the result of what may be said to be one of the important offices of the septic tank, the conversion of the non-hydrolized sludge into a residuum no longer amenable to putrefaction and without an appreciable odor.

In addition to the above mentioned points in regard to the efficiency of septic tanks, there is still another phase of this form of preparatory treatment which deserves more than a passing notice, that is, the periodic upheaval of the sludge deposits and the consequent clogging of the oxidizing units by the suspended matters thus carried onto the surface material. It is a well-known fact that there are periods in the operation of a septic tank usually subject to continuous quiet ebullition of gases, and with a relatively high subsidence efficiency, when of a sudden there rises to the surface of the sewage large masses of undigested suspended matters borne upward by the sudden release of a comparatively large quantity of gas confined under perhaps a heavy deposit of sludge. At such times, the suspended matters in the effluent increase abnormally and tend to choke the pores of the filters, and in certain cases cause the production of decided odors in and about the tank and the plant. This feature of the periodic upheavals in septic tanks, in many ways is, of course, a marked detriment to the process, owing to the load of finely divided suspended matters that are forced upon the oxidizing devices; it is, however, a condition which may be considered as inevitable in the case of most sewages and to a certain degree it would be desirable to provide means to prevent the damage which is caused by the sudden discharge of suspended matters in such large quantities. Generally, aside from surface baffles located near the outlet end of the tank, these being intended to cause the sewage in discharging to pass out with a minimum of disturbance, no special devices have been employed to reduce the suspended matters at the periods of unusually violent septic activity, and the effluent heavily charged with suspended matters passes on to the filters. At such periods filters of fine grain require especial care in their operation, and unfortunately for the general efficiency of the plants, the lack of attention they receive is in many cases deplorable. In the case of strong sewages it appears to be a difficult matter to control these fomenting periods in septic tanks, although tanks on the comparment plan and those operated in series may quite possibly be effective in some instances.

About the time sudden impetus was given to the construction of sewage plants by the rise in favor of the septic tank as a part of the design of such plants, considerable work was carried out particularly in England as to the feasibility of treating sewage in filters composed of fairly coarse grain material. The first of these were operated upon the contact plan, wherein the outlet of the filter is closed, sewage admitted until the pores of the filter are filled, after which the sewage is allowed to stand for a stated period in contact with the filtering material, thus subjecting it to the action of the bacteria retained thereon. The contact filter will be recalled as a type of filter resulting from the increased knowledge of the bacteriology of sewage treatment brought forward particularly as, by its adoption, the purification of sewage was hoped to be the more economically accomplished in cases where fine grain material was scarce and where a limited area was available as a site for the sewage plant. As the head required for the operation of a sewage plant involving contact filters is less than that necessary for the most recent development —the sprinkling filter—there are many cases where the installation of a contact filter plant may successfully solve the problem of sewage purification especially where sand filtration is impracticable.

The plants operated on the contact priniple in Ohio number eight, and in each case the sewage is subjected to some form of preparatory treatment before being oxidized in the filters. The efficiency of these plants varies considerably. In some instances the resulting effluents are carried to the non-putrescible stage as a result of the preparatory and the oxidizing treatment, while in others, the effluents of the contact filters possess considerable odor, are free from dissolved oxygen and protecting nitrates, and do not successfully pass tests for putrescibility.

In the majority of cases the effluents as discharged are low in suspended matters and hence of good apeparance. This feature of the retention of the suspended matters of the applied sewage is characteristic of the contact filter and it is evident that the amount of suspended matter contained in the sewage applied to filters of this type controls in a measure their holding capacity and thus the period between obligatory cleanings of the filtering material. Owing to the detrimental effect caused by flooding contact filters with a poorly prepared sewage, that is, an influent of high suspended matter content, the operation of contact filters in conjunction with septic tanks should be carefully watched. By taking advantage of the flexibility of the design of the preparatory devices, the endeavor should be so to operate them, that, changing conditions being met by modified operating procedures, the sewage applied to the contact filters may be as free as possible from suspended matter, never showing evidences of too prolonged retention, conditions

which will tend to enable the contact filters to operate at their best with a minimum of clogging.

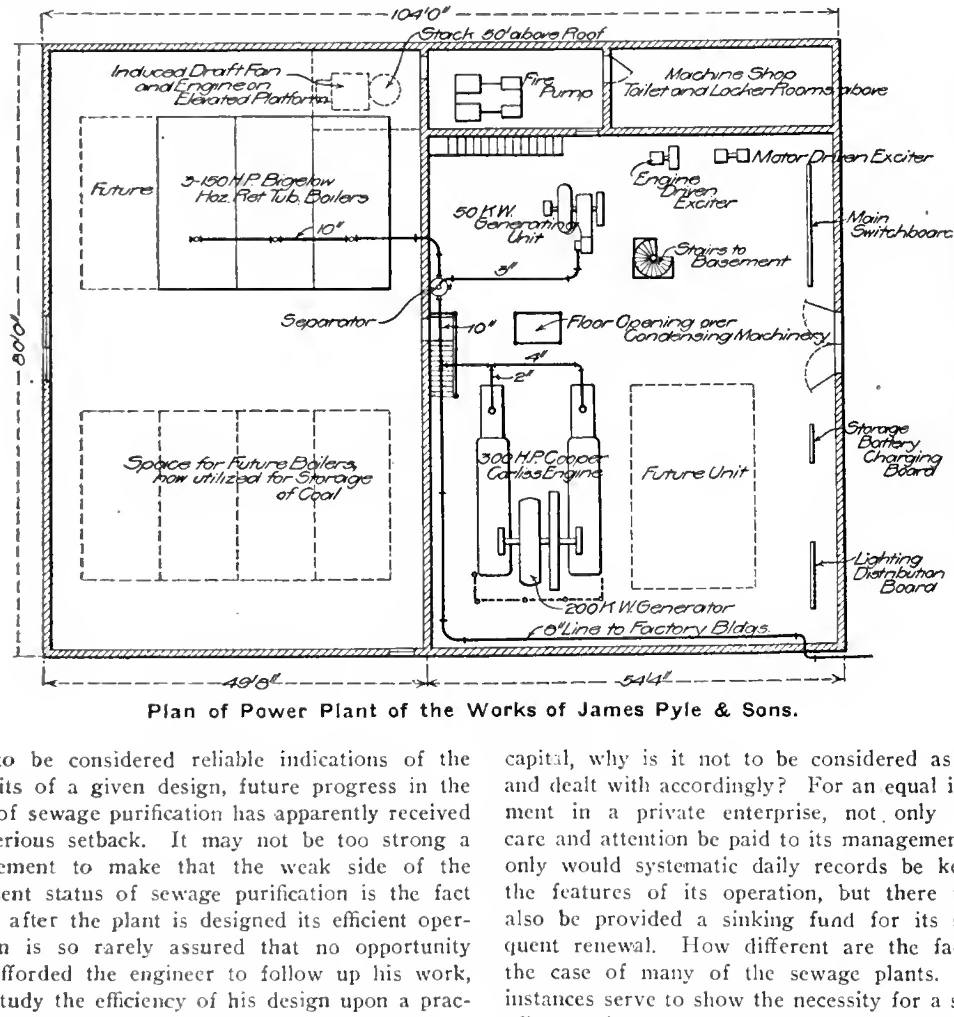
While the sandy area or the artificial sand filter receiving practically crude sewage or that treated by subsidence in septic tanks, are chiefly represented among Ohio plants, yet there are certain cases where a finishing process follows the oxidizing treatment, by which are obtained effluents of considerably purity, generally stable and of low suspended matter content.

Neglect of Sewage Plants.—The failure of the sewage plants at present in operation, is due in many instances to the lack of careful supervision, to the utter disregard of the principles underlying the successful prevention of a nuisance by the use of the sewage plant, to exceeded capacity and at times to faulty design. The types of sewage plants represented by those just reviewed, depend for their success upon the manner in which they are operated.

The idea that the construction of a sewage plant ends the matter in so far as relates to those responsible for its construction, is clearly false in the extreme. New conditions are constantly arising brought about, if you will, by the ever-increasing volume and strength of the sewage due to new connections, especially in towns recently sewered, and to meet such changed and ever-changing conditions means should be provided for the due care and attention of the sewage plant at all times. In planning the purification of the sewage of a city or town questions of economy at times demand that the areas initially provided shall be limited to such as will effectively handle the estimated sewage flow for the immediate needs of the community, together with slight additional amounts to provide for future growth. In addition to the quantity of sewage provided for by the design, the flexibility of the design should be such that additions to the plant may readily be made when the future demands upon the plant require such extensions. As the period of service of the sewage plant increases and as the adoption of the water carriage system of sewage becomes more general in a community, the sewage plant in many instances subject to but scant attention has become so overburdened by the largely increased volume of sewage reaching it daily, that under the best of supervision and management it will not be adequate to meet the increased volume of sewage flow. There appears to be but little attention paid to this side of the sewage purification question and as a result there are to be noted a number of plants which are fast approaching the nuisance stage. The needed increase in the area of a sewage plant commensurate with the increased number of connections with the sewage system brings up the further point that before drawing definite conclusions as to the problem of the sewerage of a city or town, in cases where disposal by dilution may serve for a time to prevent nuisance, the details of the sewerage system should be such that a sewage purification plant may be installed without undue cost when dilution facilities become inadequate with the increased use of the sewers.

With the installation of an automatic device, the idea seems to have become fixed in the minds of some, that such devices eliminate for all time the necessity for all supervision and at times plants so equipped are to be found in a state of sad neglect. Not alone do the filters themselves suffer from this lack of care and attention, but the dosing or discharging apparatus itself has gradually deteriorated, its moving parts have become rusty for want of oil with a final result that the feature of automatic operation has to be abandoned and the plant is then hand operated with enforced supervision, often times but little more systematic than obtained during the life of the automatic appliances.

In the case of plants operated on the intermittent basis, it is apparent that considerable care is necessary to keep the surface material porous and free from vegetation, in this way overcoming the deterioration of the effluent resulting from the inability to operate the filters intermittently. The cost of maintenance for sewage plants is not as great as might first appear and surely by due regard to the condition of the plant at comparatively frequent intervals, thereby insuring its high efficiency at all times, there will be entailed less cost in the long run than the extensive repairs, weed cutting, grubbing, plowing, etc., eventually necessary when plants have been utterly neglected for long periods.



Plan of Power Plant of the Works of James Pyle & Sons.

For the protection of the waters of this ever-growing country there is a need for the purification of all sewage within a given water shed. With a sewage plant ready for service, every effort should be made to operate it to the best advantage. Unless the results obtained from sewage plants under practical operation are such as to be considered reliable indications of the merits of a given design, future progress in the art of sewage purification has apparently received a serious setback. It may not be too strong a statement to make that the weak side of the present status of sewage purification is the fact that after the plant is designed its efficient operation is so rarely assured that no opportunity is afforded the engineer to follow up his work, to study the efficiency of his design upon a practical scale and to add to the progress of the art of sewage purification by the modification of future designs according to the experience gained from the operation of plants designed according to older standards. A neglected sewage plant can hardly be counted upon to afford much reliable information along the above mentioned lines, hence it is apparent how urgently necessary is a radical improvement in the handling of sewage purification plants.

The need for the expert supervision of the sewage plant, especially in the early history of its service, is well expressed by Alvord in a paper read before the Western Society of Engineers, several years ago. He says: "The termination of the expert supervision of sewage purification plants usually takes place a few weeks after their completion. The engineer who had their inception and formation, and who has studied every phase of their environment, who knows what kind of sewage is to be dealt with and its quantity and variations, who understands how such variations are to be met, and who will be equal to any emergencies, drops out, is paid off, and the plant is turned over to the tender mercies of a place-hunter perhaps, or is forced on the unwilling care of some city official with other duties which already fill his time. This is wrong, and to this condition can be traced many cases of dissatisfaction on all sides. The engineer who has carefully designed and constructed a sewage disposal plant should be retained to supervise its operation for at least a year after it is started. He is the one of all others who can successfully launch it on a successful career, and meet the problems of control."

Another phase of the neglect of the sewage plant is the indifference exhibited by officials. The sewage plant is not a revenue producer, it was installed in many cases as a result of suit, it will probably reflect no special credit on the political administration, hence a tendency to cut to a minimum charges for operating expenses, to allow it to pass into oblivion. As the sewage plant represents so much of the city's invested capital, why is it not to be considered as such, and dealt with accordingly? For an equal investment in a private enterprise, not only would care and attention be paid to its management, not only would systematic daily records be kept of the features of its operation, but there would also be provided a sinking fund for its subsequent renewal. How different are the facts in the case of many of the sewage plants. Such instances serve to show the necessity for a strong effort to improve present conditions, and all in any way associated with sewage purification plants should take advantage of every opportunity to place the practical side of the purification of sewage on a better footing.

In these days of the rapid advance of sanitary science, it is signally fortunate that by recent Ohio legislation there has been provided a means whereby attention may be called to the neglected sewage plant and whereby opportunities may be afforded for closer study of the sewage problem upon a practical basis, with the endeavor to raise the operating standards of all sewage plants that they may effectively solve the problems of sewage purification.

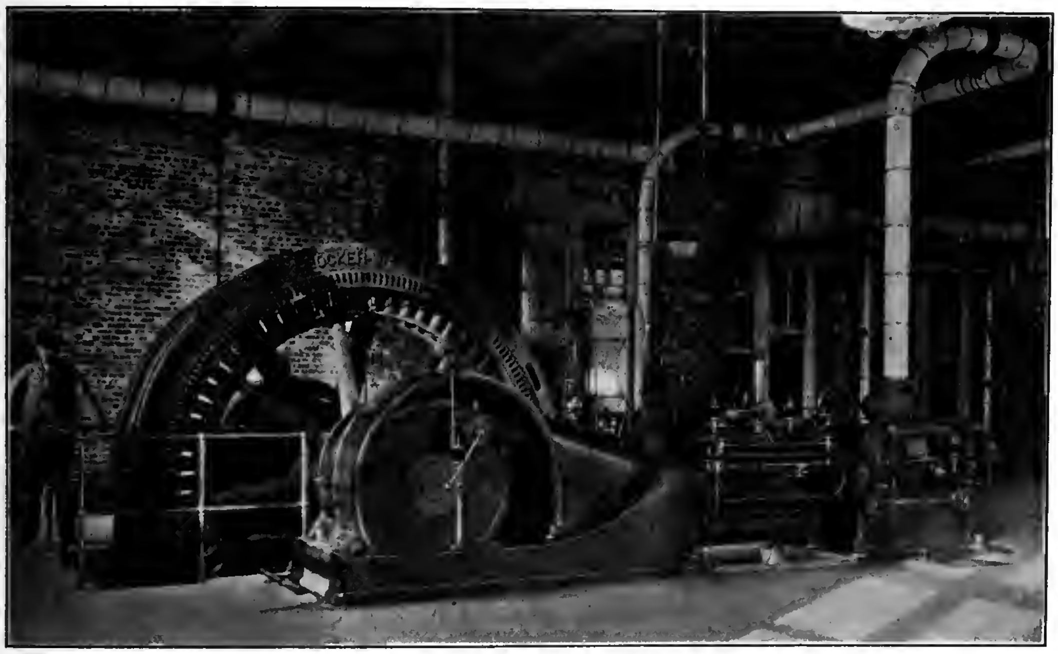
Peat Briquettes are now being made at Norfolk, Mass., with a machine invented by Mr. M. C. Sharpneck, and controlled by Dr. S. D. Treible, of 41 Boylston St., Boston. The peat is cut up by revolving knives like a meat chopper and then pressed through a die in a continuous bar, which is sliced into briquettes by a knife operated automatically.

Power Plant of the New Works of James Pyle & Sons.

An extensive plant has recently been completed for James Pyle & Sons, at Shadyside, N. J., for the manufacture of Pearline powder and other soap products. The location of the works is at the foot of the Palisades on the west shore of the Hudson River, some six miles north of Jersey City and directly opposite 90th St., Manhattan. Ample space available at this site permitted an arrangement of plant best suited to the handling of materials and processes of manufacture, and a scattered lay-out of buildings was selected with power transmission for its operation from a central power plant. There are two large manufacturing buildings, one three stories and the other five stories in height, and a two-story stock and office building. The former are of fireproof construction throughout, while the latter is of modified mill construction. The power requirements of the plant include the supply of steam for heating the buildings and for the operation of boiling tanks for the manufacturing processes, and also the supply of power for the operation of machinery and lighting. The power plant is located at the rear of the site, convenient to rail connections for the receipt of coal.

The station is a brick structure nearly square in shape with concrete floors and wooden roof carried on steel trusses, and is divided through the middle by a brick wall separating the boiler rooms from the engine and pump rooms. The boiler room is 50x80 ft. in size, having its floor practically on ground level, with a clear headroom under roof trusses of 20 ft. The engine room is 54x68 ft. in size with 15 ft. headroom under roof trusses and its floor elevated for an 8-ft. basement underneath. The remaining 12 ft. space at the north end of the engine room is a pump room and a workshop at the boiler room floor level, and above these a laboratory and locker room. A feature of the design is the simplicity of building construction and layout, which provides for very considerable extension in capacity without alteration of the present structure. In the boiler room there are at present but three boilers, although the projected arrangement provides for another unit to the present row at the east side and subsequently four more on the opposite side of the firing floor in the space which is now utilized for the storage of fuel. In the engine room there is sufficient space for the addition of another large generating unit alongside the present one, while additional smaller units may be located in the northerly section of the room.

There are three Bigelow horizontal return tubular boilers, each of which has a heating surface equivalent to a rating of 150 h.-p. The shells are 72 in. in diameter by 18 ft. in length, without domes, and contain 72 4-in. tubes, 18 ft. long. The settings are fitted with U. S. shaking grates for hand firing, a fine grade of anthracite fuel being used. In preference to a tall stack for natural draft, an induced draft equipment has been installed consisting of a Sturtevant fan located on a platform above the boiler settings at the rear and discharging through a 48-in. steel stack which extends about 50 ft. above the power house roof. The fan has an overhung wheel to remove the bearings from the heat and is driven by a direct-connected Sturtevant enclosed engine. No coal or ash handling equipment has been installed, coal being stored in a pile at the rear of the boiler house and also in a vacant portion of the boiler room, from which it is wheeled to the firing floor. Ashes are at present utilized for filling in low portions of the property.



Cooper Corliss Engine and 185-Kw. Generator.

The steam piping has been laid out with special reference to future extension of the plant. There are two boiler room headers which lead to a separator at a central point in the engine room, from which the engine supplies and the high-pressure line to the manufacturing buildings are taken off. Only one of the boiler room headers is now installed, a blank opening being provided on the separator for connection to the future header on the other side. The boiler room header is a 10-in. line from which 6-in. branches connect to each of the three boilers. In the engine room there is a 10-in. connection from the separator which feeds an 8-in. high-pressure line extending to the manufacturing buildings and a 4-in. line to the compound Corliss engine which drives the large generator, this branch having a 2-in. by-pass connection to the low-pressure cylinder. From the opposite side of the separator a 3-in. branch is extended to supply a 75-kw. generating unit and also a 3-in. main to the boiler-room basement for the supply of pumps and the exciter engine at the rear of the engine-room floor.

The engine-room equipment consists of a 300-h.-p. cross compound Corliss engine direct-connected to a 185-kw. alternating current generator, a 100 h.-p. engine driving a 75-kw. generator and two exciter units, one steam-driven and the other electrically-driven. The cross compound engine is a 13 and 26x36-in. horizontal Corliss engine, built by the C. & G. Cooper Co., Mount Vernon, Ohio. It operates at a 120 r. p. m., and with a normal boiler pressure of 150 lb. and operating condensing, it has a rating of 300 h.-p. The condensing equipment, which has been installed for the operation of this engine, is of the surface type and is located in the basement between the cylinder foundations, and an opening in the floor at the rear of the cylinders facilitates inspection of the pumps and connections by the operating engineer from the main engine-room floor. Circulating water is obtained from the adjoining river through an intake line about 500 ft. in length. The smaller unit consists of a Harrisburg simple horizontal high-speed engine direct-connected to the 75-kw. generator, which, operating at 277 r. p. m. with a boiler pressure of 150 lb., non-condensing, has a rating of 100 h.-p. The exhaust steam from this engine as well as from such auxiliary machinery as may be in operation is utilized in a Cochrane open feedwater heater in the basement for the preheating of the boiler feed water. The remaining unit in the engine-room is the 30-kw. exciter which is direct driven by a New Britain simple vertical high-speed engine. Another steam-using unit is a standard underwriter's fire pump, located in the pump room enclosure adjoining the north side of the engine-room, and connected to pressure mains that lead throughout the buildings for protection of the plant from fire.

The electrical equipment consists of the 185-kw. alternator direct-connected to the cross-compound engine and the 75-kw. alternator direct-connected to the simple engine, auxiliary to which are two exciter units, one of 18-kw. capacity direct-connected to the New Britian steam engine and the other of 15 kw. capacity direct-driven by a 25 h.-p. General Electric induction motor. Both main generators are of the new alternating current type built by the Crocker-Wheeler Co., and the exciters were also supplied by that company. The generators deliver three-phase alternating current at 60 cycles and 240 volts, the large unit having 60 poles and operating at 120 r. p. m., while the 75 kw. unit has 26 poles and operates at 277 r. p. m. The exciters deliver 125 volts direct current. For the control of the generator and distribution circuits, three switchboards have been installed, one of four panels, 16 ft. in length, for the control of the two main generators, the exciters and the main feeders to the distribution board; a three-panel board 9 ft. in length on which the power and lighting distribution circuits to the different portions of the plant are controlled, and the third, a single panel board, 5 ft. in length, through which the charging circuits of an electric automobile truck that is operated about the plant are handled.

The engineer for James S. Pyle & Sons is Mr. R. S. Woodward, Jr., and the contractor for the installation of the plant was the New York Steam Fitting Co., New York.

Grouting Mine Shafts in water-bearing strata has been quite successful in work described by the "Genie Civil," Paris. The quantity of cement for each injection varied widely according to the inclination of the strata, and when these approached the vertical not only was the quantity of cement required excessive but the success of the operation was by no means so pronounced. When the strata are thus steeply inclined greater efficiency has been obtained by sinking the shaft by short lengths and injecting each new length in advance by means of radial boreholes driven from the last completed length of shaft. The greatest care is necessary to prevent the fine mud from mixing with the grout.

Electrical Machinery Used in Coke Operations.

The total annual capacity for the production of pig iron by the U. S. Steel Corporation at the present time is about 25,000,000 tons. This enormous production makes the company a correspondingly large consumer of coke for use in its furnaces. With the exception of a comparatively small percentage all the coke which is used is supplied by its subsidiary companies. The two principal operators furnishing this coke are known as the H. C. Frick Coke Co. and the U. S. Coal & Coke Co. The mines and works of the former are located in the Connellsville district, largely comprising Fayette and Westmoreland Counties, Pa. Those of the U. S. Coal & Coke Co. are located at Gary, McDowell Co., W. Va. Both of these companies are operated along the same general lines. The H. C. Frick Coke Co. at present owns about seventy separate coal mines, each mine having its own set of ovens which it supplies with coal. The number of ovens at each mine ranges from approximately 100 to 800, depending upon the output of the mine and other conditions. These are located close to the openings of the mines and conveniently arranged in relation to railroad sidings. The coke ovens are, with few exceptions, of the beehive type, into which the coal is introduced at the top. The residual heat and that of the adjoining ovens starts the coking process, in which the volatile portion of the coal is driven off through the top of the oven into the atmosphere. When all of the volatile matter is driven off, the bed of coke is raked out at the bottom and loaded into cars for shipment.

The continued increase in furnace capacity of the Steel Corporation calls for a corresponding increase in coke production. It is estimated that the new furnaces under construction will add at least 2,000,000 tons to the present productive capacity of pig iron. This will necessitate between 6,000 and 7,000 more coke ovens with the necessary additional mining capacity and machinery equipment. Similar conditions prevail in respect to independent furnaces.

In coal mining power is used for operating haulage locomotives inside the mines, pumps which drain the mines and large ventilating fans. In shaft and slope mines power is also required for hoisting purposes. From the mine the coal is carried to a tipple, whence it is discharged into what are known as coke oven larries, small steel cars equipped with electric motors for propulsion and supplied with chutes for discharging the coal into the ovens. It is customary to arrange the ovens on either side of the track on which the larry runs; coal being discharged from both sides. The electric motors on the larries are small railway type machines. Electrically operated drawing machines are used for removing the coke from the ovens. The machine draws the coke out of the oven by a scraper, discharging it on a conveying belt whence it is dumped directly into freight cars. Two motors are used on this machine; one is of the series wound railway type and the other a shunt wound constant speed motor.

The operations of the H. C. Frick Coke Co. at their Yorkrun plant are of special interest on account of modern features. Of the ovens here 100 are especially selected and so connected by flues as to conduct the hot gases from the ovens to the boiler house. The heat discharged from the coke ovens represents an enormous waste, and its use under the boilers therefore saves the use of a corresponding quantity of coal to produce the same heat; thus a large amount of heat is economically obtained at Yorkrun. It is roughly estimated that the heat developed by each oven is the equivalent continuously of 18 h.p.

The powerhouse is supplied with four alternating-current generators rated 400 kw., 2,300 volt 3-phase, 25 cycles, built by Allis-Chalmers Co. The equipment is complete with motor and engine driven exciters. In the main powerhouse is located a rotary converter sub-station supplied with two 200-kw. rotary converters and six 75-kw. step-down transformers. All the machinery in the powerhouse is controlled by a large 17 panel blue Vermont marble switchboard with complement of oil switches, indicating and recording meters. The rotary converters supply direct current at 600 volts for haulage locomotives and coke oven larries at the Yorkrun mine. Alternating current is used for pumps, mine fans, hoists and scrapers. Within a radius of between two and three miles there are located at various points four additional rotary converter sub-stations; each is equipped with one 200-kw. rotary converter, three 75-kw. step-down transformers and complete switchboard. These sub-stations are located so as to supply both alternating and direct current for mining and coking operations required by one or more mines. The switchboard in the main station is provided with feeder panels for the sub-station feeder lines. By means of integrating and recording meters a record of the power consumption is afforded at each mining and coking operation.

Additional mining and coking operations can be supplied from this same powerhouse by running additional high tension lines. Instances arise, however, where this is not practicable. Where locations are too remote, or when intervening property cannot be traversed by high tension lines, it becomes necessary to install separate isolated plants. A number of such plants are now being installed to meet the increased demand for coke. At the Phillips mines two 100-kw. direct-current railway type generators with switchboards are being installed; also at Ronco mines two 200-kw. direct-current engine type railway generators with switchboard are being started and at Dearth mines two 200-kw. direct-current engine type generators with switchboard. All of this electrical equipment is being supplied by the Allis-Chalmers Co.

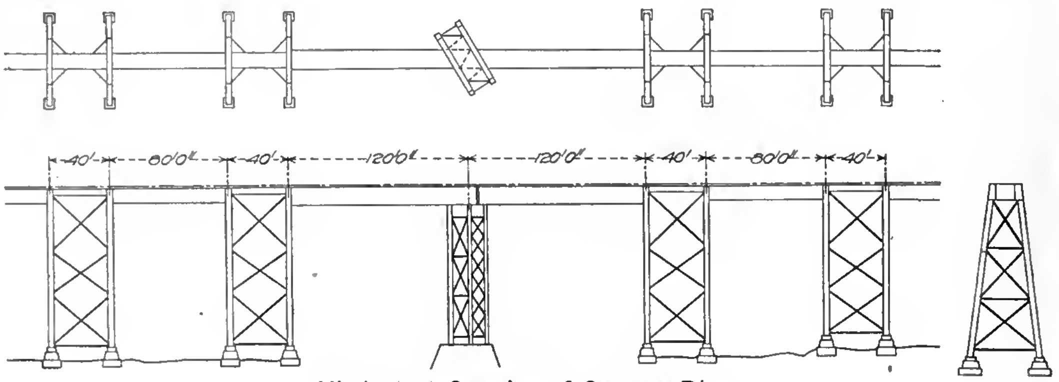
The powerhouse of the U. S. Coal & Coke Co. at Gary, W. Va., is equipped with two 24 and 42x42-in. cross compound heavy duty Allis-Chalmers Corliss engines driving 750-kw. 6,600 volt generators. In sub-stations there is a total of twenty-seven 75-kw. Allis-Chalmers transformers used for rotary converters. The general lay-out of this plant is similar to that of the H. C. Frick Coke Co. at Yorkrun except that waste heat from the ovens is not used.

A Third Pipe Line has been begun on the Thirlmere aqueduct bringing water to Manchester, England, thus completing the project as originally planned by Messrs. Hill & Sons. The water of Thirlmere Lake must be raised 50 ft. above its natural level, or 15 ft. higher than it is now, in order to supply all three pipes.

The Genesee River Viaduct, Erie R. R.

The Genesee River R. R., about 33 miles long, from Cuba, N. Y., to Hunts, N. Y., is a branch of the Erie R. R. system, which is now under construction, as described at considerable length in this journal on March 2. It crosses the Genesee River and valley on a viaduct with a steel plate girder superstructure, 3,121 ft. long and about 120 ft. in height from the water level to the base of rail. It is made of alternating 40 and 80-ft. plate girder spans, except immediately at the river crossing, and is intended to carry a single track at first and afterwards to be widened to a double-track structure. The towers are designed for the latter service, excepting that the columns will then be reinforced and the longitudinal girders are so arranged that the two lines at first erected will later serve for the inside girders of two parallel tracks. The general features of the design and the regular spans and connections are like those of the Moodna Creek Viaduct, illustrated in the Engineering Record of July 6, 1907.

The principal difference between the two structures lies in the crossing of the Genesee River, which is made with two 120-ft. (nominal) plate



Viaduct at Crossing of Genesee River.

girder spans supported at their adjacent ends on a 10x28-ft. 3½-in. vertical tower 120 ft. high with their piers skewed to the axis of the bridge and the direction of the river. The girders of one span have expansion bearings and those of the other span have fixed bearings on this tower, while the opposite ends of both spans have fixed connections to the regular towers. The span has square ends on both sides of the river and oblique ends on the skew center pier.

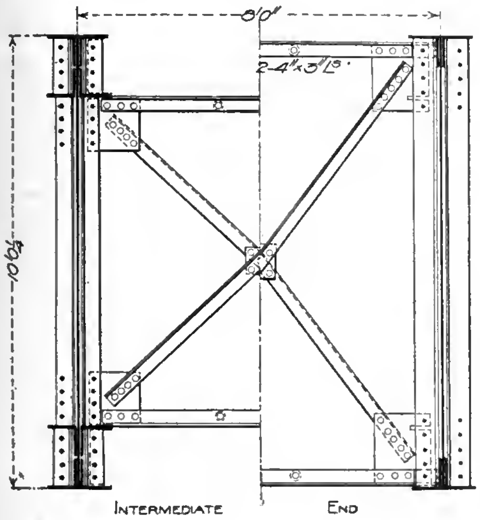
The columns of the river tower correspond with those in the other bents except that they are vertical instead of battered and that they are field riveted to the full-length webs of the transverse girders which is also field riveted to the top flanges of wide solid web knee-brace shop riveted to the columns. Each column is made in two sections and the lower section 65 ft. 3½ in. long is provided with a 54x60-in. base plate 1¼ in. thick, stiffened by wide connection angles and four pairs of vertical pocket angles 22 in. long milled at both ends and engaging upper horizontal shelf angles to afford bearings for the nuts on the top of the anchor bolts which pass through the pockets and through the 5x6-in. slotted holes in the base plates. The column webs are stiffened at the lower end by a 22x½-in. x 9-ft. diaphragm faced to bear at the lower ends on the base plate. This diaphragm is in the plane of the one designed for the future reinforcement of the columns when the second track is added to the viaduct, and stiffens the posts for the distribution of stresses from the struts.

There are two transverse girders at the top of the tower carrying the longitudinal girders, each of them having two full-length 96x½-in. web plates 30 ft. 3 in. long and 26⅜in. apart in the clear. The upper ends of the columns en-

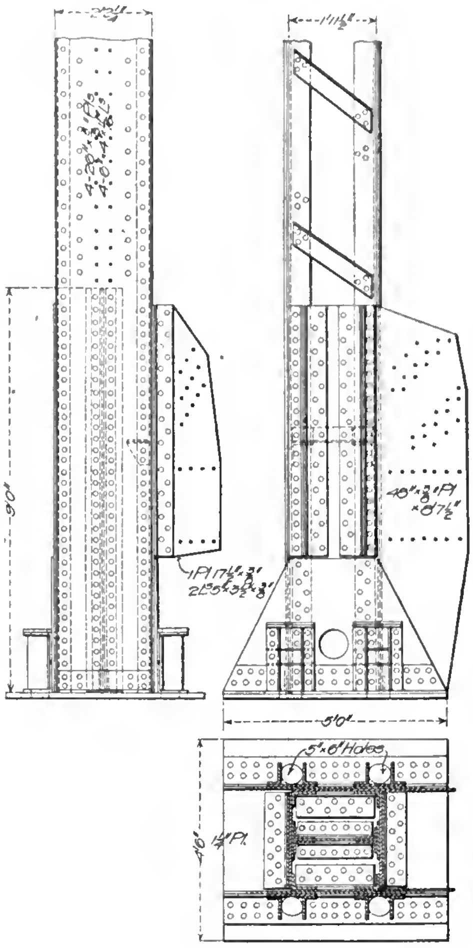
gage these webs and are field riveted between them with one hundred ⅞-in. rivets driven in holes reamed to a cast-iron template for each column. The girder webs are connected by three ⅜-in. full-depth diaphragm plates and by four top flange tie plates. The webs in reality belong to separate girders, each of the four flanges being composed of two 6x6x⅝-in. flange angles and one full-length 14x⅝-in. cover plate. The inside bottom flange angles are cut to clear the columns.

The longitudinal girders of the 120-ft. spans are made with 120x½-in. web plates, in lengths of about 15 or 16 ft., spliced with four vertical rows of shop driven rivets in pairs of 13½x⅜-in. cover plates, 7 ft. 3 in. long. The top and bottom flanges are alike, each having an H-shaped cross-section made with four 8x8x⅝-in. angles and five 18x½-in. cover plates. The angles are each made in two pieces, from about 23½ to 86 ft. long with staggered splices. The outside flange angles are spliced with pairs of 7⅜x7⅜-in. cover angles 6 ft. 4½ in. long cut down from 8x8x⅝-in. angles. The inside angles are spliced with similar cover angles and have in addition an 8x8x⅝-in. angle of the same length with its horizontal flange riveted to the horizontal flange of the main angle and its vertical flange riveted to the girder web above it. The first flange cover plate is of full length and is made in two pieces spliced by the outer plates which diminish in length to 35 ft. for the last one. The web splices are carried over the vertical legs of the flange angles with pairs of short cover plates with eight shop driven rivets in each end. The web is divided into panels 6 to 8 ft. long by pairs of vertical web stiffener angles at splices and at intermediate points. Each angle is made in three lengths with the ends carefully fitted to bearing on the horizontal legs of the flange angle.

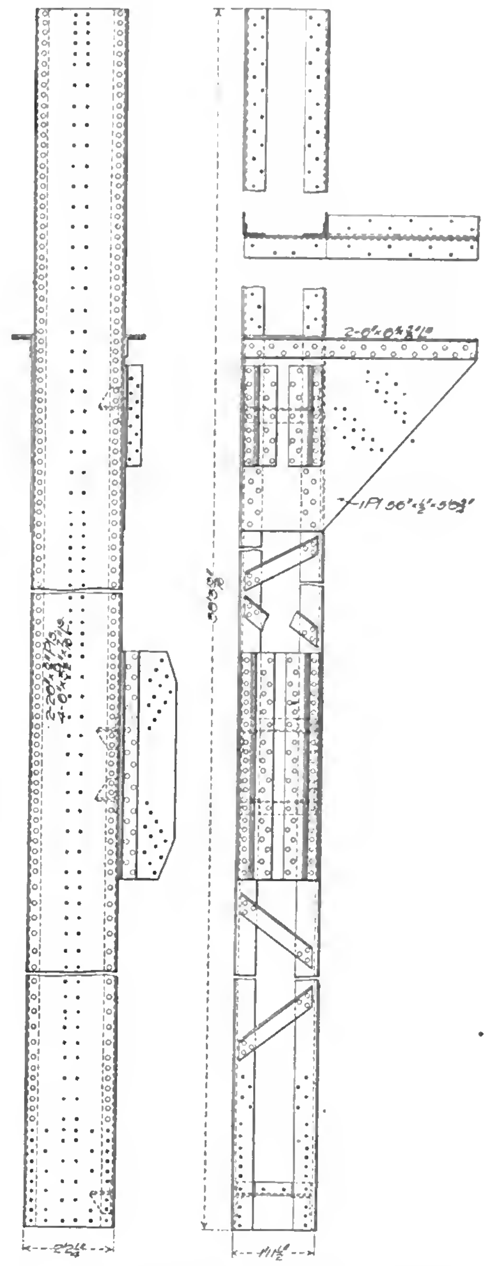
At the tower or double bent 13, the 125-ft. 4-in. and the 120-ft. 8-in. girders of span No. 7 are



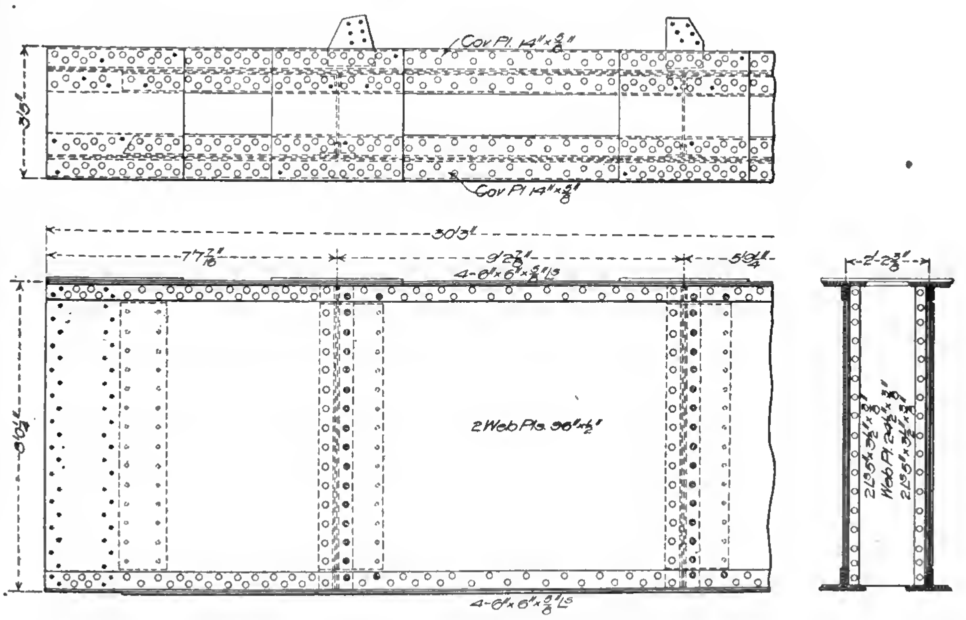
Cross Section of 120-Foot Span.



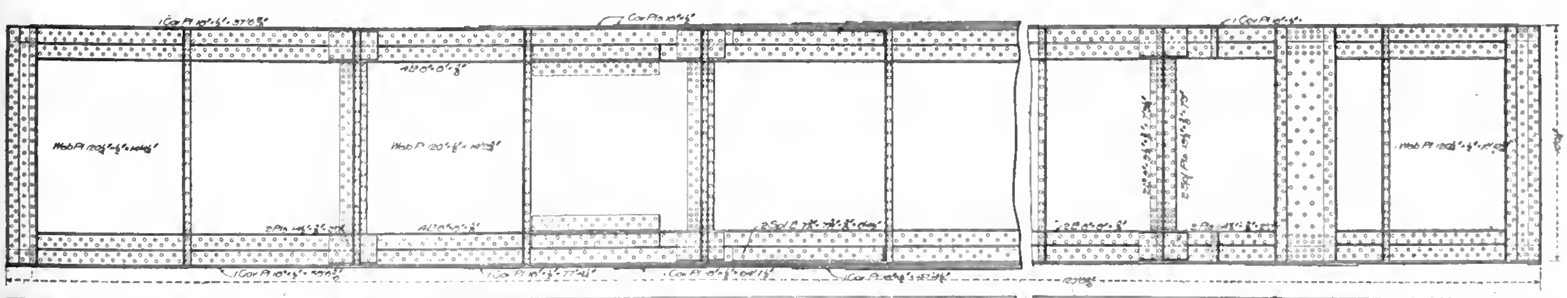
Base of Columns.



Top of Column.



Transverse Tower Girder.



Girder Over River Crossing.

seated on one of the twin transverse girders and project beyond it to the second twin transverse girder on which they take bearing with narrow sole plates. The end of the longitudinal girder is 4 in. clear of the first half of the transverse girder on center lines, thus leaving abundant clearance for the support of the longitudinal girder of the adjacent span. The girders of span 7 have their webs reinforced by double cover plates and two pairs of 6x6-in. vertical stiffener angles 31 in. apart over the bearings of the transverse girders. At all of the other bearings of the longitudinal girders the webs are similarly reinforced, but the cover plates are only 18 in. wide. The web plates are cut to make a cambre of 1¼ in.

The girders are X-braced in vertical transverse planes at alternate panel points with single 5x3½x⅜-in. diagonal angles and double 4x3x⅜-in. horizontal angles riveted together back to back on opposite sides of the vertical connection plates field riveted to the web stiffener angles and slotted near their center point to clear the horizontal leg of the inner flange angle. At intermediate panel points the horizontal transverse angles are flush with the horizontal legs of the inner flange angles, at the ends of the girders they are separated farther and are made flush with the horizontal legs of the outside flange angles. The girders are X-braced in the planes of the horizontal legs of the inside top flange angles, each diagonal member is made with a pair of 4x3x½-in. angles riveted together back to back. One member is continuous in each angle and the other is cut to clear it and splices with a horizontal flange plate shop riveted to the flange of the long angles.

The transverse girders in the top of the tower are conected together by full-depth solid web vertical diaphragms perpendicular to the transverse girder webs and the center lines of the columns and of the longitudinal girders. The diaphragms are made with 96x⅜-in. web plates and pairs of top and bottom 6x4x⅜-in. flange angles. The diaphragms are connected to the webs of the tranverse girders with field riveted bent plates about 14 in. wide.

The Erie Railroad construction department is in charge of Mr. J. M. Graham, vice-president, and Mr. Francis Lee Stuart, chief engineer, under whose approval the viaduct, including the foundations, was designed by Mr. Mason R. Strong, engineer of bridges and buildings, with the assistance of Mr. F. A. Howard, assistant engineer of bridges and buildings. The inspection is in charge of Mr. W. H. Wilkinson, inspector of bridges of the Erie R. R. The metal work was furnished by the McClintic-Marshall Construction Co. and will also be erected by them.

A Burr Truss Bridge consisting of five spans, each about 225 ft. long, was taken down recently at Pittsburg. It spanned the Allegheny River at its confluence with the Monongahela River, and was built in 1874 for the Union Bridge Co. and maintained as a toll bridge. The entire structure, including trusses, footwalks and roadway, was enclosed by a wooden covering, roofed with sheet iron. The removal of the bridge disclosed the fact that, though it had deteriorated in parts, it could have been made serviceable for many years with easy repairs. The principal reason for its removal was the fact that it was too low and hindered river traffic. The timbers and the iron tension rods were, on the whole, in excellent condition. The removal of the bridge was accomplished by placing ten timber bents under each span, five to each truss, and then dismantling the arch, allowing the weight of the trusses to come on the stringers on top of the bents. Each bent rested on five piles driven for that purpose in the river bed. The bridge was taken down by the Dravo Contracting Co.

Speed Regulation of High-Head Water-Wheels.

There are few features of hydraulic power plants operating under high heads that are more puzzling than the speed regulation of the wheels. It is not many years since serious troubles were experienced in starting up some plants in the West which had been provided with sensitive governors that had given entire satisfaction in plants operating under low or medium heads. This trouble took the form of great speed fluctuations, which the governor seemed to increase rather than diminish, and it is understood that occasionally the long steel penstocks leading to the wheels were injured by violent pulsations of the water. An interesting discussion of this problem has recently been contributed by Mr. H. E. Warren to the "Technology Quarterly," from which the following notes have been taken.

In the case of an impulse wheel, the great waste of energy which occurs when speed regulation is attained by deflecting a part of the water from the vanes, has brought about the design of such wheels where the jet of water is not deflected at all, but instead the cross-section of the stream is altered by means of a needle valve in the nozzle. The construction is such that the stream flows through the annular space between the inner surface of the nozzle tip and a peculiar valve spindle, the two parts being held concentric by force of the flowing water. When these parts are properly designed the stream does not remain hollow, as might be expected, but converges to a solid cylinder of water a short distance from the nozzle. By moving the valve spindle back and forth axially, the width of the annular space through which the water flows may be changed at will, and thus the efficiency of the wheel may be kept high throughout the entire range of output. the only important objection to this type of wheel, according to Mr. Warren, is that an element of great danger is introduced by such sudden variations in the velocity of the water in the long pipe line which must invariably be used.

In order to get the benefit of safe and good speed regulation, impulse wheels are now furnished with combination deflecting nozzles which have needle valves, the governors being designed to control the deflection, and some other means provided to produce slow movements of the needle valves. Ordinarily with this arrangement the needle valve which regulates the cross-section of the jet is adjusted from time to time by hand as the maximum load varies, so that the governor in order to maintain constant speed is obliged most of the time to direct the stream almost, but not quite, squarely against the moving buckets. If the load increases so that the portion of the stream which is held in reserve by the governor is inadequate to maintain the speed during sudden peaks in the load curve, the cross-section of the jet is increased by an attendant.

By a device recently invented the need of an attendant to look after this detail may be eliminated. Instead, a small electric or water motor is mounted on the nozzle, so that it may move the needle valve in or out very slowly. Control contacts or valves for the motor are arranged to actuate it in a proper direction whenever the main nozzle is deflected away from a predetermined position by the governor. As a result, the cross-section of the jet will be maintained at a certain margin above that necessary to carry the average load.

The function of a governor in connection with a water-wheel is to maintain the speed nearly constant. In order to do this it must be able to control the water acting upon the wheel; generally it must be able to exert great force. Since the load is liable to change rapidly, the governor must move quickly. Since the governor cannot act at all until the speed has departed from the normal, it is important that it should be exceedingly sensitive to slight speed variations and should begin to move as soon as they occur. Because the speed cannot return to its normal value as quickly as the governor moves, the machine must act and then wait for the speed to return. The governor ought to be able to act, according to Mr. Warren, when the water-wheel is standing still, for otherwise some other means must be used in starting.

As regards force exerted in action, governors are now in constant service which develop at their normal rating 50,000 lb. push at the piston rod. For speed of action the limit at present on small governors is somewhat less than one-half of one second for a complete stroke, which means that the governor can shut off or turn on the entire supply of water to the wheel within that interval. The largest governors have a maximum speed of from one to three seconds per stroke. Regarding sensitiveness, it is possible to make adjustment while the governor is in action. Variations within one-half of 1 per cent. cause prompt movement; in fact, it is not easy to measure the smallest variations which will be felt by the machine. The feature of waiting, after it has moved the gates a proper distance, for the speed to return is called anti-racing. This may not be expressed in units, but is quite satisfactory under actual conditions.

The speed regulation of high pressure impulse wheels with deflecting nozzles is the easiest problem in governor engineering. A small regulator developing from 2,500 to 7,000 ft.-lb. is powerful enough for the largest units, and should be of the oil-pressure type, according to Mr. Warren. The degree of speed regulation which can be obtained is about the same as with a steam engine.
